A transaction can issue/request a conflicting operation and be *in conflict* with another transaction while its conflicting operation is delayed and not executed (e.g., blocked by a lock). Only executed (*materialized*) conflicting operations are relevant to *conflict serializability* (see more below).

Enforcing conflict serializability

Testing conflict serializability

Schedule compliance with conflict serializability can be tested with the precedence graph (*serializability graph*, *serialization graph*, *conflict graph*) for committed transactions of the schedule. It is the directed graph representing precedence of transactions in the schedule, as reflected by precedence of conflicting operations in the transactions.

> In the **precedence graph** transactions are nodes and precedence relations are directed edges. There exists an edge from a first transaction to a second transaction, if the second transaction is *in conflict* with the first (see Conflict serializability above), and the conflict is **materialized** (i.e., if the requested conflicting operation is actually executed: in many cases a requested/issued conflicting operation by a transaction is delayed and even never executed, typically by a lock on the operation's object, held by another transaction, or when writing to a transaction's temporary private workspace and materializing, copying to the database itself, upon commit; as long as a requested/issued conflicting operation is not executed upon the database itself, the conflict is **non-materialized**; non-materialized conflicts are not represented by an edge in the precedence graph).
>
> **Comment:** In many text books only *committed transactions* are included in the precedence graph. Here all transactions are included for convenience in later discussions.

The following observation is a **key characterization of conflict serializability**:

> A schedule is *conflict-serializable* if and only if its precedence graph of *committed transactions* (when only *committed* transactions are considered) is *acyclic*. This means that a cycle consisting of committed transactions only is generated in the (general) precedence graph, if and only if conflict-serializability is violated.

Cycles of committed transactions can be prevented by aborting an *undecided* (neither committed, nor aborted) transaction on each cycle in the precedence graph of all the transactions, which can otherwise turn into a cycle of committed transactions (and a committed transaction cannot be aborted). One transaction aborted per cycle is both required and sufficient number to break and eliminate the cycle (more aborts are possible, and can happen in some mechanisms, but unnecessary for serializability). The probability of cycle generation is typically low, but nevertheless, such a situation is carefully handled, typically with a considerable overhead, since correctness is involved. Transactions aborted due to serializability violation prevention are *restarted* and executed again immediately.

Serializability enforcing mechanisms typically do not maintain a precedence graph as a data structure, but rather prevent or break cycles implicitly (e.g., SS2PL below).

Common mechanism - SS2PL

Strong strict two phase locking (SS2PL) is a common mechanism utilized in database systems since their early days in the 1970s (the "SS" in the name SS2PL is newer though) to enforce both conflict serializability and *strictness* (a special case of recoverability which allows effective database recovery from failure) of a schedule. In this mechanism each datum is locked by a transaction before accessing it (any read or write operation): The item is marked by, associated with a *lock* of a certain type, depending on operation (and the specific implementation; various models with different lock types exist; in some models locks may change type during the transaction's life). As a result access by another transaction may be blocked, typically upon a conflict (the lock delays or completely prevents the conflict from being materialized and be reflected in the precedence graph by blocking the conflicting operation), depending on lock type and the other transaction's access operation type. Employing an SS2PL mechanism means that all locks on data on behalf of a transaction are released only after the transaction has ended (either committed or aborted).

SS2PL is the name of the resulting schedule property as well, which is also called *rigorousness*. SS2PL is a special case (proper subset) of Two-phase locking (2PL)

Mutual blocking between transactions results in a *deadlock*, where execution of these transactions is stalled, and no completion can be reached. Thus deadlocks need to be resolved to complete these transactions' execution and release related computing resources. A deadlock is a reflection of a potential cycle in the precedence graph, that would occur without the blocking when conflicts are materialized. A deadlock is resolved by aborting a transaction involved with such potential cycle, and breaking the cycle. It is often detected using a *wait-for graph* (a graph of conflicts blocked by locks from being materialized; it can be also defined as the graph of non-materialized conflicts; conflicts not materialized are not reflected in the precedence graph and do not affect serializability), which indicates which transaction is "waiting for" lock release by which transaction, and a cycle means a deadlock. Aborting one transaction per cycle is sufficient to break the cycle. Transactions aborted due to deadlock resolution are *restarted* and executed again immediately.

Other enforcing techniques

Other known mechanisms include:

- Precedence graph (or Serializability graph, Conflict graph) cycle elimination
- Two-phase locking (2PL)
- Timestamp ordering (TO)
- Serializable snapshot isolation[4] (SerializableSI)

The above (conflict) serializability techniques in their general form do not provide recoverability. Special enhancements are needed for adding recoverability.

Optimistic versus pessimistic techniques

Concurrency control techniques are of three major types:

1. *Pessimistic*: In Pessimistic concurrency control a transaction blocks data access operations of other transactions upon conflicts, and conflicts are *non-materialized* until blocking is removed. This is done to ensure that operations that may violate serializability (and in practice also recoverability) do not occur.
2. *Optimistic*: In Optimistic concurrency control data access operations of other transactions are not blocked upon conflicts, and conflicts are immediately *materialized*. When the transaction reaches the *ready* state, i.e., its *running* state has been completed, possible serializability (and in practice also recoverability) violation by the transaction's operations (relatively to other running transactions) is checked: If violation has occurred, the transaction is typically *aborted* (sometimes aborting *another* transaction to handle serializability violation is preferred). Otherwise it is *committed*.
3. *Semi-optimistic*: Mechanisms that mix blocking in certain situations with not blocking in other situations and employ both materialized and non-materialized conflicts

The main differences between the technique types is the conflict types that are generated by them. A pessimistic method blocks a transaction operation upon conflict and generates a non-materialized conflict, while an optimistic method does not block and generates a materialized conflict. A semi-optimistic method generates both conflict types. Both conflict types are generated by the chronological orders in which transaction operations are invoked, independently of the type of conflict. A cycle of committed transactions (with materialized conflicts) in the *precedence graph* (conflict graph) represents a serializability violation, and should be avoided for maintaining serializability. A cycle of (non-materialized) conflicts in the *wait-for graph* represents a deadlock situation, which should be resolved by breaking the cycle. Both cycle types result from conflicts, and should be broken. At any technique type conflicts should be detected and considered, with similar overhead for both materialized and non-materialized conflicts (typically by using mechanisms like locking, while either blocking for locks, or not blocking but recording conflict for materialized conflicts). In a blocking method typically a context switching occurs upon conflict, with (additional) incurred overhead. Otherwise blocked transactions' related computing resources remain idle, unutilized, which may be a worse alternative. When conflicts do not occur frequently, optimistic

methods typically have an advantage. With different transactions loads (mixes of transaction types) one technique type (i.e., either optimistic or pessimistic) may provide better performance than the other.

Unless schedule classes are *inherently blocking* (i.e., they cannot be implemented without data-access operations blocking; e.g., 2PL, SS2PL and SCO above; see chart), they can be implemented also using optimistic techniques (e.g., Serializability, Recoverability).

Serializable multi-version concurrency control

See also Multiversion concurrency control (partial coverage)

and Serializable_Snapshot_Isolation in Snapshot isolation

Multi-version concurrency control (MVCC) is a common way today to increase concurrency and performance by generating a new version of a database object each time the object is written, and allowing transactions' read operations of several last relevant versions (of each object), depending on scheduling method. MVCC can be combined with all the serializability techniques listed above (except SerializableSI which is originally MVCC based). It is utilized in most general-purpose DBMS products.

MVCC is especially popular nowadays through the *relaxed serializability* (see above) method *Snapshot isolation* (SI) which provides better performance than most known serializability mechanisms (at the cost of possible serializability violation in certain cases). SerializableSI, which is an efficient enhancement of SI to make it serializable, is intended to provide an efficient serializable solution. SerializableSI has been analyzed[5] via a general theory of MVCC

Distributed serializability

Overview

Distributed serializability is the serializability of a schedule of a transactional distributed system (e.g., a distributed database system). Such system is characterized by *distributed transactions* (also called *global transactions*), i.e., transactions that span computer processes (a process abstraction in a general sense, depending on computing environment; e.g., operating system's thread) and possibly network nodes. A distributed transaction comprises more than one *local sub-transactions* that each has states as described above for a database transaction. A local sub-transaction comprises a single process, or more processes that typically fail together (e.g., in a single processor core). Distributed transactions imply a need in Atomic commit protocol to reach consensus among its local sub-transactions on whether to commit or abort. Such protocols can vary from a simple (one-phase) hand-shake among processes that fail together, to more sophisticated protocols, like Two-phase commit, to handle more complicated cases of failure (e.g., process, node, communication, etc. failure). Distributed serializability is a major goal of distributed concurrency control for correctness. With the proliferation of the Internet, Cloud computing, Grid computing, and small, portable, powerful computing devices (e.g., smartphones) the need for effective distributed serializability techniques to ensure correctness in and among distributed applications seems to increase.

Distributed serializability is achieved by implementing distributed versions of the known centralized techniques. Typically all such distributed versions require utilizing conflict information (either of materialized or non-materialized conflicts, or equivalently, transaction precedence or blocking information; conflict serializability is usually utilized) that is not generated locally, but rather in different processes, and remote locations. Thus information distribution is needed (e.g., precedence relations, lock information, timestamps, or tickets). When the distributed system is of a relatively small scale, and message delays across the system are small, the centralized concurrency control methods can be used unchanged, while certain processes or nodes in the system manage the related algorithms. However, in a large-scale system (e.g., *Grid* and *Cloud*), due to the distribution of such information, substantial performance penalty is typically incurred, even when distributed versions of the methods (Vs. centralized) are used, primarily due to computer and communication latency. Also, when such information is

distributed, related techniques typically do not scale well. A well-known example with scalability problems is a distributed lock manager, which distributes lock (non-materialized conflict) information across the distributed system to implement locking techniques.

Read–write conflict

In computer science, in the field of databases, **Read-Write Conflict**, also known as **unrepeatable reads**, is a computational anomaly associated with interleaved execution of transactions.

Given a schedule S

$$S = \begin{bmatrix} T1 & T2 \\ R(A) & \\ & R(A) \\ & W(A) \\ & Com. \\ R(A) & \\ W(A) & \\ Com. & \end{bmatrix}$$

In this example, T1 has read the original value of A, and is waiting for T2 to finish. T2 also reads the original value of A, overwrites A, and commits.

However, when T1 reads to A, it discovers two different versions of A, and T1 would be forced to abort, because T1 would not know what to do. This is an unrepeatable read. This could never occur in a serial schedule. Strict two-phase locking (Strict 2PL) prevents this conflict.

Real world example

Alice and Bob are using Ticketmaster website to book tickets for a specific show. Only one ticket is left for the specific show. Alice signs on to Ticketmaster first and finds one left, and finds it expensive. Alice takes time to decide. Bob signs on and finds one ticket left, orders it instantly. Bob purchases and logs off. Alice decides to buy a ticket, to find there are no tickets. This is a typical Read-Write Conflict situation.

Write–read conflict

In computer science, in the field of databases, **Write-Read Conflict**, also known as **reading uncommitted data**, is a computational anomaly associated with interleaved execution of transactions.

Given a schedule S

$$S = \begin{bmatrix} T1 & T2 \\ R(A) & \\ W(A) & \\ & R(A) \\ & W(A) \\ & R(B) \\ & W(B) \\ & Com. \\ R(B) & \\ W(B) & \\ Com. & \end{bmatrix}$$

T2 could read a database object A, modified by T1 which hasn't committed. This is a ***dirty read***.

T1 may write some value into A which makes the database inconsistent. It is possible that interleaved execution can expose this inconsistency and lead to inconsistent final database state, violating ACID rules.

Strict 2PL overcomes this inconsistency by locking T2 out from performing a Read/Write on A. Note however that Strict 2PL can have a number of drawbacks, such as the possibility of deadlocks.

Write–write conflict

In computer science, in the field of databases, **Write-Write Conflict**, also known as **overwriting uncommitted data** is a computational anomaly associated with interleaved execution of transactions.

Given a schedule S

$$S = \begin{bmatrix} T1 & T2 \\ W(A) & \\ & W(B) \\ W(B) & \\ Com. & \\ & W(A) \\ & Com. \end{bmatrix}$$

note that there is no read in this schedule. The writes are called ***blind writes***.

We have a ***lost update***. Any attempts to make this schedule serial would give off two different results (either T1's version of A and B is shown, or T2's version of A and B is shown), and would not be the same as the above schedule. This schedule would not be serializable.

Strict 2PL, overcomes this inconsistency by locking T1 out from B. Unfortunately, deadlocks are something Strict 2PL does not overcome all the time.

Lock (database)

A **lock**, as a **read lock** or **write lock**, is used when multiple users need to access a database concurrently. This prevents data from being corrupted or invalidated when multiple users try to read while others write to the database. Any single user can only modify those database records (that is, items in the database) to which they have applied a lock that gives them exclusive access to the record until the lock is released. Locking not only provides exclusivity to writes but also prevents (or controls) reading of unfinished modifications (AKA uncommitted data).

A read lock can be used to prevent other users from reading a record (or page) which is being updated, so that others will not act upon soon-to-be-outdated information.

Mechanisms for locking

There are two mechanisms for locking data in a database: *pessimistic locking*, and *optimistic locking*. In pessimistic locking a record or page is locked immediately when the lock is requested, while in an optimistic lock the record or page is only locked when the changes made to that record are updated. The latter situation is only appropriate when there is less chance of someone needing to access the record while it is locked; otherwise it cannot be certain that the update will succeed because the attempt to update the record will fail if another user updates the record first. With pessimistic locking it is guaranteed that the record will be updated.

The degree of locking can be controlled by isolation level. Change of a lock is called lock conversion and the lock may be upgraded (lock upgrade) or downgraded (lock downgrade).

Transactional isolation is usually implemented by locking whatever is accessed in a transaction. There are two different approaches to transactional locking: Pessimistic locking and optimistic locking. The disadvantage of pessimistic locking is that a resource is locked from the time it is first accessed in a transaction until the transaction

is finished, making it inaccessible to other transactions during that time. If most transactions simply look at the resource and never change it, an exclusive lock may be overkill as it may cause lock contention, and optimistic locking may be a better approach. With pessimistic locking, locks are applied in a fail-safe way. In the banking application example, an account is locked as soon as it is accessed in a transaction. Attempts to use the account in other transactions while it is locked will either result in the other process being delayed until the account lock is released, or that the process transaction will be rolled back. The lock exists until the transaction has either been committed or rolled back. With optimistic locking, a resource is not actually locked when it is first is accessed by a transaction. Instead, the state of the resource at the time when it would have been locked with the pessimistic locking approach is saved. Other transactions are able to concurrently access to the resource and the possibility of conflicting changes is possible. At commit time, when the resource is about to be updated in persistent storage, the state of the resource is read from storage again and compared to the state that was saved when the resource was first accessed in the transaction. If the two states differ, a conflicting update was made, and the transaction will be rolled back. In the banking application example, the balance of an account is saved when the account is first accessed in a transaction. If the transaction changes the account balance, the balance is read from the store again just before the balance is about to be updated. If the balance has changed since the transaction began, the transaction will fail itself, otherwise the new balance is written to persistent storage. A lock is used when multiple users need to access a database concurrently. This prevents data from being corrupted or invalidated when multiple users try to write to the database. Any single user can only modify those database records (that is, items in the database) to which they have applied a lock that gives them exclusive access to the record until the lock is released. Locking not only provides exclusivity to writes but also prevents (or controls) reading of unfinished modifications (AKA uncommitted data).

Record locking

Record locking is the technique of preventing simultaneous access to data in a database, to prevent inconsistent results.

The classic example is demonstrated by two bank clerks attempting to update the same bank account for two different transactions. Clerks 1 and 2 both retrieve (i.e., copy) the account's record. Clerk 1 applies and saves a transaction. Clerk 2 applies a different transaction to his saved copy, and saves the result, based on the original record and his changes, overwriting the transaction entered by clerk 1. The record no longer reflects the first transaction, as if it had never taken place.

A simple way to prevent this is to lock the file whenever a record is being modified by any user, so that no other user can save data. This prevents records from being overwritten incorrectly, but allows only one record to be processed at a time, locking out other users who need to edit records at the same time.

To allow several users to edit a database table at the same time and also prevent inconsistencies created by unrestricted access, a single record can be *locked* when retrieved for editing or updating. Anyone attempting to retrieve the same record for editing is denied write access because of the lock (although, depending on the implementation, they may be able to view the record without editing it). Once the record is saved or edits are canceled, the lock is released. Records can never be saved so as to overwrite other changes, preserving data integrity.

In database management theory, locking is used to implement *isolation* among multiple database users. This is the "I" in the acronym ACID.

A thorough and authoritative description of locking was written by Jim Gray.

Granularity of locks

If the bank clerks (to follow the illustration above) are serving two customers, but their accounts are contained in one ledger, then the entire ledger, or one or more database tables, would need to be made available for editing to the clerks in order for each to complete a transaction, one at a time (file locking). While safe, this method can cause unnecessary waiting.

If the clerks can remove one page from the ledger, containing the account of the current customer (plus several other accounts), then multiple customers can be serviced concurrently, provided that each customer's account is found on a different page than the others. If two customers have accounts on the same page, then only one may be serviced at a time. This is analogous to a *page level lock* in a database.

A higher degree of granularity is achieved if each individual account may be taken by a clerk. This would allow any customer to be serviced without waiting for another customer who is accessing a different account. This is analogous to a *record level lock* and is normally the highest degree of locking granularity in a database management system.

In a SQL database, a record is typically called a "row."

The introduction of granular (subset) locks creates the possibility for a situation called deadlock. Deadlock is possible when *incremental locking* (locking one entity, then locking one or more additional entities) is used. To illustrate, if two bank customers asked two clerks to obtain their account information so they could transfer some money into other accounts, the two accounts would essentially be locked. Then, if the customers told their clerks that the money was to be transferred into each other's accounts, the clerks would search for the other accounts but find them to be "in use" and wait for them to be returned. Unknowingly, the two clerks are waiting for each other, and neither of them can complete their transaction until the other gives up and returns the account. Various techniques are used to avoid such problems.

Use of locks

Record locks need to be managed between the entities requesting the records such that no entity is given too much service via successive **grants**, and no other entity is effectively locked out. The entities that request a lock can be either individual applications (programs) or an entire processor.

The application or system should be designed such that any lock is held for the shortest time possible. Data reading, without editing facilities, does not require a lock, and reading locked records is usually permissible.

Two main types of locks can be requested:

Exclusive locks

Exclusive locks are, as the name implies, exclusively held by a single entity, usually for the purpose of writing to the record. If the locking schema was represented by a list, the **holder list** would contain only one entry. Since this type of lock effectively blocks any other entity that requires the lock from processing, care must be used to:

- ensure the lock is held for the shortest time possible;
- not hold the lock across system or function calls where the entity is no longer running on the processor - this can lead to deadlock;
- ensure that if the entity is unexpectedly exited for any reason, the lock is freed.

Non-holders of the lock (aka **waiters**) can be held in a list that is serviced in a round robin fashion, or in a FIFO queue. This would ensure that any possible waiter would get equal chance to obtain the lock and not be locked out. To further speed up the process, if an entity has gone to sleep waiting for a lock, performance is improved if the entity is notified of the grant, instead of discovering it on some sort of system timeout driven wakeup.

Shared locks

Shared locks differ from exclusive locks in that the **holder list** can contain multiple entries. Shared locks allow all holders to read the contents of the record knowing that the record cannot be changed until after the lock has been released by all holders. Exclusive locks cannot be obtained when a record is already locked (exclusively or shared) by another entity.

If lock requests for the same entity are queued, then once a shared lock is granted, any queued shared locks may also be granted. If an exclusive lock is found next on the queue, it must wait until all shared locks have been released. As with exclusive locks, these shared locks should be held for the least time possible.

References

Multiple granularity locking

In computer science, **multiple granularity locking** (MGL) is a locking method used in database management systems (DBMS) and relational databases.

In MGL, locks are set on objects that contain other objects. MGL exploits the hierarchical nature of the *contains* relationship. For example, a database may have files, which contain pages, which further contain records. This can be thought of as a tree of objects, where each node contains its children. A lock on such as a shared or exclusive lock locks the targeted node as well as all of its descendants.

Multiple granularity locking is usually used with non-strict two-phase locking to guarantee serializability.

Lock Modes

In addition to shared (S) locks and exclusive (X) locks from other locking schemes, like strict two-phase locking, MGL also uses *intention shared* and *intention exclusive* locks. IS locks conflict with X locks, while IX locks conflict with S and X locks. The null lock (NL) is compatible with everything.

To lock a node in S (or X), MGL has the transaction lock on all of its ancestors with IS (or IX), so if a transaction locks a node in S (or X), no other transaction can access its ancestors in X (or S and X). This protocol is shown in the following table:

To Get	Must Have on all Ancestors
IS or S	IS or IX
IX, SIX or X	IX or SIX

Determining what level of granularity to use for locking is done by locking the finest level possible (at the lowest leaf level), and then escalating these locks to higher levels in the file hierarchy to cover more records or file elements as needed. This process is known as Lock Escalation. MGL locking modes are compatible with each other as defined in the following matrix.

Mode	NL	IS	IX	S	SIX	X
NL	Yes	Yes	Yes	Yes	Yes	Yes
IS	Yes	Yes	Yes	Yes	Yes	No
IX	Yes	Yes	Yes	No	No	No
S	Yes	Yes	No	Yes	No	No
SIX	Yes	Yes	No	No	No	No
X	Yes	No	No	No	No	No

Following the locking protocol and the compatibility matrix, if one transaction holds a node in S mode, no other transactions can have locked any ancestor in X mode.

Two-phase locking

In databases and transaction processing, **two-phase locking** (**2PL**) is a concurrency control method that guarantees serializability.[1][2] It is also the name of the resulting set of database transaction schedules (histories). The protocol utilizes locks, applied by a transaction to data, which may block (interpreted as signals to stop) other transactions from accessing the same data during the transaction's life.

By the 2PL protocol locks are applied and removed in two phases:

1. Expanding phase: locks are acquired and no locks are released.
2. Shrinking phase: locks are released and no locks are acquired.

Two types of locks are utilized by the basic protocol: *Shared* and *Exclusive* locks. Refinements of the basic protocol may utilize more lock types. Using locks that block processes, 2PL may be subject to deadlocks that result from the mutual blocking of two or more transactions.

2PL is a superset of **strong strict two-phase locking** (**SS2PL**),[3] also called **rigorousness**,[4] which has been widely utilized for concurrency control in general-purpose database systems since the 1970s. SS2PL implementations have many variants. SS2PL was called *strict 2PL* but this name usage is not recommended now. Now **strict 2PL** (**S2PL**) is the intersection of strictness and 2PL, which is different from SS2PL. SS2PL is also a special case of commitment ordering, and inherits many of CO's useful properties. SS2PL actually comprises only one phase: phase-2 does not exist, and all locks are released only after transaction end. Thus this useful 2PL type is not two-phased at all.

Neither 2PL nor S2PL in their general forms are known to be used in practice. Thus 2PL by itself does not seem to have much practical importance, and whenever 2PL or S2PL utilization has been mentioned in the literature, the intention has been SS2PL. What has made SS2PL so popular (probably the most utilized serializability mechanism) is the effective and efficient locking-based combination of two ingredients (the first does not exist in both general 2PL and S2PL; the second does not exist in general 2PL):

1. Commitment ordering, which provides both serializability, and effective distributed serializability and global serializability, and
2. Strictness, which provides cascadelessness (ACA, cascade-less recoverability) and (independently) allows efficient database recovery from failure.

Additionally SS2PL is easier, with less overhead to implement than both 2PL and S2PL, provides exactly the same locking, but sometimes releases locks later. However, practically (though not simplistically theoretically) such later lock release occurs only slightly later, and this apparent disadvantage is insignificant and disappears next to the advantages of SS2PL.

Thus, the importance of the general *Two-phase locking* (2PL) is historic only, while *Strong strict two-phase locking* (SS2PL) is practically the important mechanism and resulting schedule property.

Data-access locks

A lock is a system object associated with a shared resource such as a data item of an elementary type, a row in a database, or a page of memory. In a database, a lock on a database object (a data-access lock) may need to be acquired by a transaction before accessing the object. Correct use of locks prevents undesired, incorrect or inconsistent operations on shared resources by other concurrent transactions. When a database object with an existing lock acquired by one transaction needs to be accessed by another transaction, the existing lock for the object and the type of the intended access are checked by the system. If the existing lock type does not allow this specific attempted concurrent access type, the transaction attempting access is blocked (according to a predefined agreement/scheme). In practice a lock on an object does not directly block a transaction's operation upon the object, but rather blocks that transaction from acquiring another lock on the same object, needed to be held/owned by the transaction before performing this operation. Thus, with a locking mechanism, needed operation blocking is controlled by a proper lock blocking scheme, which indicates which lock type blocks which lock type.

Two major types of locks are utilized:

- **Write-lock** (**exclusive lock**) is associated with a database object by a transaction (Terminology: "the transaction locks the object," or "acquires lock for it") before *writing* (inserting/modifying/deleting) this object.
- **Read-lock** (**shared lock**) is associated with a database object by a transaction before *reading* (retrieving the state of) this object.

The common interactions between these lock types are defined by blocking behavior as follows:

- An existing *write-lock* on a database object blocks an intended *write* upon the same object (already requested/issued) by another transaction by blocking a respective *write-lock* from being acquired by the other transaction. The second write-lock will be acquired and the requested write of the object will take place (materialize) after the existing write-lock is released.
- A *write-lock* blocks an intended (already requested/issued) *read* by another transaction by blocking the respective *read-lock* .
- A *read-lock* blocks an intended *write* by another transaction by blocking the respective *write-lock* .
- A *read-lock* does not block an intended *read* by another transaction. The respective *read-lock* for the intended read is acquired (shared with the previous read) immediately after the intended read is requested, and then the intended read itself takes place.

Several variations and refinements of these major lock types exist, with respective variations of blocking behavior. If a first lock blocks another lock, the two locks are called *incompatible*; otherwise the locks are *compatible*. Often lock types blocking interactions are presented in the technical literature by a *Lock compatibility table*. The following is an example with the common, major lock types:

Lock compatibility table

Lock type	read-lock	write-lock
read-lock		**X**
write-lock	**X**	**X**

X indicates incompatibility, i.e, a case when a lock of the first type (in left column) on an object blocks a lock of the second type (in top row) from being acquired on the same object (by another transaction). An object typically has a queue of waiting requested (by transactions) operations with respective locks. The first blocked lock for operation in the queue is acquired as soon as the existing blocking lock is removed from the object, and then its respective operation is executed. If a lock for operation in the queue is not blocked by any existing lock (existence of multiple compatible locks on a same object is possible concurrently) it is acquired immediately.

Comment: In some publications the table entries are simply marked "compatible" or "incompatible", or respectively "yes" or "no".

Two-phase locking and its special cases

Two-phase locking

According to the **two-phase locking** protocol a transaction handles its locks in two distinct, consecutive phases during the transaction's execution:

1. **Expanding phase** (aka Growing phase): locks are acquired and no locks are released (the number of locks can only increase).
2. **Shrinking phase**: locks are released and no locks are acquired.

The serializability property is guaranteed for a schedule with transactions that obey the protocol. The 2PL *schedule class* is defined as the class of all the schedules comprising transactions with data access orders that could be generated by the 2PL protocol (or in other words, all the schedules that the 2PL protocol can generate).

Typically, without explicit knowledge in a transaction on end of phase-1, it is safely determined only when a transaction has entered its *ready* state in all its processes (processing has ended, and it is ready to be committed; no additional data access and locking are needed and can happen). In this case phase-2 can end immediately (no additional processing is needed), and actually no phase-2 is needed. Also, if several processes (two or more) are involved, then a synchronization point (similar to *atomic commitment*) among them is needed to determine end of phase-1 for all of them (i.e., in the entire distributed transaction), to start releasing locks in phase-2 (otherwise it is very likely that both 2PL and Serializability are quickly violated). Such synchronization point is usually too costly (involving a distributed protocol similar to atomic commitment), and end of phase-1 is usually postponed to be merged with transaction end (atomic commitment protocol for a multi-process transaction), and again phase-2 is not needed. This turns 2PL to SS2PL (see below). All known implementations of 2PL in products are SS2PL based, and whenever 2PL (or Strict 2PL, S2PL) practical utilization has been mentioned in the professional literature, the intention has been SS2PL.

Strict two-phase locking

The **strict two-phase locking** (S2PL) class of schedules is the intersection of the 2PL class with the class of schedules possessing the *Strictness* property.

To comply with the S2PL protocol a transaction needs to comply with 2PL, and release its *write (exclusive)* locks only after it has ended, i.e., being either *committed* or *aborted*. On the other hand, *read (shared)* locks are released regularly during phase 2. Implementing general S2PL requires explicit support of phase-1 end, separate from transaction end, and no such widely utilized product implementation is known.

S2PL is a special case of 2PL, i.e., the S2PL class is a proper subclass of 2PL

Strong strict two-phase locking

or **Rigorousness**, or **Rigorous scheduling**, or **Rigorous two-phase locking**

To comply with **strong strict two-phase locking** (SS2PL) the locking protocol releases both *write (exclusive)* and *read (shared)* locks applied by a transaction only after the transaction has ended, i.e., only after both completing executing (being *ready*) and becoming either *committed* or *aborted*. This protocol also complies with the S2PL rules. A transaction obeying SS2PL can be viewed as having phase-1 that lasts the transaction's entire execution duration, and no phase-2 (or a degenerate phase-2). Thus, only one phase is actually left, and "two-phase" in the name seems to be still utilized due to the historical development of the concept from 2PL, and 2PL being a super-class. The SS2PL property of a schedule is also called **Rigorousness**. It is also the name of the class of schedules having this property, and an SS2PL schedule is also called a "rigorous schedule". The term "Rigorousness" is free of the unnecessary legacy of "two-phase," as well as being independent of any (locking) mechanism (in principle other blocking mechanisms can be utilized). The property's respective locking mechanism is sometimes referred to as **Rigorous 2PL**.

SS2PL is a special case of S2PL, i.e., the SS2PL class of schedules is a proper subclass of S2PL (every SS2PL schedule is also an S2PL schedule, but S2PL schedules exist that are not SS2PL).

SS2PL has been the concurrency control protocol of choice for most database systems and utilized since their early days in the 1970s. It is proven to be an effective mechanism in many situations, and provides besides Serializability also Strictness (a special case of cascadeless Recoverability), which is instrumental for efficient database recovery, and also Commitment ordering (CO) for participating in distributed environments where a CO based distributed serializability and global serializability solutions are employed. Being a subset of CO, an efficient implementation of *distributed SS2PL* exists without a distributed lock manager (DLM), while distributed deadlocks (see below) are resolved automatically. The fact that SS2PL employed in multi database systems ensures global serializability has been known for years before the discovery of CO, but only with CO came the understanding of the role of an atomic commitment protocol in maintaining global serializability, as well as the observation of automatic distributed deadlock resolution (see a detailed example of Distributed SS2PL). As a matter of fact, SS2PL inheriting properties of Recoverability and CO is more significant than being a subset of 2PL, which by itself in its general form, besides comprising a simple serializability mechanism (however serializability is also implied by CO), in not known to provide SS2PL with any other significant qualities. 2PL in its general form, as well as when combined with Strictness, i.e., Strict 2PL (S2PL), are not known to be utilized in practice. The popular SS2PL does not require to mark "end of phase-1" as 2PL and S2PL do, and thus is simpler to implement. Also unlike the general 2PL, SS2PL provides, as mentioned above, the useful Strictness and Commitment ordering properties.

Many variants of SS2PL exist that utilize various lock types with various semantics in different situations, including cases of lock-type change during a transaction. Notable are variants that use Multiple granularity locking.

Comments:

1. SS2PL Vs. S2PL: Both provide Serializability and Strictness. Since S2PL is a super class of SS2PL it may, in principle, provide more concurrency. However no concurrency advantage is typically practically noticed (exactly

same locking exists for both, with practically not much earlier lock release for S2PL), and the overhead of dealing with an end-of-phase-1 mechanism in S2PL, separate from transaction-end, is not justified. Also, while SS2PL provides Commitment ordering, S2PL does not. This explains the preference of SS2PL over S2PL.

2. Especially before 1990, but also after, in many articles and books, e.g., (Bernstein et al. 1987, p. 59), the term "Strict 2PL" (S2PL) has been frequently defined by the locking protocol "Release all locks only after transaction end," which is the protocol of SS2PL. Thus, "Strict 2PL" could not be there the name of the intersection of Strictness and 2PL, which is larger than the class generated by the SS2PL protocol. This has caused confusion. With an explicit definition of S2PL as the intersection of Strictness and 2PL, a new name for SS2PL, and an explicit distinction between the classes S2PL and SS2PL, the articles (Breitbart et al. 1991) and (Raz 1992) have intended to clear the confusion: The first using the name "Rigorousness," and the second "SS2PL."
3. A more general property than SS2PL exists (a schedule super-class), **Strict commitment ordering** (Strict CO, or SCO), which as well provides both serializability, strictness, and CO, and has similar locking overhead. Unlike SS2PL, SCO does not block upon a read-write conflict (a read-lock does not block acquiring a write-lock; both SCO and SS2PL have the same behavior for write-read and write-write conflicts) at the cost of a possible delayed commit, and upon such conflict type SCO has shorter average transaction completion time and better performance than SS2PL.[5] While SS2PL obeys the *lock compatibility table* above, SCO has the following table:

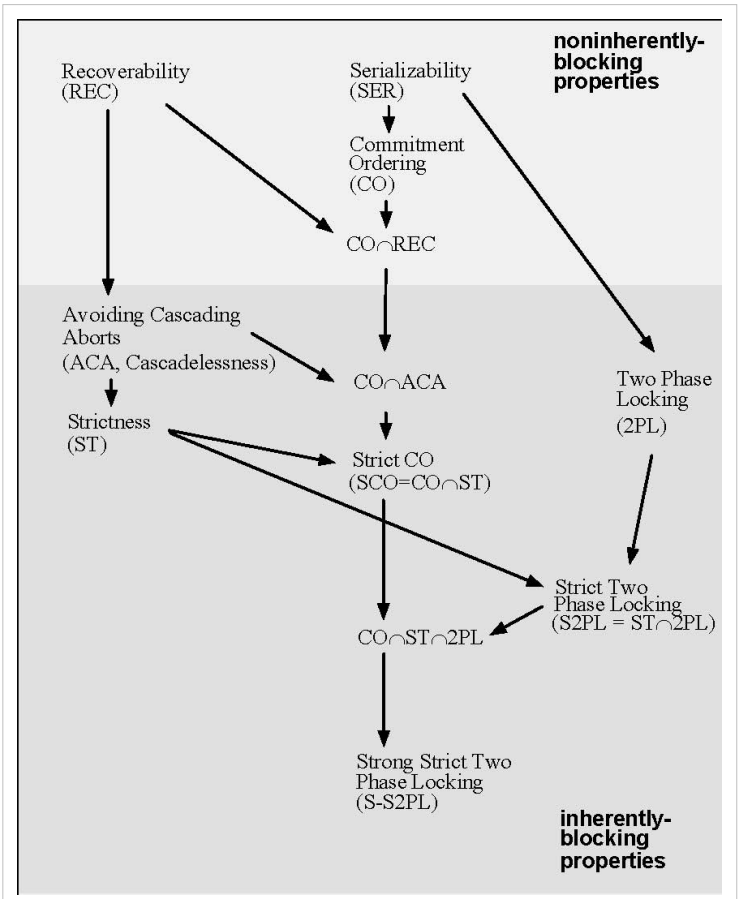
Lock compatibility for SCO

Lock type	read-lock	write-lock
read-lock		
write-lock	**X**	**X**

Note that though SCO releases all locks at transaction end and complies with the 2PL locking rules, SCO is not a subset of 2PL because of its different lock compatibility table. SCO allows materialized read-write conflicts between two transactions in their phases 1, which 2PL does not allow in phase-1 (see about materialized conflicts in Serializability). On the other hand 2PL allows other materialized conflict types in phase-2 that SCO does not allow at all. Together this implies that the schedule classes 2PL and SCO are incomparable (i.e., no class contains the other class).

Summary - Relationships among classes

Between any two schedule classes (define by their schedules' respective properties) that have common schedules, either one *contains* the other (*strictly contains* if they are not equal), or they are *incomparable*. The containment relationships among the 2PL classes and other major schedule classes are summarized in the following diagram. 2PL and its subclasses are *inherently blocking*, which means that no optimistic implementations for them exist (and whenever "Optimistic 2PL" is mentioned it refers to a different mechanism with a class that includes also schedules not in the 2PL class).



Schedule classes containment: An arrow from class A to class B indicates that class A strictly contains B; a lack of a directed path between classes means that the classes are incomparable.A property is inherently blocking, if it can be enforced only by blocking transaction's data access operations until certain events occur in other transactions. (#Raz1992Raz 1992)

Deadlocks in 2PL

Locks block data-access operations. Mutual blocking between transactions results in a *deadlock*, where execution of these transactions is stalled, and no completion can be reached. Thus deadlocks need to be resolved to complete these transactions' executions and release related computing resources. A deadlock is a reflection of a potential cycle in the *precedence graph*, that would occur without the blocking. A deadlock is resolved by aborting a transaction involved with such potential cycle, and breaking the cycle. It is often detected using a *wait-for graph* (a graph of conflicts blocked by locks from being materialized; conflicts not materialized in the database due to blocked operations are not reflected in the precedence graph and do not affect *serializability*), which indicates which transaction is "waiting for" lock release by which transaction, and a cycle means a deadlock. Aborting one transaction per cycle is sufficient to break the cycle. Transactions aborted due to deadlock resolution are executed again immediately.

In a distributed environment an atomic commitment protocol, typically the Two-phase commit (2PC) protocol, is utilized for atomicity. When recoverable data (data under transaction control) are partitioned among 2PC participants (i.e., each data object is controlled by a single 2PC participant), then distributed (global) deadlocks, deadlocks involving two or more participants in 2PC, are resolved automatically as follows:

When SS2PL is effectively utilized in a distributed environment, then global deadlocks due to locking generate voting-deadlocks in 2PC, and are resolved automatically by 2PC (see Commitment ordering (CO), in Exact characterization of voting-deadlocks by global cycles; No reference except the CO articles is known to notice this). For the general case of 2PL, global deadlocks are similarly resolved automatically by the synchronization point protocol of phase-1 end in a distributed transaction (synchronization point is achieved by "voting" (notifying local phase-1 end), and being propagated to the participants in a distributed transaction the same way as a decision point in atomic commitment; in analogy to decision point in CO, a conflicting operation in 2PL cannot happen before

phase-1 end synchronization point, with the same resulting voting-deadlock in the case of a global data-access deadlock; the voting-deadlock (which is also a locking based global deadlock) is automatically resolved by the protocol aborting some transaction involved, with a missing vote, typically using a timeout).

Comment:

When data are partitioned among the *atomic commitment protocol* (e.g., 2PC) participants, automatic *global deadlock* resolution has been overlooked in the database research literature, though deadlocks in such systems has been a quite intensive research area:

- For CO and its special case SS2PL, the automatic resolution by the *atomic commitment protocol* has been noticed only in the CO articles. However, it has been noticed in practice that in many cases global deadlocks are very infrequently detected by the dedicated resolution mechanisms, less than could be expected ("Why do we see so few global deadlocks?"). The reason is probably the deadlocks that are automatically resolved and thus not handled and uncounted by the mechanisms;
- For 2PL in general, the automatic resolution by the (mandatory) *end-of-phase-one synchronization point protocol* (which has same voting mechanism as atomic commitment protocol, and same missing vote handling upon voting deadlock, resulting in global deadlock resolution) has not been mentioned until today (2009). Practically only the special case SS2PL is utilized, where no end-of-phase-one synchronization is needed in addition to atomic commit protocol.

In a distributed environment where recoverable data are not partitioned among atomic commitment protocol participants, no such automatic resolution exists, and distributed deadlocks need to be resolved by dedicated techniques.

Readers–writer lock

In computer science, a **readers-writer** or **shared-exclusive** lock (also known as the **multiple readers / single-writer lock** or the **multi-reader lock**,[1] or by typographical variants such as **readers/writers lock**) is a **synchronization primitive** that solves one of the readers-writers problems. A readers-writer lock is like a mutex, in that it controls access to a shared resource, allowing concurrent access to multiple threads for reading but restricting access to a single thread for writes (or other changes) to the resource. A common use might be to control access to a data structure in memory that can't be updated atomically and isn't valid (and shouldn't be read by another thread) until the update is complete.

One potential problem with a conventional RW lock is that it can lead to write-starvation if contention is high enough, meaning that as long as at least one reading thread holds the lock, no writer thread will be able to acquire it. Since multiple reader threads may hold the lock at once, this means that a writer thread may continue waiting for the lock while new reader threads are able to acquire the lock, even to the point where the writer may still be waiting after all of the readers which were holding the lock when it first attempted to acquire it have released the lock. To avoid writer starvation, a variant on a readers-writer lock can be constructed which prevents any *new* readers from acquiring the lock if there is a writer queued and waiting for the lock, so that the writer will acquire the lock as soon as the readers which were already holding the lock are finished with it. The downside is that it's less performant because each operation, taking or releasing the lock for either read or write, is more complex, internally requiring taking and releasing two mutexes instead of one. This variation is sometimes known as a "write-preferring" or "write-biased" readers-writer lock.[2][3]

A solution to this problem by Brandenburg and Anderson introduces the phase fair reader-writer lock The releasing of the lock alternates between readers and writers. When no writer is requesting a lock, readers are allowed through. After a writer shows up, new readers are queued until existing readers and then the new writer finish with the lock, at which time the backlogged queued readers are released en masse. A C language phase fair implementation that requires 8 bytes per lock:

Readers–writer locks are usually constructed on top of mutexes and condition variables, or on top of semaphores.

The read-copy-update (RCU) algorithm is one solution to the readers-writers problem. RCU is wait-free for readers. The Linux-Kernel implements a special solution for few writers called seqlock.

A **read/write lock pattern** or simply **RWL** is a software design pattern that allows concurrent read access to an object but requires exclusive access for write operations. In this pattern, multiple readers can read the data in parallel but an exclusive lock is needed while writing the data. When a writer is writing the data, readers will be blocked until the writer is finished writing.

Implementations

- The POSIX standard `pthread_rwlock_t` and associated operations.
- The C language Win32 multiple-reader/single-writer lock used in Hamilton C shell. The Hamilton lock presumes contention is low enough that writers are unlikely to be starved, prompting Jordan Zimmerman to suggest a modified version to avoid starvation.
- The ReadWriteLock interface and the ReentrantReadWriteLock locks in Java version 5 or above.
- A simple Windows API implementation by Glenn Slayden.
- The Microsoft `System.Threading.ReaderWriterLockSlim` lock for C# and other .NET languages.
- The `boost::shared_mutex` read/write lock in the Boost C++ Libraries.
- A pseudo-code implementation in the Readers-writers problem article.

Blind write

In computing, a **blind write** occurs when a transaction writes a value without reading it. Any view serializable schedule that is not conflict serializable must contain a blind write.

Conservative two-phase locking

In computer science, **conservative two-phase locking (C2PL)** is a locking method used in DBMS and relational databases.

Conservative 2PL *prevents* deadlocks.

The difference between 2PL and C2PL is that C2PL's transactions obtain all the locks they need before the transactions begin. This is to ensure that a transaction that already holds some locks will not block waiting for other locks.

In heavy lock contention, C2PL reduces the time locks are held on average, relative to 2PL and Strict 2PL, because transactions that hold locks are never blocked.

In light lock contention, C2PL holds more locks than is necessary, because it is hard to tell what locks will be needed in the future, thus leads to higher overhead.

Also, a transaction will not even obtain any locks if it cannot obtain all the locks it needs in its initial request. Furthermore, each transaction needs to declare its read and write set (data items to be read/written during transaction), which is not always possible. Because of these limitations, C2PL is not used very frequently.

Strong strict two-phase locking

In databases and transaction processing, **two-phase locking** (**2PL**) is a concurrency control method that guarantees serializability.[1][2] It is also the name of the resulting set of database transaction schedules (histories). The protocol utilizes locks, applied by a transaction to data, which may block (interpreted as signals to stop) other transactions from accessing the same data during the transaction's life.

By the 2PL protocol locks are applied and removed in two phases:

1. Expanding phase: locks are acquired and no locks are released.
2. Shrinking phase: locks are released and no locks are acquired.

Two types of locks are utilized by the basic protocol: *Shared* and *Exclusive* locks. Refinements of the basic protocol may utilize more lock types. Using locks that block processes, 2PL may be subject to deadlocks that result from the mutual blocking of two or more transactions.

2PL is a superset of **strong strict two-phase locking** (**SS2PL**),[3] also called **rigorousness**,[4] which has been widely utilized for concurrency control in general-purpose database systems since the 1970s. SS2PL implementations have many variants. SS2PL was called *strict 2PL* but this name usage is not recommended now. Now **strict 2PL** (**S2PL**) is the intersection of strictness and 2PL, which is different from SS2PL. SS2PL is also a special case of commitment ordering, and inherits many of CO's useful properties. SS2PL actually comprises only one phase: phase-2 does not exist, and all locks are released only after transaction end. Thus this useful 2PL type is not two-phased at all.

Neither 2PL nor S2PL in their general forms are known to be used in practice. Thus 2PL by itself does not seem to have much practical importance, and whenever 2PL or S2PL utilization has been mentioned in the literature, the intention has been SS2PL. What has made SS2PL so popular (probably the most utilized serializability mechanism) is the effective and efficient locking-based combination of two ingredients (the first does not exist in both general 2PL and S2PL; the second does not exist in general 2PL):

1. Commitment ordering, which provides both serializability, and effective distributed serializability and global serializability, and
2. Strictness, which provides cascadelessness (ACA, cascade-less recoverability) and (independently) allows efficient database recovery from failure.

Additionally SS2PL is easier, with less overhead to implement than both 2PL and S2PL, provides exactly the same locking, but sometimes releases locks later. However, practically (though not simplistically theoretically) such later lock release occurs only slightly later, and this apparent disadvantage is insignificant and disappears next to the advantages of SS2PL.

Thus, the importance of the general *Two-phase locking* (2PL) is historic only, while *Strong strict two-phase locking* (SS2PL) is practically the important mechanism and resulting schedule property.

Data-access locks

A lock is a system object associated with a shared resource such as a data item of an elementary type, a row in a database, or a page of memory. In a database, a lock on a database object (a data-access lock) may need to be acquired by a transaction before accessing the object. Correct use of locks prevents undesired, incorrect or inconsistent operations on shared resources by other concurrent transactions. When a database object with an existing lock acquired by one transaction needs to be accessed by another transaction, the existing lock for the object and the type of the intended access are checked by the system. If the existing lock type does not allow this specific attempted concurrent access type, the transaction attempting access is blocked (according to a predefined agreement/scheme). In practice a lock on an object does not directly block a transaction's operation upon the object, but rather blocks that transaction from acquiring another lock on the same object, needed to be held/owned by the transaction before performing this operation. Thus, with a locking mechanism, needed operation blocking is

controlled by a proper lock blocking scheme, which indicates which lock type blocks which lock type.

Two major types of locks are utilized:

- **Write-lock** (**exclusive lock**) is associated with a database object by a transaction (Terminology: "the transaction locks the object," or "acquires lock for it") before *writing* (inserting/modifying/deleting) this object.
- **Read-lock** (**shared lock**) is associated with a database object by a transaction before *reading* (retrieving the state of) this object.

The common interactions between these lock types are defined by blocking behavior as follows:

- An existing *write-lock* on a database object blocks an intended *write* upon the same object (already requested/issued) by another transaction by blocking a respective *write-lock* from being acquired by the other transaction. The second write-lock will be acquired and the requested write of the object will take place (materialize) after the existing write-lock is released.
- A *write-lock* blocks an intended (already requested/issued) *read* by another transaction by blocking the respective *read-lock* .
- A *read-lock* blocks an intended *write* by another transaction by blocking the respective *write-lock* .
- A *read-lock* does not block an intended *read* by another transaction. The respective *read-lock* for the intended read is acquired (shared with the previous read) immediately after the intended read is requested, and then the intended read itself takes place.

Several variations and refinements of these major lock types exist, with respective variations of blocking behavior. If a first lock blocks another lock, the two locks are called *incompatible*; otherwise the locks are *compatible*. Often lock types blocking interactions are presented in the technical literature by a *Lock compatibility table*. The following is an example with the common, major lock types:

Lock compatibility table

Lock type	read-lock	write-lock
read-lock		**X**
write-lock	**X**	**X**

X indicates incompatibility, i.e, a case when a lock of the first type (in left column) on an object blocks a lock of the second type (in top row) from being acquired on the same object (by another transaction). An object typically has a queue of waiting requested (by transactions) operations with respective locks. The first blocked lock for operation in the queue is acquired as soon as the existing blocking lock is removed from the object, and then its respective operation is executed. If a lock for operation in the queue is not blocked by any existing lock (existence of multiple compatible locks on a same object is possible concurrently) it is acquired immediately.

Comment: In some publications the table entries are simply marked "compatible" or "incompatible", or respectively "yes" or "no".

Two-phase locking and its special cases

Two-phase locking

According to the **two-phase locking** protocol a transaction handles its locks in two distinct, consecutive phases during the transaction's execution:

1. **Expanding phase** (aka Growing phase): locks are acquired and no locks are released (the number of locks can only increase).
2. **Shrinking phase**: locks are released and no locks are acquired.

The serializability property is guaranteed for a schedule with transactions that obey the protocol. The 2PL *schedule class* is defined as the class of all the schedules comprising transactions with data access orders that could be generated by the 2PL protocol (or in other words, all the schedules that the 2PL protocol can generate).

Typically, without explicit knowledge in a transaction on end of phase-1, it is safely determined only when a transaction has entered its *ready* state in all its processes (processing has ended, and it is ready to be committed; no additional data access and locking are needed and can happen). In this case phase-2 can end immediately (no additional processing is needed), and actually no phase-2 is needed. Also, if several processes (two or more) are involved, then a synchronization point (similar to *atomic commitment*) among them is needed to determine end of phase-1 for all of them (i.e., in the entire distributed transaction), to start releasing locks in phase-2 (otherwise it is very likely that both 2PL and Serializability are quickly violated). Such synchronization point is usually too costly (involving a distributed protocol similar to atomic commitment), and end of phase-1 is usually postponed to be merged with transaction end (atomic commitment protocol for a multi-process transaction), and again phase-2 is not needed. This turns 2PL to SS2PL (see below). All known implementations of 2PL in products are SS2PL based, and whenever 2PL (or Strict 2PL, S2PL) practical utilization has been mentioned in the professional literature, the intention has been SS2PL.

Strict two-phase locking

The **strict two-phase locking** (S2PL) class of schedules is the intersection of the 2PL class with the class of schedules possessing the *Strictness* property.

To comply with the S2PL protocol a transaction needs to comply with 2PL, and release its *write (exclusive)* locks only after it has ended, i.e., being either *committed* or *aborted*. On the other hand, *read (shared)* locks are released regularly during phase 2. Implementing general S2PL requires explicit support of phase-1 end, separate from transaction end, and no such widely utilized product implementation is known.

S2PL is a special case of 2PL, i.e., the S2PL class is a proper subclass of 2PL

Strong strict two-phase locking

or **Rigorousness**, or **Rigorous scheduling**, or **Rigorous two-phase locking**

To comply with **strong strict two-phase locking** (SS2PL) the locking protocol releases both *write (exclusive)* and *read (shared)* locks applied by a transaction only after the transaction has ended, i.e., only after both completing executing (being *ready*) and becoming either *committed* or *aborted*. This protocol also complies with the S2PL rules. A transaction obeying SS2PL can be viewed as having phase-1 that lasts the transaction's entire execution duration, and no phase-2 (or a degenerate phase-2). Thus, only one phase is actually left, and "two-phase" in the name seems to be still utilized due to the historical development of the concept from 2PL, and 2PL being a super-class. The SS2PL property of a schedule is also called **Rigorousness**. It is also the name of the class of schedules having this property, and an SS2PL schedule is also called a "rigorous schedule". The term "Rigorousness" is free of the unnecessary legacy of "two-phase," as well as being independent of any (locking) mechanism (in principle other blocking mechanisms can be utilized). The property's respective locking mechanism is sometimes referred to as

Rigorous 2PL.

SS2PL is a special case of S2PL, i.e., the SS2PL class of schedules is a proper subclass of S2PL (every SS2PL schedule is also an S2PL schedule, but S2PL schedules exist that are not SS2PL).

SS2PL has been the concurrency control protocol of choice for most database systems and utilized since their early days in the 1970s. It is proven to be an effective mechanism in many situations, and provides besides Serializability also Strictness (a special case of cascadeless Recoverability), which is instrumental for efficient database recovery, and also Commitment ordering (CO) for participating in distributed environments where a CO based distributed serializability and global serializability solutions are employed. Being a subset of CO, an efficient implementation of *distributed SS2PL* exists without a distributed lock manager (DLM), while distributed deadlocks (see below) are resolved automatically. The fact that SS2PL employed in multi database systems ensures global serializability has been known for years before the discovery of CO, but only with CO came the understanding of the role of an atomic commitment protocol in maintaining global serializability, as well as the observation of automatic distributed deadlock resolution (see a detailed example of Distributed SS2PL). As a matter of fact, SS2PL inheriting properties of Recoverability and CO is more significant than being a subset of 2PL, which by itself in its general form, besides comprising a simple serializability mechanism (however serializability is also implied by CO), in not known to provide SS2PL with any other significant qualities. 2PL in its general form, as well as when combined with Strictness, i.e., Strict 2PL (S2PL), are not known to be utilized in practice. The popular SS2PL does not require to mark "end of phase-1" as 2PL and S2PL do, and thus is simpler to implement. Also unlike the general 2PL, SS2PL provides, as mentioned above, the useful Strictness and Commitment ordering properties.

Many variants of SS2PL exist that utilize various lock types with various semantics in different situations, including cases of lock-type change during a transaction. Notable are variants that use Multiple granularity locking.

Comments:

1. SS2PL Vs. S2PL: Both provide Serializability and Strictness. Since S2PL is a super class of SS2PL it may, in principle, provide more concurrency. However no concurrency advantage is typically practically noticed (exactly same locking exists for both, with practically not much earlier lock release for S2PL), and the overhead of dealing with an end-of-phase-1 mechanism in S2PL, separate from transaction-end, is not justified. Also, while SS2PL provides Commitment ordering, S2PL does not. This explains the preference of SS2PL over S2PL.
2. Especially before 1990, but also after, in many articles and books, e.g., (Bernstein et al. 1987, p. 59), the term "Strict 2PL" (S2PL) has been frequently defined by the locking protocol "Release all locks only after transaction end," which is the protocol of SS2PL. Thus, "Strict 2PL" could not be there the name of the intersection of Strictness and 2PL, which is larger than the class generated by the SS2PL protocol. This has caused confusion. With an explicit definition of S2PL as the intersection of Strictness and 2PL, a new name for SS2PL, and an explicit distinction between the classes S2PL and SS2PL, the articles (Breitbart et al. 1991) and (Raz 1992) have intended to clear the confusion: The first using the name "Rigorousness," and the second "SS2PL."
3. A more general property than SS2PL exists (a schedule super-class), **Strict commitment ordering** (Strict CO, or SCO), which as well provides both serializability, strictness, and CO, and has similar locking overhead. Unlike SS2PL, SCO does not block upon a read-write conflict (a read-lock does not block acquiring a write-lock; both SCO and SS2PL have the same behavior for write-read and write-write conflicts) at the cost of a possible delayed commit, and upon such conflict type SCO has shorter average transaction completion time and better performance than SS2PL.[5] While SS2PL obeys the *lock compatibility table* above, SCO has the following table:

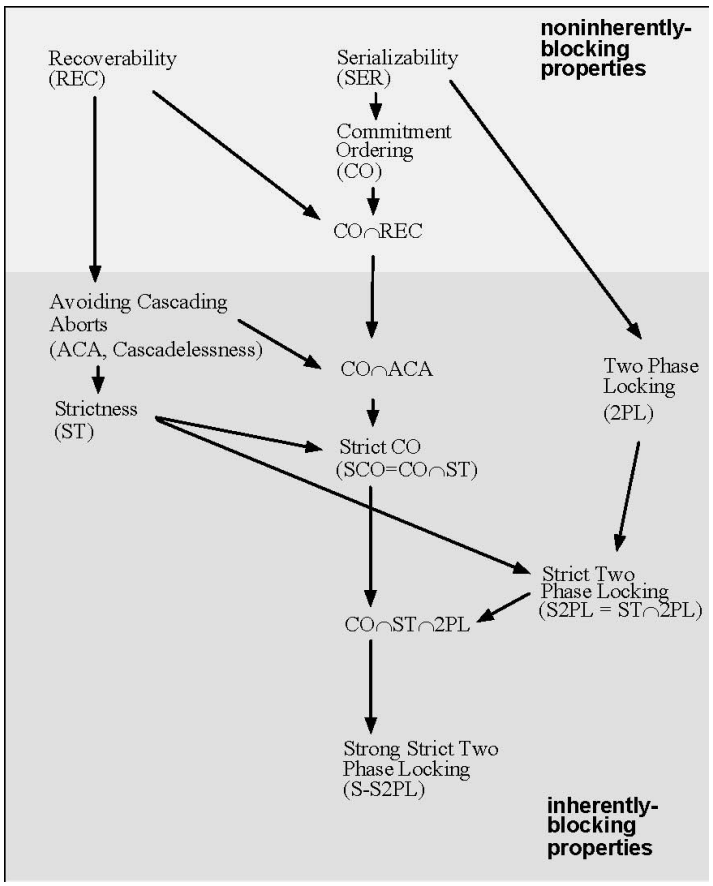
Lock compatibility for SCO

Lock type	read-lock	write-lock
read-lock		
write-lock	X	X

Note that though SCO releases all locks at transaction end and complies with the 2PL locking rules, SCO is not a subset of 2PL because of its different lock compatibility table. SCO allows materialized read-write conflicts between two transactions in their phases 1, which 2PL does not allow in phase-1 (see about materialized conflicts in Serializability). On the other hand 2PL allows other materialized conflict types in phase-2 that SCO does not allow at all. Together this implies that the schedule classes 2PL and SCO are incomparable (i.e., no class contains the other class).

Summary - Relationships among classes

Between any two schedule classes (define by their schedules' respective properties) that have common schedules, either one *contains* the other (*strictly contains* if they are not equal), or they are *incomparable*. The containment relationships among the 2PL classes and other major schedule classes are summarized in the following diagram. 2PL and its subclasses are *inherently blocking*, which means that no optimistic implementations for them exist (and whenever "Optimistic 2PL" is mentioned it refers to a different mechanism with a class that includes also schedules not in the 2PL class).



Schedule classes containment: An arrow from class A to class B indicates that class A strictly contains B; a lack of a directed path between classes means that the classes are incomparable.A property is inherently blocking, if it can be enforced only by blocking transaction's data access operations until certain events occur in other transactions. (#Raz1992Raz 1992)

Deadlocks in 2PL

Locks block data-access operations. Mutual blocking between transactions results in a *deadlock*, where execution of these transactions is stalled, and no completion can be reached. Thus deadlocks need to be resolved to complete these transactions' executions and release related computing resources. A deadlock is a reflection of a potential cycle in the *precedence graph*, that would occur without the blocking. A deadlock is resolved by aborting a transaction involved with such potential cycle, and breaking the cycle. It is often detected using a *wait-for graph* (a graph of conflicts blocked by locks from being materialized; conflicts not materialized in the database due to blocked operations are not reflected in the precedence graph and do not affect

serializability), which indicates which transaction is "waiting for" lock release by which transaction, and a cycle means a deadlock. Aborting one transaction per cycle is sufficient to break the cycle. Transactions aborted due to deadlock resolution are executed again immediately.

In a distributed environment an atomic commitment protocol, typically the Two-phase commit (2PC) protocol, is utilized for atomicity. When recoverable data (data under transaction control) are partitioned among 2PC participants (i.e., each data object is controlled by a single 2PC participant), then distributed (global) deadlocks, deadlocks involving two or more participants in 2PC, are resolved automatically as follows:

When SS2PL is effectively utilized in a distributed environment, then global deadlocks due to locking generate voting-deadlocks in 2PC, and are resolved automatically by 2PC (see Commitment ordering (CO), in Exact characterization of voting-deadlocks by global cycles; No reference except the CO articles is known to notice this). For the general case of 2PL, global deadlocks are similarly resolved automatically by the synchronization point protocol of phase-1 end in a distributed transaction (synchronization point is achieved by "voting" (notifying local phase-1 end), and being propagated to the participants in a distributed transaction the same way as a decision point in atomic commitment; in analogy to decision point in CO, a conflicting operation in 2PL cannot happen before phase-1 end synchronization point, with the same resulting voting-deadlock in the case of a global data-access deadlock; the voting-deadlock (which is also a locking based global deadlock) is automatically resolved by the protocol aborting some transaction involved, with a missing vote, typically using a timeout).

Comment:

When data are partitioned among the *atomic commitment protocol* (e.g., 2PC) participants, automatic *global deadlock* resolution has been overlooked in the database research literature, though deadlocks in such systems has been a quite intensive research area:

- For CO and its special case SS2PL, the automatic resolution by the *atomic commitment protocol* has been noticed only in the CO articles. However, it has been noticed in practice that in many cases global deadlocks are very infrequently detected by the dedicated resolution mechanisms, less than could be expected ("Why do we see so few global deadlocks?"). The reason is probably the deadlocks that are automatically resolved and thus not handled and uncounted by the mechanisms;
- For 2PL in general, the automatic resolution by the (mandatory) *end-of-phase-one synchronization point protocol* (which has same voting mechanism as atomic commitment protocol, and same missing vote handling upon voting deadlock, resulting in global deadlock resolution) has not been mentioned until today (2009). Practically only the special case SS2PL is utilized, where no end-of-phase-one synchronization is needed in addition to atomic commit protocol.

In a distributed environment where recoverable data are not partitioned among atomic commitment protocol participants, no such automatic resolution exists, and distributed deadlocks need to be resolved by dedicated techniques.

Index locking

In databases an *index* is a data structure, part of the database, used by a database system to effectively navigate access to *user data*. Index data are system data distinct from user data, and consist primarily of pointers. Changes in a database (by insert, delete, or modify operations), may require indexes to be updated to maintain accurate user data accesses.[1] **Index locking** is a technique used to maintain index integrity. A portion of an index is locked during a database transaction when this portion is being accessed by the transaction as a result of attempt to access related user data. Additionally, special database system transactions (not user-invoked transactions) may be invoked to maintain and modify an index, as part of a system's self-maintenance activities. When a portion of an index is locked by a transaction, other transactions may be blocked from accessing this index portion (blocked from modifying, and even from reading it, depending on lock type and needed operation).

Specialized concurrency control techniques exist for accessing indexes. These techniques depend on the index type, and take advantage of its structure. They are typically much more effective than applying to indexes common concurrency control methods applied to user data. Notable and widely researched are specialized techniques for B-trees (B-Tree concurrency control[2]) which are regularly used as database indexes.

Index locks are used to coordinate threads accessing indexes concurrently, and typically shorter-lived than the common transaction locks on user data. In professional literature, they are often called *latches*.

Snapshot isolation

In databases, and transaction processing (transaction management), **snapshot isolation** is a guarantee that all reads made in a transaction will see a consistent snapshot of the database (in practice it reads the last committed values that existed at the time it started), and the transaction itself will successfully commit only if no updates it has made conflict with any concurrent updates made since that snapshot.

Snapshot isolation has been adopted by several major database management systems, such as SQL Anywhere, InterBase, Firebird, Oracle, PostgreSQL and Microsoft SQL Server (2005 and later). The main reason for its adoption is that it allows better performance than serializability, yet still avoids most of the concurrency anomalies that serializability avoids (but not always all). In practice snapshot isolation is implemented within multiversion concurrency control (MVCC), where generational values of each data item (versions) are maintained: MVCC is a common way to increase concurrency and performance by generating a new version of a database object each time the object is written, and allowing transactions' read operations of several last relevant versions (of each object). Snapshot isolation has also been used to critique the ANSI SQL-92 standard's definition of isolation levels, as it exhibits none of the "anomalies" that the SQL standard prohibited, yet is not serializable (the anomaly-free isolation level defined by ANSI).

Snapshot isolation is called "serializable" mode in Oracle[1][2][3] and PostgreSQL versions prior to 9.1,[4][5] which may cause confusion with the "real serializability" mode. There are arguments both for and against this decision; what is clear is that users must be aware of the distinction to avoid possible undesired anomalous behavior in their database system logic.

Definition

A transaction executing under snapshot isolation appears to operate on a personal *snapshot* of the database, taken at the start of the transaction. When the transaction concludes, it will successfully commit only if the values updated by the transaction have not been changed externally since the snapshot was taken. Such a write-write conflict will cause the transaction to abort.

In a *write skew* anomaly, two transactions (T1 and T2) concurrently read an overlapping data set (e.g. values V1 and V2), concurrently make disjoint updates (e.g. T1 updates V1, T2 updates V2), and finally concurrently commit, neither having seen the update performed by the other. Were the system serializable, such an anomaly would be impossible, as either T1 or T2 would have to occur "first", and be visible to the other. In contrast, snapshot isolation permits write skew anomalies.

As a concrete example, imagine V1 and V2 are two balances held by a single person, Phil. The bank will allow either V1 or V2 to run a deficit, provided the total held in both is never negative (i.e. $V1 + V2 \geq 0$). Both balances are currently $100. Phil initiates two transactions concurrently, T1 withdrawing $200 from V1, and T2 withdrawing $200 from V2.

If the database guaranteed serializable transactions, the simplest way of coding T1 is to deduct $200 from V1, and then verify that $V1 + V2 \geq 0$ still holds, aborting if not. T2 similarly deducts $200 from V2 and then verifies $V1 + V2 \geq 0$. Since the transactions must serialize, either T1 happens first, leaving V1 = -$100, V2 = $100, and preventing T2 from succeeding (since V1 + (V2 - $200) is now -$200), or T2 happens first and similarly prevents T1 from committing.

Under snapshot isolation, however, T1 and T2 operate on private snapshots of the database: each deducts $200 from an account, and then verifies that the new total is zero, using the other account value that held when the snapshot was taken. Since neither *update* conflicts, both commit successfully, leaving V1 = V2 = -$100, and V1 + V2 = -$200.

If built on multiversion concurrency control, snapshot isolation allows transactions to proceed without worrying about concurrent operations, and more importantly without needing to re-verify all read operations when the

transaction finally commits. The only information that must be stored during the transaction is a list of updates made, which can be scanned for conflicts fairly easily before being committed.

Serializable Snapshot Isolation

Potential inconsistency problems arising from write skew anomalies can be fixed by adding (otherwise unnecessary) updates to the transactions in order to enforce the serializability property.

- **Materialize the conflict**: Add a special conflict table, which both transactions update in order to create a direct write-write conflict.
- **Promotion**: Have one transaction "update" a read-only location (replacing a value with the same value) in order to create a direct write-write conflict (or use an equivalent promotion, e.g. Oracle's SELECT FOR UPDATE).

In the example above, we can materialize the conflict by adding a new table which makes the hidden constraint explicit, mapping each person to their *total balance*. Phil would start off with a total balance of $200, and each transaction would attempt to subtract $200 from this, creating a write-write conflict that would prevent the two from succeeding concurrently. This approach violates the normal form.[*citation needed*]

Alternatively, we can promote one of the transaction's reads to a write. For instance, T2 could set V1 = V1, creating an artificial write-write conflict with T1 and, again, preventing the two from succeeding concurrently. This solution may not always be possible.

In general, therefore, snapshot isolation puts some of the problem of maintaining non-trivial constraints onto the user, who may not appreciate either the potential pitfalls or the possible solutions. The upside to this transfer is better performance.

With additional communication between transactions, the anomalies that snapshot isolation normally allows can be blocked by aborting one of the transactions involved, turning a snapshot isolation implementation into a full serializability guarantee.[6] This implementation of serializability is well-suited to multiversion concurrency control databases, and has been adopted in PostgreSQL 9.1, where it is referred to as "Serializable Snapshot Isolation", abbreviated to SSI. When used consistently, this eliminates the need for the above workarounds. The downside over snapshot isolation is an increase in aborted transactions. This can perform better or worse than snapshot isolation with the above workarounds, depending on workload.

History

Snapshot isolation arose from work on multiversion concurrency control databases, where multiple versions of the database are maintained concurrently to allow readers to execute without colliding with writers. Such a system allows a natural definition and implementation of such an isolation level. InterBase later owned by Borland provided SI as far back as 1984[*citation needed*].

Unfortunately, the ANSI SQL-92 standard was written with a lock-based database in mind, and hence is rather vague when applied to MVCC systems. Berenson *et al.* wrote a paper in 1995 critiquing the SQL standard, and cited snapshot isolation as an example of an isolation level that did not exhibit the standard anomalies described in the ANSI SQL-92 standard, yet still had anomalous behaviour when compared with serializable transactions.

Non-lock concurrency control

In Computer Science, in the field of databases, **non-lock concurrency control** is a concurrency control method used in relational databases without using locking.

There are several non-lock concurrency control methods, which involve the use of timestamps on transaction to determine transaction priority:

- Optimistic concurrency control
- Timestamp-based concurrency control
- Multiversion concurrency control

Commitment ordering

Commitment ordering (**CO**) is a class of interoperable *serializability* techniques in concurrency control of databases, transaction processing, and related applications. It allows optimistic (non-blocking) implementations. With the proliferation of multi-core processors, CO has been also increasingly utilized in concurrent programming, transactional memory, and especially in software transactional memory (STM) for achieving serializability optimistically. CO is also the name of the resulting transaction schedule (history) property, which was originally defined in 1988 with the name *dynamic atomicity*.[1] In a CO compliant schedule the chronological order of commitment events of transactions is compatible with the precedence order of the respective transactions. CO is a broad special case of *conflict serializability*, and effective means (reliable, high-performance, distributed, and scalable) to achieve global serializability (modular serializability) across any collection of database systems that possibly use different concurrency control mechanisms (CO also makes each system serializability compliant, if not already).

Each not-CO-compliant database system is augmented with a CO component (the commitment order coordinator—COCO) which orders the commitment events for CO compliance, with neither data-access nor any other transaction operation interference. As such CO provides a low overhead, general solution for global serializability (and distributed serializability), instrumental for global concurrency control (and distributed concurrency control) of multi database systems and other transactional objects, possibly highly distributed (e.g., within cloud computing, grid computing, and networks of smartphones). An atomic commitment protocol (ACP; of any type) is a fundamental part of the solution, utilized to break global cycles in the conflict (precedence, serializability) graph. CO is the most general property (a necessary condition) that guarantees global serializability, if the database systems involved do not share concurrency control information beyond atomic commitment protocol (unmodified) messages, and have no knowledge whether transactions are global or local (the database systems are *autonomous*). Thus CO (with its variants) is the only general technique that does not require the typically costly distribution of local concurrency control information (e.g., local precedence relations, locks, timestamps, or tickets). It generalizes the popular *strong strict two-phase locking* (SS2PL) property, which in conjunction with the *two-phase commit protocol* (2PC) is the de facto standard to achieve global serializability across (SS2PL based) database systems. As a result CO compliant database systems (with any, different concurrency control types) can transparently join such SS2PL based solutions for global serializability.

In addition, locking based *global deadlocks* are resolved automatically in a CO based multi-database environment, an important side-benefit (including the special case of a completely SS2PL based environment; a previously unnoticed fact for SS2PL).

Furthermore, **strict commitment ordering** (SCO; Raz 1991c), the intersection of *Strictness* and CO, provides better performance (shorter average transaction completion time and resulting better transaction throughput) than SS2PL whenever read-write conflicts are present (identical blocking behavior for write-read and write-write conflicts; comparable locking overhead). The advantage of SCO is especially significant during lock contention. Strictness allows both SS2PL and SCO to use the same effective *database recovery* mechanisms.

Two major generalizing variants of CO exist, **extended CO** (ECO; Raz 1993a) and **multi-version CO** (MVCO; Raz 1993b). They as well provide global serializability without local concurrency control information distribution, can be combined with any relevant concurrency control, and allow optimistic (non-blocking) implementations. Both use additional information for relaxing CO constraints and achieving better concurrency and performance. **Vote ordering** (VO or Generalized CO (GCO); Raz 2009) is a container schedule set (property) and technique for CO and all its variants. Local VO is a necessary condition for guaranteeing global serializability, if the atomic commitment protocol (ACP) participants do not share concurrency control information (have the *generalized autonomy* property). CO and its variants inter-operate transparently, guaranteeing global serializability and automatic global deadlock resolution also together in a mixed, heterogeneous environment with different variants.

Overview

The *Commitment ordering* (CO; Raz 1990, 1992, 1994, 2009) schedule property has been referred to also as *Dynamic atomicity* (since 1988), *commit ordering*, *commit order serializability*, and *strong recoverability* (since 1991). The latter is a misleading name since CO is incomparable with *recoverability*, and the term "strong" implies a special case. This means that a schedule with a strong recoverability property does not necessarily have the CO property, and vice versa.

In 2009 CO has been characterized as a major concurrency control method, together with the previously known (since the 1980s) three major methods: *Locking*, *Time-stamp ordering*, and *Serialization graph testing*, and as an enabler for the interoperability of systems using different concurrency control mechanisms.[2]

In a federated database system or any other more loosely defined multidatabase system, which are typically distributed in a communication network, transactions span multiple and possibly Distributed databases. Enforcing global serializability in such system is problematic. Even if every local schedule of a single database is serializable, still, the global schedule of a whole system is not necessarily serializable. The massive communication exchanges of conflict information needed between databases to reach conflict serializability would lead to unacceptable performance, primarily due to computer and communication latency. The problem of achieving global serializability effectively had been characterized as open until the public disclosure of CO in 1991 by its inventor Yoav Raz (Raz 1991a; see also Global serializability).

Enforcing CO is an effective way to enforce conflict serializability globally in a distributed system, since enforcing CO locally in each database (or other transactional object) also enforces it globally. Each database may use any, possibly different, type of concurrency control mechanism. With a local mechanism that already provides conflict serializability, enforcing CO locally does not cause any additional aborts, since enforcing CO locally does not affect the data access scheduling strategy of the mechanism (this scheduling determines the serializability related aborts; such a mechanism typically does not consider the commitment events or their order). The CO solution requires no communication overhead, since it uses (unmodified) *atomic commitment* protocol messages only, already needed by each distributed transaction to reach atomicity. An atomic commitment protocol plays a central role in the distributed CO algorithm, which enforces CO globally, by breaking global cycles (cycles that span two or more databases) in the global conflict graph. CO, its special cases, and its generalizations are interoperable, and achieve global serializability while transparently being utilized together in a single heterogeneous distributed environment comprising objects with possibly different concurrency control mechanisms. As such, *Commitment ordering*, including its special cases, and together with its generalizations (see CO variants below), provides a general, high performance, fully distributed solution (no central processing component or central data structure are needed) for guaranteeing global serializability in heterogeneous environments of multidatabase systems and other multiple transactional objects (objects with states accessed and modified only by transactions; e.g., in the framework of transactional processes, and within Cloud computing and Grid computing). The CO solution scales up with network size and the number of databases without any negative impact on performance (assuming the statistics of a single distributed transaction, e.g., the average number of databases involved with a single transaction, are unchanged).

With the proliferation of Multi-core processors, Optimistic CO (OCO) has been also increasingly utilized to achieve serializability in software transactional memory, and numerous STM articles and patents utilizing "commit order" have already been published (e.g., Zhang et al. 2006).

The commitment ordering solution for global serializability

General characterization of CO

Commitment ordering (CO) is a special case of conflict serializability. CO can be enforced with *non-blocking* mechanisms (each transaction can complete its task without having its data-access blocked, which allows optimistic concurrency control; however, commitment could be blocked). In a CO schedule the commitment events' (partial) precedence order of the transactions corresponds to the precedence (partial) order of the respective transactions in the (directed) conflict graph (precedence graph, serializability graph), as induced by their conflicting access operations (usually read and write (insert/modify/delete) operations; CO also applies to higher level operations, where they are conflicting if noncommutative, as well as to conflicts between operations upon multi-version data).

- **Definition: commitment ordering**

  Let T_1, T_2 be two *committed* transactions in a schedule, such that T_2 is *in a conflict* with T_1 (T_1 *precedes* T_2). The schedule has the **Commitment ordering** (CO) property, if for every two such transactions T_1 commits before T_2 commits.

The commitment decision events are generated by either a local commitment mechanism, or an atomic commitment protocol, if different processes need to reach consensus on whether to commit or abort. The protocol may be distributed or centralized. Transactions may be committed concurrently, if the commit partial order allows (if they do not have conflicting operations). If different conflicting operations induce different partial orders of same transactions, then the conflict graph has cycles, and the schedule will violate serializability when all the transactions on a cycle are committed. In this case no partial order for commitment events can be found. Thus, cycles in the conflict graph need to be broken by aborting transactions. However, any conflict serializable schedule can be made CO without aborting any transaction, by properly delaying commit events to comply with the transactions' precedence partial order.

CO enforcement by itself is not sufficient as a concurrency control mechanism, since CO lacks the recoverability property, which should be supported as well.

The distributed CO algorithm

A fully distributed *Global commitment ordering* enforcement algorithm exists, that uses local CO of each participating database, and needs only (unmodified) Atomic commitment protocol messages with no further communication. The distributed algorithm is the combination of local (to each database) CO algorithm processes, and an atomic commitment protocol (which can be fully distributed). Atomic commitment protocol is essential to enforce atomicity of each distributed transaction (to decide whether to commit or abort it; this procedure is always carried out for distributed transactions, independently of concurrency control and CO). A common example of an atomic commitment protocol is the *two-phase commit protocol*, which is resilient to many types of system failure. In a reliable environment, or when processes usually fail together (e.g., in the same integrated circuit), a simpler protocol for atomic commitment may be used (e.g., a simple handshake of distributed transaction's participating processes with some arbitrary but known special participant, the transaction's coordinator, i.e., a type of *one-phase commit* protocol). An atomic commitment protocol reaches consensus among participants on whether to *commit* or *abort* a distributed (global) transaction that spans these participants. An essential stage in each such protocol is the **YES vote** (either explicit, or implicit) by each participant, which means an obligation of the voting participant to obey the decision of the protocol, either commit or abort. Otherwise a participant can unilaterally abort the transaction by an explicit NO vote. The protocol commits the transaction only if YES votes have been received from *all* participants, and thus typically a missing YES vote of a participant is considered a NO vote by this participant. Otherwise the protocol aborts the transaction. The various atomic commit protocols only differ in their abilities to handle different computing environment failure situations, and the amounts of work and other computing resources needed in different situations.

The entire CO solution for global serializability is based on the fact that in case of a missing vote for a distributed transaction, the atomic commitment protocol eventually aborts this transaction.

Enforcing global CO

In each database system a local CO algorithm determines the needed commitment order for that database. By the characterization of CO above, this order depends on the local precedence order of transactions, which results from the local data access scheduling mechanisms. Accordingly YES votes in the atomic commitment protocol are scheduled for each (unaborted) distributed transaction (in what follows "a vote" means a YES vote). If a precedence relation (conflict) exists between two transactions, then the second will not be voted on before the first is completed (either committed or aborted), to prevent possible commit order violation by the atomic commitment protocol. Such can happen since the commit order by the protocol is not necessarily the same as the voting order. If no precedence relation exists, both can be voted on concurrently. This *vote ordering strategy* ensures that also the atomic commitment protocol maintains commitment order, and it is a *necessary condition* for guaranteeing Global CO (and the local CO of a database; without it both Global CO and Local CO (a property meaning that each database is CO compliant) may be violated).

However, since database systems schedule their transactions independently, it is possible that the transactions' precedence orders in two databases or more are not compatible (no global partial order exists that can embed the respective local partial orders together). With CO precedence orders are also the commitment orders. When participating databases in a same distributed transaction do not have compatible local precedence orders for that transaction (without "knowing" it; typically no coordination between database systems exists on conflicts, since the needed communication is massive and unacceptably degrades performance) it means that the transaction resides on a global cycle (involving two or more databases) in the global conflict graph. In this case the atomic commitment protocol will fail to collect all the votes needed to commit that transaction: By the *vote ordering strategy* above at least one database will delay its vote for that transaction indefinitely, to comply with its own commitment (precedence) order, since it will be waiting to the completion of another, preceding transaction on that global cycle, delayed indefinitely by another database with a different order. This means a ***voting-deadlock*** situation involving the databases on that cycle. As a result the protocol will eventually abort some deadlocked transaction on this global cycle, since each such transaction is missing at least one participant's vote. Selection of the specific transaction on the cycle to be aborted depends on the atomic commitment protocol's abort policies (a timeout mechanism is common, but it may result in more than one needed abort per cycle; both preventing unnecessary aborts and abort time shortening can be achieved by a dedicated abort mechanism for CO). Such abort will break the global cycle involving that distributed transaction. Both deadlocked transactions and possibly other in conflict with the deadlocked (and thus blocked) will be free to be voted on. It is worthwhile noting that each database involved with the voting-deadlock continues to vote regularly on transactions that are not in conflict with its deadlocked transaction, typically almost all the outstanding transactions. Thus, in case of incompatible local (partial) commitment orders, no action is needed since the atomic commitment protocol resolves it automatically by aborting a transaction that is a cause of incompatibility. This means that the above *vote ordering strategy* is also a *sufficient condition* for guaranteeing Global CO.

The following is concluded:

- **The Vote ordering strategy for Global CO Enforcing Theorem**

  Let T_1, T_2 be undecided (neither committed nor aborted) transactions in a database system that enforces CO for local transactions, such that T_2 is *global* and *in conflict* with T_1 (T_1 *precedes* T_2). Then, having T_1 ended (either committed or aborted) before T_2 is voted on to be committed (the *vote ordering strategy*), in each such database system in a multidatabase environment, is a necessary and sufficient condition for guaranteeing Global CO (the condition guarantees Global CO, which may be violated without it).
  Comments:

1. The *vote ordering strategy* that enforces global CO is referred to as CD^3C in (Raz 1992).
2. The Local CO property of a global schedule means that each database is CO compliant. From the necessity discussion part above it directly follows that the theorem is true also when replacing "Global CO" with "Local CO" when global transactions are present. Together it means that Global CO is guaranteed if and only if Local CO is guaranteed (which is untrue for Global conflict serializability and Local conflict serializability: Global implies Local, but not the opposite).

Global CO implies Global serializability.

The **Global CO algorithm** comprises enforcing (local) CO in each participating database system by ordering commits of local transactions (see Enforcing CO locally below) and enforcing the *vote ordering strategy* in the theorem above (for global transactions).

Exact characterization of voting-deadlocks by global cycles

The above global cycle elimination process by a **voting deadlock** can be explained in detail by the following observation:

First it is assumed, for simplicity, that every transaction reaches the ready-to-commit state and is voted on by at least one database (this implies that no blocking by locks occurs). Define a *"wait for vote to commit" graph* as a directed graph with transactions as nodes, and a directed edge from any first transaction to a second transaction if the first transaction blocks the vote to commit of the second transaction (opposite to conventional edge direction in a wait-for graph). Such blocking happens only if the second transaction is in a conflict with the first transaction (see above). Thus this "wait for vote to commit" graph is identical to the global conflict graph. A cycle in the "wait for vote to commit" graph means a deadlock in voting. Hence there is a deadlock in voting if and only if there is a cycle in the conflict graph. Local cycles (confined to a single database) are eliminated by the local serializability mechanisms. Consequently only global cycles are left, which are then eliminated by the atomic commitment protocol when it aborts deadlocked transactions with missing (blocked) respective votes.

Secondly, also local commits are dealt with: Note that when enforcing CO also waiting for a regular local commit of a local transaction can block local commits and votes of other transactions upon conflicts, and the situation for global transactions does not change also without the simplifying assumption above: The final result is the same also with local commitment for local transactions, without voting in atomic commitment for them.

Finally, blocking by a lock (which has been excluded so far) needs to be considered: A lock blocks a conflicting operation and prevents a conflict from being materialized. If the lock is released only after transaction end, it may block indirectly either a vote or a local commit of another transaction (which now cannot get to ready state), with the same effect as of a direct blocking of a vote or a local commit. In this case a cycle is generated in the conflict graph only if such a blocking by a lock is also represented by an edge. With such added edges representing events of blocking-by-a-lock, the conflict graph is becoming an *augmented conflict graph*.

- **Definition: augmented conflict graph**

  An **augmented conflict graph** is a conflict graph with added edges: In addition to the original edges a directed edge exists from transaction T_1 to transaction T_2 if two conditions are met:

1. T_2 is blocked by a data-access lock applied by T_1 (the blocking prevents the conflict of T_2 with T_1 from being materialized and have an edge in the regular conflict graph), and
2. This blocking will not stop before T_1 ends (commits or aborts; true for any locking-based CO)

   The graph can also be defined as the union of the (regular) *conflict graph* with the (reversed edge, regular) *wait-for graph*

   Comments:

1. Here, unlike the regular conflict graph, which has edges only for materialized conflicts, all conflicts, both materialized and non-materialized, are represented by edges.

2. Note that all the new edges are all the (reversed to the conventional) edges of the *wait-for graph*. The *wait-for graph* can be defined also as the graph of non-materialized conflicts. By the common conventions edge direction in a *conflict graph* defines time order between conflicting operations which is opposite to the time order defined by an edge in a *wait-for graph*.
3. Note that such global graph contains (has embedded) all the (reversed edge) regular local *wait-for* graphs, and also may include locking based global cycles (which cannot exist in the local graphs). For example, if all the databases on a global cycle are SS2PL based, then all the related vote blocking situations are caused by locks (this is the classical, and probably the only global deadlock situation dealt with in the database research literature). This is a global deadlock case where each related database creates a portion of the cycle, but the complete cycle does not reside in any local wait-for graph.

In the presence of CO the *augmented conflict graph* is in fact a (reversed edge) *local-commit and voting wait-for graph*: An edge exists from a first transaction, either local or global, to a second, if the second is waiting for the first to end in order to be either voted on (if global), or locally committed (if local). All *global cycles* (across two or more databases) in this graph generate voting-deadlocks. The graph's global cycles provide complete characterization for voting deadlocks and may include any combination of materialized and non-materialized conflicts. Only cycles of (only) materialized conflicts are also cycles of the regular conflict graph and affect serializability. One or more (lock related) non-materialized conflicts on a cycle prevent it from being a cycle in the regular conflict graph, and make it a locking related deadlock. All the global cycles (voting-deadlocks) need to be broken (resolved) to both maintain global serializability and resolve global deadlocks involving data access locking, and indeed they are all broken by the atomic commitment protocol due to missing votes upon a voting deadlock.

Comment: This observation also explains the correctness of *Extended CO (ECO)* below: Global transactions' voting order must follow the conflict graph order with vote blocking when order relation (graph path) exists between two global transactions. Local transactions are not voted on, and their (local) commits are not blocked upon conflicts. This results in same voting-deadlock situations and resulting global cycle elimination process for ECO.

The *voting-deadlock* situation can be summarized as follows:

- **The CO Voting-Deadlock Theorem**

  Let a multidatabase environment comprise CO compliant (which eliminates *local cycles*) database systems that enforce, each, *Global CO* (using the condition in the theorem above). Then a *voting-deadlock* occurs if and only if a *global cycle* (spans two or more databases) exists in the *Global augmented conflict graph* (also blocking by a data-access lock is represented by an edge). If the cycle does not break by any abort, then all the *global transactions* on it are involved with the respective voting-deadlock, and eventually each has its vote blocked (either directly, or indirectly by a data-access lock); if a local transaction resides on the cycle, eventually it has its (local) commit blocked.

  Comment: A rare situation of a voting deadlock (by missing blocked votes) can happen, with no voting for any transaction on the related cycle by any of the database systems involved with these transactions. This can occur when local sub-transactions are multi-threaded. The highest probability instance of such rare event involves two transactions on two simultaneous opposite cycles. Such global cycles (deadlocks) overlap with local cycles which are resolved locally, and thus typically resolved by local mechanisms without involving atomic commitment. Formally it is also a global cycle, but practically it is local (portions of local cycles generate a global one; to see this, split each global transaction (node) to local sub-transactions (its portions confined each to a single database); a directed edge exists between transactions if an edge exists between any respective local sub-transactions; a cycle is local if all its edges originate from a cycle among sub-transactions of the same database, and global if not; global and local can overlap: a same cycle among transactions can result from several different cycles among sub-transactions, and be both local and global).

Also the following locking based special case is concluded:

- **The CO Locking-based Global-Deadlock Theorem**

In a CO compliant multidatabase system a locking-based global-deadlock, involving at least one data-access lock (non-materialized conflict), and two or more database systems, is a reflection of a global cycle in the *Global augmented conflict graph*, which results in a voting-deadlock. Such cycle is not a cycle in the (regular) *Global conflict graph* (which reflects only materialized conflicts, and thus such cycle does not affect *serializability*).

Comments:

1. Any blocking (edge) in the cycle that is not by a data-access lock is a direct blocking of either voting or local commit. All voting-deadlocks are resolved (almost all by *Atomic commitment*; see comment above), including this locking-based type.
2. Locking-based global-deadlocks can be generated also in a completely SS2PL-based distributed environment (special case of CO based), where all the vote blocking (and voting-deadlocks) are caused by data-access locks. Many research articles have dealt for years with resolving such global deadlocks, but none (except the CO articles) is known (as of 2009) to notice that *atomic commitment* automatically resolves them. Such automatic resolutions are regularly occurring unnoticed in all existing SS2PL based multidatabase systems, often bypassing dedicated resolution mechanisms.

Voting-deadlocks are the key for the operation of distributed CO.

Global cycle elimination (here voting-deadlock resolution by *atomic commitment*) and resulting aborted transactions' re-executions are time consuming, regardless of concurrency control used. If databases schedule transactions independently, global cycles are unavoidable (in a complete analogy to cycles/deadlocks generated in local SS2PL; with distribution, any transaction or operation scheduling coordination results in autonomy violation, and typically also in substantial performance penalty). However, in many cases their likelihood can be made very low by implementing database and transaction design guidelines that reduce the number of conflicts involving a global transaction. This, primarily by properly handling hot spots (database objects with frequent access), and avoiding conflicts by using commutativity when possible (e.g., when extensively using counters, as in finances, and especially multi-transaction *accumulation counters*, which are typically hot spots).

Atomic commitment protocols are intended and designed to achieve atomicity without considering database concurrency control. They abort upon detecting or heuristically finding (e.g., by timeout; sometimes mistakenly, unnecessarily) missing votes, and typically unaware of global cycles. These protocols can be specially enhanced for CO (including CO's variants below) both to prevent unnecessary aborts, and to accelerate aborts used for breaking global cycles in the global augmented conflict graph (for better performance by earlier release upon transaction-end of computing resources and typically locked data). For example, existing locking based global deadlock detection methods, other than timeout, can be generalized to consider also local commit and vote direct blocking, besides data access blocking. A possible compromise in such mechanisms is effectively detecting and breaking the most frequent and relatively simple to handle length-2 global cycles, and using timeout for undetected, much less frequent, longer cycles.

Enforcing CO locally

Commitment ordering can be enforced locally (in a single database) by a dedicated CO algorithm, or by any algorithm/protocol that provides any special case of CO. An important such protocol, being utilized extensively in database systems, which generates a CO schedule, is the *strong strict two phase locking* protocol (SS2PL: "release transaction's locks only after the transaction has been either committed or aborted"; see below). SS2PL is a proper subset of the intersection of 2PL and strictness.

A generic local CO algorithm

A **generic local CO algorithm** (Raz 1992; Algorithm 4.1) is an algorithm independent of implementation details, that enforces exactly the CO property. It does not block data access (nonblocking), and consists of aborting a certain set of transactions (only if needed) upon committing a transaction. It aborts a (uniquely determined at any given time) minimal set of other undecided (neither committed, nor aborted) transactions that run locally and can cause serializability violation in the future (can later generate cycles of committed transactions in the conflict graph; this is the ABORT set of a committed transaction T; after committing T no transaction in ABORT at commit time can be committed, and all of them are doomed to be aborted). This set consists of all undecided transactions with directed edges in the conflict graph to the committed transaction. The size of this set cannot increase when that transaction is waiting to be committed (in ready state: processing has ended), and typically decreases in time as its transactions are being decided. Thus, unless real-time constraints exist to complete that transaction, it is preferred to wait with committing that transaction and let this set decrease in size. If another serializability mechanism exists locally (which eliminates cycles in the local conflict graph), or if no cycle involving that transaction exists, the set will be empty eventually, and no abort of set member is needed. Otherwise the set will stabilize with transactions on local cycles, and aborting set members will have to occur to break the cycles. Since in the case of CO conflicts generate blocking on commit, local cycles in the *augments conflict graph* (see above) indicate local commit-deadlocks, and deadlock resolution techniques as in SS2PL can be used (e.g., like *timeout* and *wait-for graph*). A local cycle in the *augmented conflict graph* with at least one non-materialized conflict reflects a locking-based deadlock. The local algorithm above, applied to the local augmented conflict graph rather than the regular local conflict graph, comprises the **generic enhanced local CO algorithm**, a single local cycle elimination mechanism, for both guaranteeing local serializability and handling locking based local deadlocks. Practically an additional concurrency control mechanism is always utilized, even solely to enforce recoverability. The generic CO algorithm does not affect local data access scheduling strategy, when it runs alongside of any other local concurrency control mechanism. It affects only the commit order, and for this reason it does not need to abort more transactions than those needed to be aborted for serializability violation prevention by any combined local concurrency control mechanism. The net effect of CO may be, at most, a delay of commit events (or voting in a distributed environment), to comply with the needed commit order (but not more delay than its special cases, for example, SS2PL, and on the average significantly less).

The following theorem is concluded:

- **The Generic Local CO Algorithm Theorem**

  When running alone or alongside any concurrency control mechanism in a database system then

1. The *Generic local CO algorithm* guarantees (local) CO (a CO compliant schedule).
2. The *Generic enhanced local CO algorithm* guarantees both (local) CO and (local) locking based deadlock resolution.

   and (when not using *timeout*, and no *real-time* transaction completion constraints are applied) neither algorithm aborts more transactions than the minimum needed (which is determined by the transactions' operations scheduling, out of the scope of the algorithms).

Example: Concurrent programming and Transactional memory

See also *Concurrent programming and Transactional memory*

With the proliferation of Multi-core processors, variants of the Generic local CO algorithm have been also increasingly utilized in Concurrent programming, Transactional memory, and especially in Software transactional memory for achieving serializability optimistically by "commit order" (e.g., Ramadan et al. 2009,[3] Zhang et al. 2006,[] von Parun et al. 2007[4]). Numerous related articles and patents utilizing CO have already been published.

Implementation considerations: The Commitment Order Coordinator (COCO)

A database system in a multidatabase environment is assumed. From a software architecture point of view a CO component that implements the generic CO algorithm locally, the *Commitment Order Coordinator* (COCO), can be designed in a straightforward way as a mediator between a (single) database system and an atomic commitment protocol component (Raz 1991b). However, the COCO is typically an integral part of the database system. The COCO's functions are to vote to commit on ready global transactions (processing has ended) according to the local commitment order, to vote to abort on transactions for which the database system has initiated an abort (the database system can initiate abort for any transaction, for many reasons), and to pass the atomic commitment decision to the database system. For local transactions (when can be identified) no voting is needed. For determining the commitment order the COCO maintains an updated representation of the local conflict graph (or local augmented conflict graph for capturing also locking deadlocks) of the undecided (neither committed nor aborted) transactions as a data structure (e.g., utilizing mechanisms similar to locking for capturing conflicts, but with no data-access blocking). The COCO component has an interface with its database system to receive "conflict," "ready" (processing has ended; readiness to vote on a global transaction or commit a local one), and "abort" notifications from the database system. It also interfaces with the atomic commitment protocol to vote and to receive the atomic commitment protocol's decision on each global transaction. The decisions are delivered from the COCO to the database system through their interface, as well as local transactions' commit notifications, at a proper commit order. The COCO, including its interfaces, can be enhanced, if it implements another variant of CO (see below), or plays a role in the database's concurrency control mechanism beyond voting in atomic commitment.

The COCO also guarantees CO locally in a single, isolated database system with no interface with an atomic commitment protocol.

CO is a necessary condition for global serializability across autonomous database systems

If the databases that participate in distributed transactions (i.e., transactions that span more than a single database) do not use any shared concurrency control information and use unmodified atomic commitment protocol messages (for reaching atomicity), then maintaining (local) *commitment ordering* or one of its generalizing variants (see below) is a necessary condition for guaranteeing global serializability (a proof technique can be found in (Raz 1992), and a different proof method for this in (Raz 1993a)); it is also a sufficient condition. This is a mathematical fact derived from the definitions of *serializability* and a *transaction*. It means that if not complying with CO, then global serializability cannot be guaranteed under this condition (the condition of no local concurrency control information sharing between databases beyond atomic commit protocol messages). Atomic commitment is a minimal requirement for a distributed transaction since it is always needed, which is implied by the definition of transaction.

(Raz 1992) defines *database autonomy* and *independence* as complying with this requirement without using any additional local knowledge:

- **Definition:** (concurrency control based) **autonomous database system**

  A database system is **Autonomous**, if it does not share with any other entity any concurrency control information beyond unmodified atomic commitment protocol messages. In addition it does not use for concurrency control any additional local information beyond conflicts (the last sentence does not appear explicitly but rather implied by further discussion in Raz 1992).

Using this definition the following is concluded:

- **The CO and Global serializability Theorem**

1. CO compliance of every *autonomous* database system (or transactional object) in a multidatabase environment is a *necessary condition* for guaranteeing Global serializability (without CO Global serializability may be violated).
2. CO compliance of every database system is a *sufficient condition* for guaranteeing Global serializability.

However, the definition of autonomy above implies, for example, that transactions are scheduled in a way that local transactions (confined to a single database) cannot be identified as such by an autonomous database system. This is realistic for some transactional objects, but too restrictive and less realistic for general purpose database systems. If autonomy is augmented with the ability to identify local transactions, then compliance with a more general property, *Extended commitment ordering* (ECO, see below), makes ECO the necessary condition.

Only in (Raz 2009) the notion of *Generalized autonomy* captures the intended notion of autonomy:

- **Definition: generalized autonomy**

  A database system has the *Generalized autonomy* property, if it does not share with any other database system any local concurrency information beyond (unmodified) atomic commit protocol messages (however any local information can be utilized).

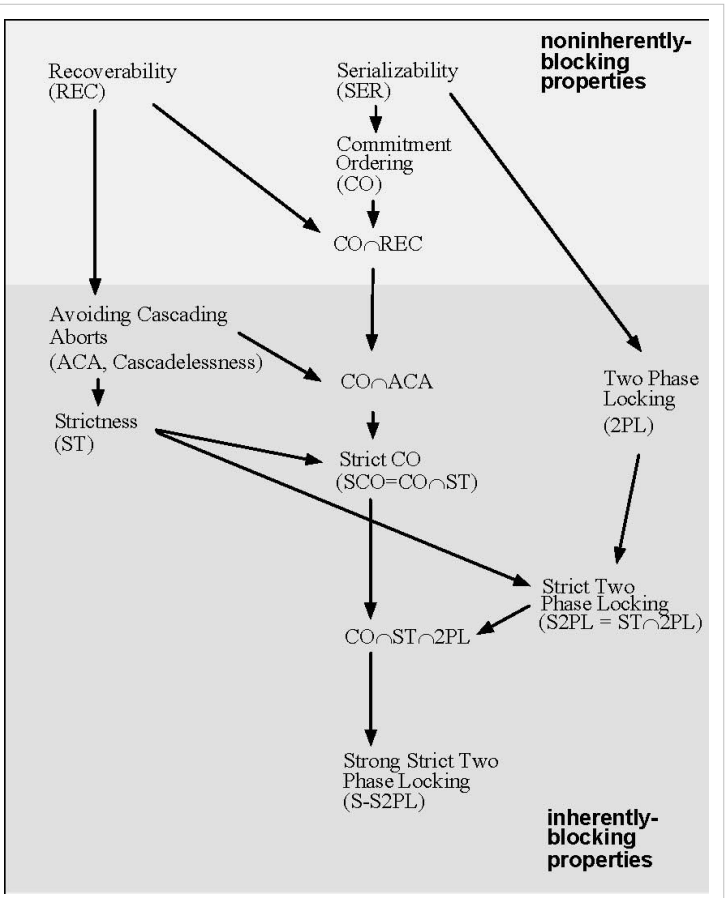
This definition is probably the broadest such definition possible in the context of database concurrency control, and it makes CO together with any of its (useful: No concurrency control information distribution) generalizing variants (Vote ordering (VO); see CO variants below) the necessary condition for Global serializability (i.e., the union of CO and its generalizing variants is the necessary set VO, which may include also new unknown useful generalizing variants).

Summary

The *Commitment ordering* (CO) solution (technique) for global serializability can be summarized as follows:

If each *database* (or any other *transactional object*) in a multidatabase environment complies with CO, i.e., arranges its local transactions' commitments and its votes on (global, distributed) transactions to the *atomic commitment* protocol according to the local (to the database) partial order induced by the local conflict graph (serializability graph) for the respective transactions, then *Global CO* and *Global serializability* are guaranteed. A database's CO compliance can be achieved effectively with any local conflict serializability based concurrency control mechanism, with neither affecting any transaction's execution process or scheduling, nor aborting it. Also the database's autonomy is not violated. The only low overhead incurred is detecting conflicts (e.g., as with locking, but with no data-access blocking; if not already detected for other purposes), and ordering votes and local transactions' commits according to the conflicts.

In case of incompatible partial orders of two or more databases (no global partial order can embed the respective local partial orders together), a global cycle (spans two databases or more) in the global conflict graph is generated. This, together with CO, results in a cycle of blocked votes, and a *voting-deadlock* occurs for the databases on that cycle (however, allowed concurrent voting in each database, typically for almost all the outstanding votes, continue to execute). In this case the atomic commitment protocol fails to collect all the votes needed for the blocked transactions on that global cycle, and consequently the protocol aborts some transaction with a missing vote. This breaks the global cycle, the voting-deadlock is resolved, and the related blocked votes are free to be executed. Breaking the global cycle in the global conflict graph ensures that both global CO and global serializability are maintained. Thus, in case of incompatible local (partial) commitment orders no action is needed since the atomic commitment protocol resolves it automatically by aborting a transaction that is a cause for the incompatibility. Furthermore, also global deadlocks due to locking (global cycles in the *augmented conflict graph* with at least one data access blocking) result in voting deadlocks and are resolved automatically by the same mechanism.



Schedule classes containment: An arrow from class A to class B indicates that class A strictly contains B; a lack of a directed path between classes means that the classes are incomparable.A property is inherently blocking, if it can be enforced only by blocking transaction's data access operations until certain events occur in other transactions. (#Raz1992Raz 1992)

Local CO is a necessary condition for guaranteeing *Global serializability,* if the databases involved do not share any concurrency control information beyond (unmodified) atomic commitment protocol messages, i.e., if the databases are *autonomous* in the context of concurrency control. This means that every global serializability solution for autonomous databases must comply with CO. Otherwise global serializability may be violated (and thus, is likely to be violated very quickly in a high-performance environment).

The CO solution scales up with network size and the number of databases without performance penalty when it utilizes common distributed atomic commitment architecture.

Distributed serializability and CO

Distributed CO

A distinguishing characteristic of the CO solution to distributed serializability from other techniques is the fact that it requires no conflict information distributed (e.g., local precedence relations, locks, timestamps, tickets), which makes it uniquely effective. It utilizes (unmodified) atomic commitment protocol messages (which are already used) instead.

A common way to achieve distributed serializability in a (distributed) system is by a distributed lock manager (DLM). DLMs, which communicate lock (non-materialized conflict) information in a distributed environment, typically suffer from computer and communication latency, which reduces the performance of the system. CO allows to achieve distributed serializability under very general conditions, without a distributed lock manager, exhibiting the benefits already explored above for multidatabase environments; in particular: reliability, high performance, scalability, possibility of using *optimistic concurrency control* when desired, no conflict information related communications over the network (which have incurred overhead and delays), and automatic distributed deadlock resolution.

All *distributed transactional systems* rely on some atomic commitment protocol to coordinate atomicity (whether to commit or abort) among processes in a distributed transaction. Also, typically *recoverable data* (i.e., data under transactions' control, e.g., database data; not to be confused with the *recoverability* property of a schedule) are directly accessed by a single *transactional data manager* component (also referred to as a *resource manager*) that handles local sub-transactions (the distributed transaction's portion in a single location, e.g., network node), even if these data are accessed indirectly by other entities in the distributed system during a transaction (i.e., indirect access requires a direct access through a local sub-transaction). Thus recoverable data in a distributed transactional system are typically partitioned among transactional data managers. In such system these transactional data managers typically comprise the participants in the system's atomic commitment protocol. If each participant complies with CO (e.g., by using SS2PL, or COCOs, or a combination; see above), then the entire distributed system provides CO (by the theorems above; each participant can be considered a separate transactional object), and thus (distributed) serializability. Furthermore: When CO is utilized together with an atomic commitment protocol also *distributed deadlocks* (i.e., deadlocks that span two or more data managers) caused by data-access locking are resolved automatically. Thus the following corollary is concluded:

- **The CO Based Distributed Serializability Theorem**

  Let a *distributed transactional system* (e.g., a distributed database system) comprise *transactional data managers* (also called *resource managers*) that manage all the system's *recoverable data*. The data managers meet three conditions:

1. **Data partition:** Recoverable data are partitioned among the data managers, i.e., each recoverable datum (data item) is controlled by a single data manager (e.g., as common in a Shared nothing architecture; even copies of a same datum under different data managers are physically distinct, *replicated*).
2. **Participants in atomic commitment protocol:** These data managers are the participants in the system's atomic commitment protocol for coordinating distributed transactions' atomicity.
3. **CO compliance:** Each such data manager is CO compliant (or some CO variant compliant; see below).

   Then

1. The entire distributed system guarantees (distributed CO and) *serializability*, and
2. Data-access based *distributed deadlocks* (deadlocks involving two or more data managers with at least one non-materialized conflict) are resolved automatically.

   Furthermore: The data managers being CO compliant is a *necessary condition* for (distributed) serializability in a system meeting conditions 1, 2 above, when the data managers are *autonomous*, i.e., do not share

concurrency control information beyond unmodified messages of atomic commitment protocol.

This theorem also means that when SS2PL (or any other CO variant) is used locally in each transactional data manager, and each data manager has exclusive control of its data, no distributed lock manager (which is often utilized to enforce distributed SS2PL) is needed for distributed SS2PL and serializability. It is relevant to a wide range of distributed transactional applications, which can be easily designed to meet the theorem's conditions.

Distributed optimistic CO (DOCO)

For implementing Distributed Optimistic CO (DOCO) the generic local CO algorithm is utilized in all the atomic commitment protocol participants in the system with no data access blocking and thus with no local deadlocks. The previous theorem has the following corollary:

- **The Distributed optimistic CO (DOCO) Theorem**

  If DOCO is utilized, then:

  1. No local deadlocks occur, and
  2. Global (voting) deadlocks are resolved automatically (and all are serializability related (with non-blocking conflicts) rather than locking related (with blocking and possibly also non-blocking conflicts)).

  Thus, no deadlock handling is needed.

Examples

Distributed SS2PL

A distributed database system that utilizes SS2PL resides on two remote nodes, A and B. The database system has two *transactional data managers* (*resource managers*), one on each node, and the database data are partitioned between the two data managers in a way that each has an exclusive control of its own (local to the node) portion of data: Each handles its own data and locks without any knowledge on the other manager's. For each distributed transaction such data managers need to execute the available atomic commitment protocol.

Two distributed transactions, $T_1$and T_2, are running concurrently, and both access data x and y. x is under the exclusive control of the data manager on A (B's manager cannot access x), and y under that on B.

T_1reads x on A and writes y on B, i.e., $T_1 = R_{1A}(x)\ W_{1B}(y)$when using notation common for concurrency control.

T_2reads y on B and writes x on A, i.e., $T_2 = R_{2B}(y)\ W_{2A}(x)$

The respective *local sub-transactions* on A and B (the portions of $T_1$and T_2on each of the nodes) are the following:

Local sub-transactions

Transaction \ Node	A	B
T_1	$T_{1A} = R_{1A}(x)$	$T_{1B} = W_{1B}(y)$
T_2	$T_{2A} = W_{2A}(x)$	$T_{2B} = R_{2B}(y)$

The database system's schedule at a certain point in time is the following:

$R_{1A}(x)\ R_{2B}(y)$

(also $R_{2B}(y)\ R_{1A}(x)$is possible)

T_1holds a read-lock on x and T_2holds read-locks on y. Thus $W_{1B}(y)$and $W_{2A}(x)$are blocked by the lock compatibility rules of SS2PL and cannot be executed. This is a distributed deadlock situation, which is also a voting-deadlock (see below) with a distributed (global) cycle of length 2 (number of edges, conflicts; 2 is the most

frequent length). The local sub-transactions are in the following states:

T_{1A} is *ready* (execution has ended) and *voted* (in atomic commitment)

T_{1B} is *running* and blocked (a non-materialized conflict situation; no vote on it can occur)

T_{2B} is *ready* and *voted*

T_{2A} is *running* and blocked (a non-materialized conflict; no vote).

Since the atomic commitment protocol cannot receive votes for blocked sub-transactions (a voting-deadlock), it will eventually abort some transaction with a missing vote(s) by timeout, either T_1, or T_2, (or both, if the timeouts fall very close). This will resolve the global deadlock. The remaining transaction will complete running, be voted on, and committed. An aborted transaction is immediately *restarted* and re-executed.

Comments:

1. The data partition (x on A; y on B) is important since without it, for example, x can be accessed directly from B. If a transaction T_3 is running on B concurrently with T_1 and T_2 and directly writes x, then, without a distributed lock manager the read-lock for x held by T_1 on A is not visible on B and cannot block the write of T_3 (or signal a materialized conflict for a non-blocking CO variant; see below). Thus serializability can be violated.
2. Due to data partition, x cannot be accessed directly from B. However, functionality is not limited, and a transaction running on B still can issue a write or read request of x (not common). This request is communicated to the transaction's local sub-transaction on A (which is generated, if does not exist already) which issues this request to the local data manager on A.

Variations

In the scenario above both conflicts are *non-materialized*, and the global voting-deadlock is reflected as a cycle in the global *wait-for graph* (but not in the global *conflict graph*; see Exact characterization of voting-deadlocks by global cycles above). However the database system can utilize any CO variant with exactly the same conflicts and voting-deadlock situation, and same resolution. Conflicts can be either *materialized* or *non-materialized*, depending on CO variant used. For example, if SCO (below) is used by the distributed database system instead of SS2PL, then the two conflicts in the example are *materialized*, all local sub-transactions are in *ready* states, and vote blocking occurs in the two transactions, one on each node, because of the CO voting rule applied independently on both A and B: due to conflicts $T_{2A} = W_{2A}(x)$ is not voted on before $T_{1A} = R_{1A}(x)$ ends, and $T_{1B} = W_{1B}(y)$ is not voted on before $T_{2B} = R_{2B}(y)$ ends, which is a voting-deadlock. Now the *conflict graph* has the global cycle (all conflicts are materialized), and again it is resolved by the atomic commitment protocol, and distributed serializability is maintained. Unlikely for a distributed database system, but possible in principle (and occurs in a multi-database), A can employ SS2PL while B employs SCO. In this case the global cycle is neither in the wait-for graph nor in the serializability graph, but still in the *augmented conflict graph* (the union of the two). The various combinations are summarized in the following table:

Voting-deadlock situations

Case	Node A	Node B	Possible schedule	Materialized conflicts on cycle	Non-materialized conflicts	$T_{1A} = R_{1A}(x)$	$T_{1B} = W_{1B}(y)$	$T_{2A} = W_{2A}(x)$	$T_{2B} = R_{2B}(y)$
1	SS2PL	SS2PL	$R_{1A}(x)\ R_{2B}(y)$	0	2	Ready Voted	Running (Blocked)	Running (Blocked)	Ready Voted
2	SS2PL	SCO	$R_{1A}(x)\ R_{2B}(y)\ W_{1B}(y)$	1	1	Ready Voted	Ready Vote blocked	Running (Blocked)	Ready Voted
3	SCO	SS2PL	$R_{1A}(x)\ R_{2B}(y)\ W_{2A}(x)$	1	1	Ready Voted	Running (Blocked)	Ready Vote blocked	Ready Voted

4	SCO	SCO	$R_{1A}(x)\ R_{2B}(y)\ W_{1B}(y)\ W_{2A}(x)$	2	0	Ready Voted	Ready Vote blocked	Ready Vote blocked	Ready Voted

Comments:

1. Conflicts and thus cycles in the *augmented conflict graph* are determined by the transactions and their initial scheduling only, independently of the concurrency control utilized. With any variant of CO, any *global cycle* (i.e., spans two databases or more) causes a *voting deadlock*. Different CO variants may differ on whether a certain conflict is *materialized* or *non-materialized*.
2. Some limited operation order changes in the schedules above are possible, constrained by the orders inside the transactions, but such changes do not change the rest of the table.
3. As noted above, only case 4 describes a cycle in the (regular) conflict graph which affects serializability. Cases 1-3 describe cycles of locking based global deadlocks (at least one lock blocking exists). All cycle types are equally resolved by the atomic commitment protocol. Case 1 is the common Distributed SS2PL, utilized since the 1980s. However, no research article, except the CO articles, is known to notice this automatic locking global deadlock resolution as of 2009. Such global deadlocks typically have been dealt with by dedicated mechanisms.
4. Case 4 above is also an example for a typical voting-deadlock when Distributed optimistic CO (DOCO) is used (i.e., Case 4 is unchanged when Optimistic CO (OCO; see below) replaces SCO on both A and B): No data-access blocking occurs, and only materialized conflicts exist.

Hypothetical Multi Single-Threaded Core (MuSiC) environment

Comment: While the examples above describe real, recommended utilization of CO, this example is hypothetical, for demonstration only.

Certain experimental distributed memory-resident databases advocate multi single-threaded core (MuSiC) transactional environments. "Single-threaded" refers to transaction threads only, and to *serial* execution of transactions. The purpose is possible orders of magnitude gain in performance (e.g., H-Store[5] and VoltDB) relatively to conventional transaction execution in multiple threads on a same core. In what described below MuSiC is independent of the way the cores are distributed. They may reside in one integrated circuit (chip), or in many chips, possibly distributed geographically in many computers. In such an environment, if recoverable (transactional) data are partitioned among threads (cores), and it is implemented in the conventional way for distributed CO, as described in previous sections, then DOCO and Strictness exist automatically. However, downsides exist with this straightforward implementation of such environment, and its practicality as a general-purpose solution is questionable. On the other hand tremendous performance gain can be achieved in applications that can bypass these downsides in most situations.

Comment: The MuSiC straightforward implementation described here (which uses, for example, as usual in distributed CO, voting (and transaction thread) blocking in atomic commitment protocol when needed) is for demonstration only, and has **no connection** to the implementation in H-Store or any other project.

In a MuSiC environment local schedules are *serial*. Thus both local Optimistic CO (OCO; see below) and the *Global CO enforcement vote ordering strategy* condition for the atomic commitment protocol are met automatically. This results in both distributed CO compliance (and thus distributed serializability) and automatic global (voting) deadlock resolution.

Furthermore, also local *Strictness* follows automatically in a serial schedule. By Theorem 5.2 in (Raz 1992; page 307), when the CO vote ordering strategy is applied, also Global Strictness is guaranteed. Note that *serial* locally is the only mode that allows strictness and "optimistic" (no data access blocking) together.

The following is concluded:

- **The MuSiC Theorem**

  In MuSiC environments, if recoverable (transactional) data are partitioned among cores (threads), then both

1. *OCO* (and implied *Serializability*; i.e., DOCO and Distributed serializability)
2. *Strictness* (allowing effective recovery; 1 and 2 implying Strict CO—see SCO below) and
3. (voting) *deadlock resolution*

automatically exist globally with unbounded scalability in number of cores used.

Comment: However, two major downsides, which need special handling, may exist:

1. Local sub-transactions of a global transaction are blocked until commit, which makes the respective cores idle. This reduces core utilization substantially, even if scheduling of the local sub-transactions attempts to execute all of them in time proximity, almost together. It can be overcome by detaching execution from commit (with some atomic commitment protocol) for global transactions, at the cost of possible cascading aborts.
2. increasing the number of cores for a given amount of recoverable data (database size) decreases the average amount of (partitioned) data per core. This may make some cores idle, while others very busy, depending on data utilization distribution. Also a local (to a core) transaction may become global (multi-core) to reach its needed data, with additional incurred overhead. Thus, as the number of cores increases, the amount and type of data assigned to each core should be balanced according to data usage, so a core is neither overwhelmed to become a bottleneck, nor becoming idle too frequently and underutilized in a busy system. Another consideration is putting in a same core partition all the data that are usually accessed by a same transaction (if possible), to maximize the number of local transactions (and minimize the number of global, distributed transactions). This may be achieved by occasional data re-partition among cores based on load balancing (data access balancing) and patterns of data usage by transactions. Another way to considerably mitigate this downside is by proper physical data replication among some core partitions in a way that read-only global transactions are possibly (depending on usage patterns) completely avoided, and replication changes are synchronized by a dedicated commit mechanism.

CO variants: Interesting special cases and generalizations

Special case schedule property classes (e.g., SS2PL and SCO below) are strictly contained in the CO class. The generalizing classes (ECO and MVCO) strictly contain the CO class (i.e., include also schedules that are not CO compliant). The generalizing variants also guarantee global serializability without distributing local concurrency control information (each database has the *generalized autonomy* property: it uses only local information), while relaxing CO constraints and utilizing additional (local) information for better concurrency and performance: ECO uses knowledge about transactions being local (i.e., confined to a single database), and MVCO uses availability of data versions values. Like CO, both generalizing variants are *non-blocking*, do not interfere with any transaction's operation scheduling, and can be seamlessly combined with any relevant concurrency control mechanism.

The term **CO variant** refers in general to CO, ECO, MVCO, or a combination of each of them with any relevant concurrency control mechanism or property (including Multi-version based ECO, MVECO). No other interesting generalizing variants (which guarantee global serializability with no local concurrency control information distribution) are known, but may be discovered.

Strong strict two phase locking (SS2PL)

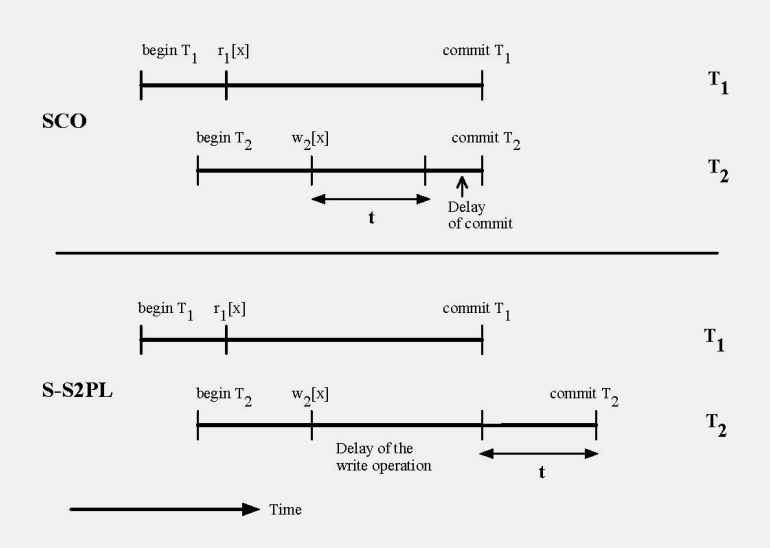
Strong Strict Two Phase Locking (SS2PL; also referred to as *Rigorousness* or *Rigorous scheduling*) means that both read and write locks of a transaction are released only after the transaction has ended (either committed or aborted). The set of SS2PL schedules is a proper subset of the set of CO schedules. This property is widely utilized in database systems, and since it implies CO, databases that use it and participate in global transactions generate together a serializable global schedule (when using any atomic commitment protocol, which is needed for atomicity in a multi-database environment). No database modification or addition is needed in this case to participate in a CO distributed solution: The set of undecided transactions to be aborted before committing in the local generic CO algorithm above is empty because of the locks, and hence such an algorithm is unnecessary in this case. A transaction can be voted on by a database system immediately after entering a "ready" state, i.e., completing running

its task locally. Its locks are released by the database system only after it is decided by the atomic commitment protocol, and thus the condition in the *Global CO enforcing theorem* above is kept automatically. Interestingly, if a local timeout mechanism is used by a database system to resolve (local) SS2PL deadlocks, then aborting blocked transactions breaks not only potential local cycles in the global conflict graph (real cycles in the augmented conflict graph), but also database system's potential global cycles as a side effect, if the atomic commitment protocol's abort mechanism is relatively slow. Such independent aborts by several entities typically may result in unnecessary aborts for more than one transaction per global cycle. The situation is different for a local *wait-for graph* based mechanisms: Such cannot identify global cycles, and the atomic commitment protocol will break the global cycle, if the resulting voting deadlock is not resolved earlier in another database.

Local SS2PL together with atomic commitment implying global serializability can also be deduced directly: All transactions, including distributed, obey the 2PL (SS2PL) rules. The atomic commitment protocol mechanism is not needed here for consensus on commit, but rather for the end of phase-two synchronization point. Probably for this reason, without considering the atomic commitment voting mechanism, automatic global deadlock resolution has not been noticed before CO.

Strict CO (SCO)

Strict Commitment Ordering (SCO; (Raz 1991c)) is the intersection of strictness (a special case of recoverability) and CO, and provides an upper bound for a schedule's concurrency when both properties exist. It can be implemented using blocking mechanisms (locking) similar to those used for the popular SS2PL with similar overheads.



Read-write conflict: SCO Vs. SS2PL. Duration of transaction T2 is longer with SS2PL than with SCO.SS2PL delays write operation w2[x] of T2 until T1 commits, due to a lock on x by T1 following read operation r1[x]. If t time units are needed for transaction T2 after starting write operation w2[x] in order to reach ready state, than T2 commits t time units after T1 commits. However, SCO does not block w2[x], and T2 can commit immediately after T1 commits. (#Raz1991cRaz 1991c)

Unlike SS2PL, SCO does not block on a read-write conflict but possibly blocks on commit instead. SCO and SS2PL have identical blocking behavior for the other two conflict types: write-read, and write-write. As a result SCO has shorter average blocking periods, and more concurrency (e.g., performance simulations of a single database for the most significant variant of *locks with ordered sharing,* which is identical to SCO, clearly show this, with approximately 100% gain for some transaction loads; also for identical transaction loads SCO can reach higher transaction rates than SS2PL before *lock thrashing* occurs). More concurrency means that with given computing resources more transactions are completed in time unit (higher transaction rate, throughput), and the average duration of a transaction is shorter (faster completion; see chart). The advantage of SCO is especially significant during lock contention.

- **The SCO Vs. SS2PL Performance Theorem**

  SCO provides shorter average transaction completion time than SS2PL, if read-write conflicts exist. SCO and SS2PL are identical otherwise (have identical blocking behavior with write-read and write-write conflicts).

SCO is as practical as SS2PL since as SS2PL it provides besides serializability also strictness, which is widely utilized as a basis for efficient recovery of databases from failure. An SS2PL mechanism can be converted to an SCO one for better performance in a straightforward way without changing recovery methods. A description of a SCO implementation can be found in (Perrizo and Tatarinov 1998). See also *Semi-optimistic database scheduler*.

SS2PL is a proper subset of SCO (which is another explanation why SCO is less constraining and provides more concurrency than SS2PL).

Optimistic CO (OCO)

For implementing **Optimistic commitment ordering** (OCO) the generic local CO algorithm is utilized without data access blocking, and thus without local deadlocks. OCO without transaction or operation scheduling constraints covers the entire CO class, and is not a special case of the CO class, but rather a useful CO variant and mechanism characterization.

Extended CO (ECO)

General characterization of ECO

Extended Commitment Ordering (ECO; (Raz 1993a)) generalizes CO. When local transactions (transactions confined to a single database) can be distinguished from global (distributed) transactions (transactions that span two databases or more), commitment order is applied to global transactions only. Thus, for a local (to a database) schedule to have the ECO property, the chronological (partial) order of commit events of global transactions only (unimportant for local transactions) is consistent with their order on the respective local conflict graph.

- **Definition: extended commitment ordering**

  Let T_1, T_2 be two committed *global* transactions in a schedule, such that a *directed path* of unaborted transactions exists in the *conflict graph* (precedence graph) from T_1 to T_2 (T_1 precedes T_2, possibly transitively, indirectly). The schedule has the **Extended commitment ordering** (ECO) property, if for every two such transactions T_1 commits before T_2 commits.

A distributed algorithm to guarantee global ECO exists. As for CO, the algorithm needs only (unmodified) atomic commitment protocol messages. In order to guarantee global serializability, each database needs to guarantee also the conflict serializability of its own transactions by any (local) concurrency control mechanism.

- **The ECO and Global Serializability Theorem**

1. (Local, which implies global) ECO together with local conflict serializability, is a sufficient condition to guarantee global conflict serializability.
2. When no concurrency control information beyond atomic commitment messages is shared outside a database (autonomy), and local transactions can be identified, it is also a necessary condition.

   See a necessity proof in (Raz 1993a).

This condition (ECO with local serializability) is weaker than CO, and allows more concurrency at the cost of a little more complicated local algorithm (however, no practical overhead difference with CO exists).

When all the transactions are assumed to be global (e.g., if no information is available about transactions being local), ECO reduces to CO.

The ECO algorithm

Before a global transaction is committed, a generic local (to a database) ECO algorithm aborts a minimal set of undecided transactions (neither committed, nor aborted; either local transactions, or global that run locally), that can cause later a cycle in the conflict graph. This set of aborted transactions (not unique, contrary to CO) can be optimized, if each transaction is assigned with a weight (that can be determined by transaction's importance and by the computing resources already invested in the running transaction; optimization can be carried out, for example, by a reduction from the *Max flow in networks* problem (Raz 1993a)). Like for CO such a set is time dependent, and becomes empty eventually. Practically, almost in all needed implementations a transaction should be committed only when the set is empty (and no set optimization is applicable). The local (to the database) concurrency control mechanism (separate from the ECO algorithm) ensures that local cycles are eliminated (unlike with CO, which implies serializability by itself; however, practically also for CO a local concurrency mechanism is utilized, at least to ensure Recoverability). Local transactions can be always committed concurrently (even if a precedence relation exists, unlike CO). When the overall transactions' local partial order (which is determined by the local conflict graph, now only with possible temporary local cycles, since cycles are eliminated by a local serializability mechanism) allows, also global transactions can be voted on to be committed concurrently (when all their transitively (indirect) preceding (via conflict) *global* transactions are committed, while transitively preceding local transactions can be at any state. This in analogy to the distributed CO algorithm's stronger concurrent voting condition, where all the transitively preceding transactions need to be committed).

The condition for guaranteeing *Global ECO* can be summarized similarly to CO:

- **The Global ECO Enforcing Vote ordering strategy Theorem**

  Let T_1, T_2 be undecided (neither committed nor aborted) *global transactions* in a database system that ensures serializability locally, such that a *directed path* of unaborted transactions exists in the *local conflict graph* (that of the database itself) from T_1 to T_2. Then, having T_1 ended (either committed or aborted) before T_2 is voted on to be committed, in every such database system in a multidatabase environment, is a necessary and sufficient condition for guaranteeing Global ECO (the condition guarantees Global ECO, which may be violated without it).

Global ECO (all global cycles in the global conflict graph are eliminated by atomic commitment) together with Local serializability (i.e., each database system maintains serializability locally; all local cycles are eliminated) imply Global serializability (all cycles are eliminated). This means that if each database system in a multidatabase environment provides local serializability (by *any* mechanism) and enforces the *vote ordering strategy* in the theorem above (a generalization of CO's vote ordering strategy), then *Global serializability* is guaranteed (no local CO is needed anymore).

Similarly to CO as well, the ECO *voting-deadlock* situation can be summarized as follows:

- **The ECO Voting-Deadlock Theorem**

  Let a multidatabase environment comprise database systems that enforce, each, both *Global ECO* (using the condition in the theorem above) and *local conflict serializability* (which eliminates local cycles in the global conflict graph). Then, a *voting-deadlock* occurs if and only if a *global cycle* (spans two or more databases) exists in the *Global augmented conflict graph* (also blocking by a data-access lock is represented by an edge). If the cycle does not break by any abort, then all the *global transactions* on it are involved with the respective voting-deadlock, and eventually each has its vote blocked (either directly, or indirectly by a data-access lock). If a local transaction resides on the cycle, it may be in any unaborted state (running, ready, or committed; unlike CO no local commit blocking is needed).

As with CO this means that also global deadlocks due to data-access locking (with at least one lock blocking) are voting deadlocks, and are automatically resolved by atomic commitment.

Multi-version CO (MVCO)

Multi-version Commitment Ordering (MVCO; (Raz 1993b)) is a generalization of CO for databases with multi-version resources. With such resources *read-only transactions* do not block or being blocked for better performance. Utilizing such resources is a common way nowadays to increase concurrency and performance by generating a new version of a database object each time the object is written, and allowing transactions' read operations of several last relevant versions (of each object). MVCO implies *One-copy-serializability* (1SER or 1SR) which is the generalization of serializability for multi-version resources. Like CO, MVCO is non-blocking, and can be combined with any relevant multi-version concurrency control mechanism without interfering with it. In the introduced underlying theory for MVCO conflicts are generalized for different versions of a same resource (differently from earlier multi-version theories). For different versions conflict chronological order is replaced by version order, and possibly reversed, while keeping the usual definitions for conflicting operations. Results for the regular and augmented conflict graphs remain unchanged, and similarly to CO a distributed MVCO enforcing algorithm exists, now for a mixed environment with both single-version and multi-version resources (now single-version is a special case of multi-version). As for CO, the MVCO algorithm needs only (unmodified) atomic commitment protocol messages with no additional communication overhead. Locking-based global deadlocks translate to voting deadlocks and are resolved automatically. In analogy to CO the following holds:

- **The MVCO and Global one-copy-serializability Theorem**

1. MVCO compliance of every *autonomous* database system (or transactional object) in a mixed multidatabase environment of single-version and multi-version databases is a *necessary condition* for guaranteeing Global one-copy-serializability (1SER).
2. MVCO compliance of every database system is a *sufficient condition* for guaranteeing Global 1SER.
3. Locking-based global deadlocks are resolved automatically.

Comment: Now a CO compliant single-version database system is automatically also MVCO compliant.

MVCO can be further generalized to employ the generalization of ECO (MVECO).

Example: CO based snapshot isolation (COSI)

CO based snapshot isolation (COSI) is the intersection of *Snapshot isolation* (SI) with MVCO. SI is a multiversion concurrency control method widely utilized due to good performance and similarity to serializability (1SER) in several aspects. The theory in (Raz 1993b) for MVCO described above is utilized later in (Fekete et al. 2005) and other articles on SI, e.g., (Cahill et al. 2008);[6] see also Making snapshot isolation serializable and the references there), for analyzing conflicts in SI in order to make it serializable. The method presented in (Cahill et al. 2008), *Serializable snapshot isolation* (SerializableSI), a low overhead modification of SI, provides good performance results versus SI, with only small penalty for enforcing serializability. A different method, by combining SI with MVCO (COSI), makes SI serializable as well, with a relatively low overhead, similarly to combining the generic CO algorithm with single-version mechanisms. Furthermore, the resulting combination, COSI, being MVCO compliant, allows COSI compliant database systems to inter-operate and transparently participate in a CO solution for distributed/global serializability (see below). Besides overheads also protocols' behaviors need to be compared quantitatively. On one hand, all serializable SI schedules can be made MVCO by COSI (by possible commit delays when needed) without aborting transactions. On the other hand, SerializableSI is known to unnecessarily abort and restart certain percentages of transactions also in serializable SI schedules.

CO and its variants are transparently interoperable for global serializability

With CO and its variants (e.g., SS2PL, SCO, OCO, ECO, and MVCO above) global serializability is achieved via *atomic commitment* protocol based distributed algorithms. For CO and all its variants atomic commitment protocol is the instrument to eliminate global cycles (cycles that span two or more databases) in the *global augmented* (and thus also regular) *conflict graph* (implicitly; no global data structure implementation is needed). In cases of either incompatible local commitment orders in two or more databases (when no global partial order can embed the respective local partial orders together), or a data-access locking related voting deadlock, both implying a global cycle in the global augmented conflict graph and missing votes, the atomic commitment protocol breaks such cycle by aborting an undecided transaction on it (see The distributed CO algorithm above). Differences between the various variants exist at the local level only (within the participating database systems). Each local CO instance of any variant has the same role, to determine the position of every global transaction (a transaction that spans two or more databases) within the local commitment order, i.e., to determine when it is the transaction's turn to be voted on locally in the atomic commitment protocol. Thus, all the CO variants exhibit the same behavior in regard to atomic commitment. This means that they are all interoperable via atomic commitment (using the same software interfaces, typically provided as services, some already standardized for atomic commitment, primarily for the two phase commit protocol, e.g., X/Open XA) and transparently can be utilized together in any distributed environment (while each CO variant instance is possibly associated with any relevant local concurrency control mechanism type).

In summary, any single global transaction can participate simultaneously in databases that may employ each any, possibly different, CO variant (while concurrently running processes in each such database, and running concurrently with local and other global transactions in each such database). The atomic commitment protocol is indifferent to CO, and does not distinguish between the various CO variants. Any *global cycle* generated in the augmented global conflict graph may span databases of different CO variants, and generate (if not broken by any local abort) a voting deadlock that is resolved by atomic commitment exactly the same way as in a single CO variant environment. *local cycles* (now possibly with mixed materialized and non-materialized conflicts, both serializability and data-access-locking deadlock related, e.g., SCO) are resolved locally (each by its respective variant instance's own local mechanisms).

Vote ordering (VO or Generalized CO (GCO); Raz 2009), the union of CO and all its above variants, is a useful concept and global serializability technique. To comply with VO, local serializability (in it most general form, commutativity based, and including multi-versioning) and the *vote order strategy* (voting by local precedence order) are needed.

Combining results for CO and its variants, the following is concluded:

- **The CO Variants Interoperability Theorem**

1. In a multi-database environment, where each database system (transactional object) is compliant with some CO variant property (VO compliant), any global transaction can participate simultaneously in databases of possibly different CO variants, and Global serializability is guaranteed (*sufficient condition* for Global serializability; and Global one-copy-serializability (1SER), for a case when a multi-version database exists).
2. If only local (to a database system) concurrency control information is utilized by every database system (each has the *generalized autonomy* property, a generalization of *autonomy*), then compliance of each with some (any) CO variant property (VO compliance) is a *necessary condition* for guaranteeing Global serializability (and Global 1SER; otherwise they may be violated).
3. Furthermore, in such environment data-access-locking related global deadlocks are resolved automatically (each such deadlock is generated by a global cycle in the *augmented conflict graph* (i.e., a *voting deadlock*; see above), involving at least one data-access lock (non-materialized conflict) and two database systems; thus, not a cycle in the regular conflict graph and does not affect serializability).

Long-running transaction

Long-running transactions are computer database transactions that avoid locks on non-local resources, use compensation to handle failures, potentially aggregate smaller ACID transactions (also referred to as atomic transactions), and typically use a coordinator to complete or abort the transaction. In contrast to rollback in ACID transactions, compensation restores the original state, or an equivalent, and is business-specific. For example, the compensating action for making a hotel reservation is canceling that reservation, possibly with a penalty.

A number of protocols have been specified for long-running transactions using Web services within business processes. OASIS Business Transaction Processing [1] and WS-CAF [2] are examples. These protocols use a coordinator to mediate the successful completion or use of compensation in a long-running transaction.

Timestamp-based concurrency control

In computer science, a **timestamp-based concurrency control** algorithm is a non-lock concurrency control method. It is used in some databases to safely handle transactions, using timestamps.

Operation

Assumptions

- Every timestamp value is unique and accurately represents an instant in time.
- No two timestamps can be the same.
- A higher-valued timestamp occurs later in time than a lower-valued timestamp.

Generating a Timestamp

A number of different ways have been used to generate timestamp

- Use the value of the system's clock at the start of a transaction as the timestamp.
- Use a thread-safe shared counter that is incremental at the start of a transaction as the timestamp.
- A combination of the above two methods.

Formal

Each transaction (T_i) is an ordered list of actions (A_{ix}). Before the transaction performs its first action (A_{i1}), it is marked with the current timestamp, or any other strictly totally ordered sequence: $TS(T_i) = NOW()$. Every transaction is also given an initially empty set of transactions upon which it depends, $DEP(T_i) = []$, and an initially empty set of old objects which it updated, $OLD(T_i) = []$.
Each object (O_j) in the database is given two timestamp fields which are not used other than for concurrency control: $RTS(O_j)$ is the time at which the value of object was last used by a transaction, $WTS(O_j)$ is the time at which the value of the object was last updated by a transaction.
For all T_i:

For each action A_{ix}:

If A_{ix} wishes to use the value of O_j:

If $WTS(O_j) > TS(T_i)$ then **abort** (a more recent thread has overwritten the value),

Otherwise update the set of dependencies $DEP(T_i).\text{add}(WTS(O_j))$ and set $RTS(O_j) = \max(RTS(O_j), TS(T_i))$;

If A_{ix} wishes to update the value of O_j:

If $RTS(O_j) > TS(T_i)$ then **abort** (a more recent thread is already relying on the old value),

If $WTS(O_j) > TS(T_i)$ then **skip** (the Thomas Write Rule),

Otherwise store the previous values, $OLD(T_i).\text{add}(O_j, WTS(O_j))$, set $WTS(O_j) = TS(T_i)$, and update the value of O_j.

While there is a transaction in $DEP(T_i)$ that has not ended: **wait**

If there is a transaction in $DEP(T_i)$ that aborted then **abort**

Otherwise: **commit**.

To **abort**:

For each $(\text{old}O_j, \text{old}WTS(O_j))$ in $OLD(T_i)$

If $WTS(O_j)$ equals $TS(T_i)$ then restore $O_j = \text{old}O_j$ and $WTS(O_j) = \text{old}WTS(O_j)$

Informal

Whenever a transaction starts, it is given a timestamp. This is so we can tell which order that the transactions are supposed to be applied in. So given two transactions that affect the same object, the transaction that has the earlier timestamp is meant to be applied before the other one. However, if the wrong transaction is actually presented first, it is aborted and must be restarted.

Every object in the database has a **read timestamp**, which is updated whenever the object's data is read, and a **write timestamp**, which is updated whenever the object's data is changed.

If a transaction wants to read an object,

- but the transaction started *before* the object's **write timestamp** it means that something changed the object's data after the transaction started. In this case, the transaction is canceled and must be restarted.
- and the transaction started *after* the object's **write timestamp**, it means that it is *safe* to read the object. In this case, if the transaction timestamp is after the object's **read timestamp**, the read timestamp is set to the transaction timestamp.

If a transaction wants to write to an object,

- but the transaction started *before* the object's **read timestamp** it means that something has had a look at the object, and we assume it took a copy of the object's data. So we can't write to the object as that would make any copied data invalid, so the transaction is aborted and must be restarted.
- and the transaction started *before* the object's **write timestamp** it means that something has changed the object since we started our transaction. In this case we use the Thomas Write Rule and simply skip our write operation and continue as normal; the transaction does not have to be aborted or restarted
- otherwise, the transaction writes to the object, and the object's **write timestamp** is set to the transaction's timestamp.

Recoverability

For an explanation of the terms **recoverable** (RC), **avoids cascading aborts** (ACA) and **strict** (ST) see Schedule (computer science).

Note that timestamp ordering in its basic form does not produce recoverable histories. Consider for example the following history with transactions T_1 and T_2:

$$W_1(x)\ R_2(x)\ W_2(y)\ C_2\ R_1(z)\ C_1$$

This could be produced by a TO scheduler, but is not recoverable, as T_2 commits even though having read from an uncomitted transaction. To make sure the it produces recoverable histories, a scheduler can keep a list of other transactions each transaction has *read from*, and not let a transaction commit before this list consisted of only committed transactions. To avoid cascading aborts, the scheduler could tag data written by uncommitted transactions as *dirty*, and never let a read operation commence on such a data item before it was untagged. To get a strict history, the scheduler should not allow any operations on dirty items.

Implementation Issues

Timestamp Resolution

This is the minimum time elapsed between two adjacent timestamps. If the resolution of the timestamp is too large (coarse), the possibility of two or more timestamps being equal is increased and thus enabling some transactions to commit out of correct order. For example, assuming that we have a system that can create one hundred unique timestamps per second, and given two events that occur 2 milliseconds apart, they will probably be given the same timestamp even though they actually occurred at different times.

Timestamp Locking

Even though this technique is a non-locking one, in as much as the Object is not locked from concurrent access for the duration of a transaction, the act of recording each timestamp against the Object requires an extremely short duration lock on the Object or its proxy.

Pseudoconversational transaction

In transaction processing, a **pseudoconversational transaction** is a type of transaction that emulates a true conversation in an interactive session. To the end user, it appears as though the program has simply "paused" to request further input, whereas in reality, most resources are released while the input is waiting to be received.

Transparent termination and restart

The controlling program has deliberately saved most of its state during the delay, terminated, and then, on being restarted through new input, restores its previous state. A single control variable is usually retained to hold the current state in terms of the stage of input reached (and therefore what must be recovered at any stage in order to resume processing). The state, including the control variable, is usually preserved in a 'temporary storage record' that maps the variables needing restoration as an aggregate set, usually contained in a single structure (other variables will be re-initialized on restart).

Conserving resources

This method of programming frees up pooled resources (such as memory) for an indeterminate time. This delay is the end-user 'thinking time' (or response time) and depends on human factors including speed of typing. For systems supporting many thousands of users on a single processor, it allows the transparent 'look and feel' of a true conversational session without tying up limited resources.

Thomas write rule

In computer science, particularly the field of databases, the **Thomas Write rule** is a rule in timestamp-based concurrency control. It can be summarized as *ignore outdated writes*.

It states that, if a more recent transaction has already written the value of an object, then a less recent transaction does not need perform its own write since it will eventually be overwritten by the more recent one.

The Thomas Write rule is applied in situations where a predefined **logical** order is assigned to transactions when they start. For example a transactions might be assigned a monotonically increasing timestamp when it is created. The rule prevents changes in the order in which the transactions are executed from creating different outputs: The outputs will always be consistent with the predefined logical order.

For example consider a database with 3 variables (A, B, C), and two atomic operations C := A (T1), and C := B (T2). Each transaction involves a read (A or B), and a write (C). The only conflict between these transactions is the write on C. The following is one possible schedule for the operations of these transactions:

$$\begin{bmatrix} T_1 & T_2 \\ & Read(A) \\ Read(B) & \\ & Write(C) \\ Write(C) & \\ Commit & \\ & Commit \end{bmatrix} \Longleftrightarrow \begin{bmatrix} T_1 & T_2 \\ & Read(A) \\ Read(B) & \\ & Write(C) \\ & \\ Commit & \\ & Commit \end{bmatrix}$$

If (when the transactions are created) T1 is assigned a timestamp that precedes T2 (i.e., according to the logical order, T1 comes first), then only T2's write should be visible. If, however, T1's write is executed after T2's write, then we need a way to detect this and discard the write.

One practical approach to this is to label each value with a write timestamp (WTS) that indicates the timestamp of the last transaction to modify the value. Enforcing the Thomas Write rule only requires checking to see if the write timestamp of the object is greater than the time stamp of the transaction performing a write. If so, the write is discarded

In the example above, if we call TS(T) the timestamp of transaction T, and WTS(O) the write timestamp of object O, then T2's write sets WTS(C) to TS(T2). When T1 tries to write C, it sees that TS(T1) < WTS(C), and discards the write. If a third transaction T3 (with TS(T3) > TS(T2)) were to then write to C, it would get TS(T3) > WTS(C), and the write would be allowed.

Global concurrency control

Global concurrency control typically pertains to the concurrency control of a system comprising several components, each with its own concurrency control. The overall concurrency control of the whole system, the *Global concurrency control*, is determined by the concurrency control of its components, modules. In this case also the term **Modular concurrency control** is used.

In many cases a system may be distributed over a communication network. In this case we deal with distributed concurrency control of the system, and the two terms sometimes overlap. However, distributed concurrency control typically relates to a case where the distributed system's components do not have each concurrency control of its own, but rather are involved with a concurrency control mechanism that spans several components in order to operate. For example, as typical in a distributed database.

In *database systems* and *transaction processing* (*transaction management*) global concurrency control relates to the concurrency control of a *multidatabase system* (for example, a Federated database; other examples are Grid computing and Cloud computing environments). It deals with the properties of the *global schedule*, which is the unified schedule of the multidatabase system, comprising all the individual schedules of the database systems and possibly other transactional objects in the system. A major goal for global concurrency control is *Global serializability* (or *Modular serializability*). The problem of achieving global serializability in a heterogeneous environment had been open for many years, until an effective solution based on Commitment ordering (CO) has been proposed (see Global serializability). Global concurrency control deals also with relaxed forms of global serializability which compromise global serializability (and in many applications also correctness, and thus are avoided there). While local (to a database system) relaxed serializability methods compromise serializability for performance gain (utilized when the application allows), it is unclear that the various proposed relaxed global serializability methods provide any performance gain over CO, which guarantees global serializability.

Global serializability

In concurrency control of *databases*, *transaction processing* (*transaction management*), and other transactional distributed applications, **Global serializability** (or **Modular serializability**) is a property of a *global schedule* of transactions. A global schedule is the unified schedule of all the individual database (and other transactional object) schedules in a multidatabase environment (e.g., federated database). Complying with global serializability means that the global schedule is *serializable*, has the *serializability* property, while each component database (module) has a serializable schedule as well. In other words, a collection of serializable components provides overall system serializability, which is usually incorrect. A need in correctness across databases in multidatabase systems makes global serializability a major goal for *global concurrency control* (or *modular concurrency control*). With the proliferation of the Internet, Cloud computing, Grid computing, and small, portable, powerful computing devices (e.g., smartphones), as well as increase in systems management sophistication, the need for atomic distributed transactions and thus effective global serializability techniques, to ensure correctness in and among distributed transactional applications, seems to increase.

In a federated database system or any other more loosely defined multidatabase system, which are typically distributed in a communication network, transactions span multiple (and possibly distributed) databases. Enforcing global serializability in such system, where different databases may use different types of concurrency control, is problematic. Even if every local schedule of a single database is serializable, the global schedule of a whole system is not necessarily serializable. The massive communication exchanges of conflict information needed between databases to reach conflict serializability globally would lead to unacceptable performance, primarily due to computer and communication latency. Achieving global serializability effectively over different types of concurrency control has been open for several years. *Commitment ordering* (or Commit ordering; CO), a serializability technique publicly introduced in 1991 by Yoav Raz from Digital Equipment Corporation (DEC), provides an effective general solution for global (conflict) serializability across any collection of database systems and other transactional objects, with possibly different concurrency control mechanisms. CO does not need the distribution of conflict information, but rather utilizes the already needed (unmodified) atomic commitment protocol messages without any further communication between databases. It also allows optimistic (non-blocking) implementations. CO generalizes *Strong strict two phase locking* (SS2PL), which in conjunction with the *Two-phase commit* (2PC) protocol is the de facto standard for achieving global serializability across (SS2PL based) database systems. As a result CO compliant database systems (with any, different concurrency control types) can transparently join existing SS2PL based solutions for global serializability. The same applies also to all other multiple (transactional) object systems that use atomic transactions and need global serializability for correctness (see examples above; nowadays such need is not smaller than with database systems, the origin of atomic transactions).

The most significant aspects of CO that make it a uniquely effective general solution for global serializability are the following:

1. Seamless, low overhead integration with any concurrency control mechanism, with neither changing any transaction's operation scheduling or blocking it, nor adding any new operation.
2. Heterogeneity: Global serializability is achieved across multiple transactional objects (e.g., database management systems) with different (any) concurrency control mechanisms, without interfering with the mechanisms' operations.
3. Modularity: Transactional objects can be added and removed transparently.
4. Autonomy of transactional objects: No need of conflict or equivalent information distribution (e.g., local precedence relations, locks, timestamps, or tickets; no object needs other object's information).
5. Scalability: With "normal" global transactions, computer network size and number of transactional objects can increase unboundedly with no impact on performance, and

6. Automatic global deadlock resolution.

All these aspects, except the first two, are also possessed by the popular SS2PL, which is a (constrained, blocking) special case of CO and inherits many of CO's qualities.

The global serializability problem

Problem statement

The difficulties described above translate into the following problem:

> Find an efficient (high-performance and fault tolerant) method to enforce *Global serializability* (global conflict serializability) in a heterogeneous distributed environment of multiple autonomous database systems. The database systems may employ different concurrency control methods. No limitation should be imposed on the operations of either local transactions (confined to a single database system) or global transactions (span two or more database systems).

Quotations

Lack of an appropriate solution for the global serializability problem has driven researchers to look for alternatives to serializability as a correctness criterion in a multidatabase environment (e.g., see *Relaxing global serializability* below), and the problem has been characterized as difficult and *open*. The following two quotations demonstrate the mindset about it by the end of the year 1991, with similar quotations in numerous other articles:

- "Without knowledge about local as well as global transactions, it is highly unlikely that efficient global concurrency control can be provided... Additional complications occur when different component DBMSs [Database Management Systems] and the FDBMSs [Federated Database Management Systems] support different concurrency mechanisms... It is unlikely that a theoretically elegant solution that provides conflict serializability without sacrificing performance (i.e., concurrency and/or response time) and availability exists."[1]

Commitment ordering, publicly introduced in May 1991 (see below), provides an efficient elegant general solution, from both practical and theoretical points of view, to the global serializability problem across database systems with possibly different concurrency control mechanisms. It provides conflict serializability with no negative effect on availability, and with no worse performance than the de facto standard for global serializability, CO's special case Strong strict two-phase locking (SS2PL). It requires knowledge about neither local nor global transactions.

- "Transaction management in a heterogeneous, distributed database system is a difficult issue. The main problem is that each of the local database management systems may be using a different type of concurrency control scheme. Integrating this is a challenging problem, made worse if we wish to preserve the local autonomy of each of the local databases, and allow local and global transactions to execute in parallel. One simple solution is to restrict global transactions to retrieve-only access. However, the issue of reliable transaction management in the general case, where global and local transactions are allowed to both read and write data, is still open."[2]

The commitment ordering solution comprises effective integration of autonomous database management systems with possibly different concurrency control mechanisms. This while local and global transactions execute in parallel without restricting any read or write operation in either local or global transactions, and without compromising the systems' autonomy.

Even in later years, after the public introduction of the Commitment ordering general solution in 1991, the problem still has been considered by many unsolvable:

- "We present a transaction model for multidatabase systems with autonomous component systems, coined heterogeneous 3-level transactions. It has become evident that in such a system the requirements of guaranteeing full ACID properties and full local autonomy can not be reconciled..."[3]

The quotation above is from a 1997 article proposing a relaxed global serializability solution (see *Relaxing global serializability* below), and referencing Commitment ordering (CO) articles. The CO solution supports effectively both full ACID properties and full local autonomy, as well as meeting the other requirements posed above in the *Problem statement* section, and apparently has been misunderstood.

Similar thinking we see also in the following quotation from a 1998 article:

- "The concept of serializability has been the traditionally accepted correctness criterion in database systems. However in multidatabase systems (MDBSs), ensuring global serializability is a difficult task. The difficulty arises due to the heterogeneity of the concurrency control protocols used by the participating local database management systems (DBMSs), and the desire to preserve the autonomy of the local DBMSs. In general, solutions to the global serializability problem result in executions with a low degree of concurrency. The alternative, relaxed serializability, may result in data inconsistency."[4]

Also the above quoted article proposes a relaxed global serializability solution, while referencing the CO work. The CO solution for global serializability both bridges between different concurrency control protocols with no substantial concurrency reduction (and typically minor, if at all), and maintains the autonomy of local DBMSs. Evidently also here CO has been misunderstood. This misunderstanding continues to 2010 in a textbook by some of the same authors, where the same relaxed global serializability technique, *Two level serializability*, is emphasized and described in detail, and CO is not mentioned at all.[5]

On the other hand, the following quotation on CO appears in a 2009 book:[6]

- "Not all concurrency control algorithms use locks... Three other techniques are timestamp ordering, serialization graph testing, and commit ordering. **Timestamp ordering** assigns each transaction a timestamp and ensures that conflicting operations execute in timestamp order. **Serialization graph testing** tracks conflicts and ensures that the serialization graph is acyclic. **Commit ordering** ensures that conflicting operations are consistent with the relative order in which their transactions commit, which can enable interoperability of systems using different concurrency control mechanisms."

Comments:

1. Beyond the common locking based algorithm SS2PL, which is a CO variant itself, also additional variants of CO that use locks exist, (see below). However, generic, or "pure" CO does not use locks.
2. Since CO mechanisms order the commit events according to conflicts that already have occurred, it is better to describe CO as "**Commit ordering** ensures that the relative order in which transactions commit is consistent with the order of their respective conflicting operations."

The characteristics and properties of the CO solution are discussed below.

Proposed solutions

Several solutions, some partial, have been proposed for the global serializability problem. Among them:

- *Global conflict graph* (serializability graph, precedence graph) *checking*
- *Distributed Two phase locking* (Distributed 2PL)
- *Distributed Timestamp ordering*
- *Tickets* (local logical timestamps which define local total orders, and are propagated to determine global partial order of transactions)
- *Commitment ordering*

Technology perspective

The problem of global serializability has been a quite intensively researched subject in the late 1980s and early 1990s. *Commitment ordering* (CO) has provided an effective general solution to the problem, insight into it, and understanding about possible generalizations of *strong strict two phase locking* (SS2PL), which practically and almost exclusively has been utilized (in conjunction with the *Two-phase commit protocol* (2PC)) since the 1980s to achieve global serializability across databases. An important side-benefit of CO is the automatic *global deadlock* resolution that it provides (this is applicable also to distributed SS2PL; though global deadlocks have been an important research subject for SS2PL, automatic resolution has been overlooked, except in the CO articles, until today (2009)). At that time quite many commercial database system types existed, many non-relational, and databases were relatively very small. Multi database systems were considered a key for database scalability by database systems interoperability, and global serializability was urgently needed. Since then the tremendous progress in computing power, storage, and communication networks, resulted in orders of magnitude increases in both centralized databases' sizes, transaction rates, and remote access to database capabilities, as well as blurring the boundaries between centralized computing and distributed one over fast, low-latency local networks (e.g., Infiniband). These, together with progress in database vendors' distributed solutions (primarily the popular SS2PL with 2PC based, a de facto standard that allows interoperability among different vendors' (SS2PL-based) databases; both SS2PL and 2PC technologies have gained substantial expertise and efficiency), workflow management systems, and database replication technology, in most cases have provided satisfactory and sometimes better information technology solutions without multi database atomic distributed transactions over databases with different concurrency control (bypassing the problem above). As a result, the sense of urgency that existed with the problem at that period, and in general with high-performance distributed atomic transactions over databases with different concurrency control types, has reduced. However, the need in concurrent distributed atomic transactions as a fundamental element of reliability exists in distributed systems also beyond database systems, and so the need in global serializability as a fundamental correctness criterion for such transactional systems (see also Distributed serializability in Serializability). With the proliferation of the Internet, Cloud computing, Grid computing, small, portable, powerful computing devices (e.g., smartphones), and sophisticated systems management the need for effective global serializability techniques to ensure correctness in and among distributed transactional applications seems to increase, and thus also the need in Commitment ordering (including the popular for databases special case SS2PL; SS2PL, though, does not meet the requirements of many other transactional objects).

The commitment ordering solution

Commitment ordering[3][] (or Commit ordering; CO) is the only high-performance, fault tolerant, conflict serializability providing solution that has been proposed as a fully distributed (no central computing component or data-structure are needed), general mechanism that can be combined seamlessly with any local (to a database) concurrency control mechanism (see technical summary). Since the CO property of a schedule is a necessary condition for global serializability of *autonomous databases* (in the context of concurrency control), it provides the only general solution for autonomous databases (i.e., if autonomous databases do not comply with CO, then global serializability may be violated). Seemingly by sheer luck, the CO solution possesses many attractive properties:

1. does not interfere with any transaction's operation, particularly neither block, restrict nor delay any data-access operation (read or write) for either local or global transactions (and thus does not cause any extra aborts); thus allows seamless integration with any concurrency control mechanism.
2. allows optimistic implementations (*non-blocking*, i.e., non data access blocking).
3. allows heterogeneity: Global serializability is achieved across multiple transactional objects with different (any) concurrency control mechanisms, without interfering with the mechanisms' operations.
4. allows modularity: Transactional objects can be added and removed transparently.
5. allows full ACID transaction support.

6. maintains each database's autonomy, and does not need any concurrency control information distribution (e.g., local precedence relations, locks, timestamps, or tickets).
7. does not need any knowledge about the transactions.
8. requires no communication overhead since it only uses already needed, unmodified *atomic commitment* protocol messages (any such protocol; using fault tolerant atomic commitment protocols and database systems makes the CO solution fault tolerant).
9. automatically resolves global deadlocks due to locking.
10. scales up effectively with computer network size and number of databases, almost without any negative impact on performance, since each global transaction is typically confined to certain relatively small numbers of databases and network nodes.
11. requires no additional, artificial transaction access operations (e.g., "take timestamp" or "take ticket"), which typically result in additional, artificial conflicts that reduce concurrency.
12. requires low overhead.

The only overhead incurred by the CO solution is locally detecting conflicts (which is already done by any known serializability mechanism, both pessimistic and optimistic) and locally ordering in each database system both the (local) commits of local transactions and the voting for atomic commitment of global transactions. Such overhead is low. The net effect of CO may be some delays of commit events (but never more delay than SS2PL, and on the average less). This makes CO instrumental for global concurrency control of multidatabase systems (e.g., federated database systems). The underlying *Theory of Commitment ordering*,[] part of Serializability theory, is both sound and elegant (and even "mathematically beautiful"; referring to structure and dynamics of conflicts, graph cycles, and deadlocks), with interesting implications for transactional distributed applications.

All the qualities of CO in the list above, except the first three, are also possessed by SS2PL, which is a special case of CO, but blocking and constraining. This partially explains the popularity of SS2PL as a solution (practically, the only solution, for many years) for achieving global serializability. However, property 9 above, automatic resolution of global deadlocks, has not been noticed for SS2PL in the database research literature until today (2009; except in the CO publications). This, since the phenomenon of voting-deadlocks in such environments and their automatic resolution by the atomic commitment protocol has been overlooked.

Most existing database systems, including all major commercial database systems, are *strong strict two phase locking (SS2PL)* based and already CO compliant. Thus they can participate in a CO based solution for global serializability in multidatabase environments without any modification (except for the popular *multiversioning*, where additional CO aspects should be considered). Achieving global serializability across SS2PL based databases using atomic commitment (primarily using *two phase commit, 2PC*) has been employed for many years (i.e., using the same CO solution for a specific special case; however, no reference is known prior to CO, that notices this special case's automatic global deadlock resulotion by the atomic commitment protocol's augmented-conflict-graph global cycle elimination process). Virtually all existing distributed transaction processing environments and supporting products rely on SS2PL and provide 2PC. As a matter of fact SS2PL together with 2PC have become a de facto standard. This solution is a homogeneous concurrency control one, suboptimal (when both Serializability and Strictness are needed; see Strict commitment ordering; SCO) but still quite effective in most cases, sometimes at the cost of increased computing power needed relatively to the optimum. (However for better performance relaxed serializability is used whenever applications allow). It allows inter-operation among SS2PL-compliant different database system types, i.e., allows heterogeneity in aspects other than concurrency control. SS2PL is a very constraining schedule property, and "takes over" when combined with any other property. For example, when combined with any optimistic property, the result is not optimistic anymore, but rather characteristically SS2PL. On the other hand, CO does not change data-access scheduling patterns at all, and *any* combined property's characteristics remain unchanged. Since also CO uses atomic commitment (e.g., 2PC) for achieving global serializability, as SS2PL does, any CO compliant database system or transactional object can transparently join existing SS2PL based environments, use 2PC, and maintain global serializability without any environment change.

This makes CO a straightforward, natural generalization of SS2PL for any conflict serializability based database system, for all practical purposes.

Commitment ordering has been quite widely known inside the *transaction processing* and *databases* communities at *Digital Equipment Corporation* (DEC) since 1990. It has been under *company confidentiality* due to patenting[] [] processes. CO was disclosed outside of DEC by lectures and technical reports' distribution to database researches in May 1991, immediately after its first patent filing. It has been misunderstood by many database researchers years after its introduction, which is evident by the quotes above from articles in 1997-1998 referencing Commitment ordering articles. On the other hand CO has been utilized extensively as a solution for global serializability in works on Transactional processes, [7] [8] and more recently in the related **Re:GRIDiT**, [9] [10] which is an approach for transaction management in the converging Grid computing and Cloud computing. See more in *The History of Commitment Ordering*.

Relaxing global serializability

Some techniques have been developed for **relaxed global serializability** (i.e., they do not guarantee global serializability; see also *Relaxing serializability*). Among them (with several publications each):

- *Quasi serializability*[11]
- *Two-level serializability*

While local (to a database system) relaxed serializability methods compromise *serializability* for performance gain (and are utilized only when the application can tolerate possible resulting inaccuracies, or its integrity is unharmed), it is unclear that various proposed *relaxed global serializability* methods which compromise *global serializability*, provide any performance gain over *commitment ordering* which guarantees global serializability. Typically, the declared intention of such methods has not been performance gain over effective global serializability methods (which apparently have been unknown to the inventors), but rather correctness criteria alternatives due to lack of a known effective global serializability method. Oddly, some of them were introduced years after CO had been introduced, and some even quote CO without realizing that it provides an effective global serializability solution, and thus without providing any performance comparison with CO to justify them as alternatives to global serializability for some applications (e.g., *Two-level serializability*). *Two-level serializability* is even presented as a major global concurrency control method in a 2010 edition of a text-book on databases (authored by two of the original authors of Two-level serializability, where one of them, Avi Silberschatz, is also an author of the original *Strong recoverability* articles). This book neither mentions CO nor references it, and strangely, apparently does not consider CO a valid *Global serializability* solution.

Another common reason nowadays for Global serializability relaxation is the requirement of availability of internet products and services. This requirement is typically answered by large scale data replication. The straightforward solution for synchronizing replicas' updates of a same database object is including all these updates in a single atomic distributed transaction. However, with many replicas such a transaction is very large, and may span several computers and networks that some of them are likely to be unavailable. Thus such a transaction is likely to end with abort and miss its purpose. Consequently Optimistic replication (Lazy replication) is often utilized (e.g., in many products and services by Google, Amazon, Yahoo, and alike), while Global serializability is relaxed and compromised for Eventual consistency. In this case relaxation is done only for applications that are not expected to be harmed by it.

Classes of schedules defined by *relaxed global serializability* properties either contain the global serializability class, or are incomparable with it. What differentiates techniques for *relaxed global conflict serializability* (RGCSR) properties from those of *relaxed conflict serializability* (RCSR) properties that are not RGCSR is typically the different way *global cycles* (span two or more databases) in the *global conflict graph* are handled. No distinction between global and local cycles exists for RCSR properties that are not RGCSR. RCSR contains RGCSR. Typically RGCSR techniques eliminate local cycles, i.e., provide *local serializability* (which can be achieved effectively by

regular, known concurrency control methods), however, obviously they do not eliminate all global cycles (which would achieve global serializability).

Modular concurrency control

Global concurrency control typically pertains to the concurrency control of a system comprising several components, each with its own concurrency control. The overall concurrency control of the whole system, the *Global concurrency control*, is determined by the concurrency control of its components, modules. In this case also the term **Modular concurrency control** is used.

In many cases a system may be distributed over a communication network. In this case we deal with distributed concurrency control of the system, and the two terms sometimes overlap. However, distributed concurrency control typically relates to a case where the distributed system's components do not have each concurrency control of its own, but rather are involved with a concurrency control mechanism that spans several components in order to operate. For example, as typical in a distributed database.

In *database systems* and *transaction processing* (*transaction management*) global concurrency control relates to the concurrency control of a *multidatabase system* (for example, a Federated database; other examples are Grid computing and Cloud computing environments). It deals with the properties of the *global schedule*, which is the unified schedule of the multidatabase system, comprising all the individual schedules of the database systems and possibly other transactional objects in the system. A major goal for global concurrency control is *Global serializability* (or *Modular serializability*). The problem of achieving global serializability in a heterogeneous environment had been open for many years, until an effective solution based on Commitment ordering (CO) has been proposed (see Global serializability). Global concurrency control deals also with relaxed forms of global serializability which compromise global serializability (and in many applications also correctness, and thus are avoided there). While local (to a database system) relaxed serializability methods compromise serializability for performance gain (utilized when the application allows), it is unclear that the various proposed relaxed global serializability methods provide any performance gain over CO, which guarantees global serializability.

Multiversion concurrency control

Multiversion concurrency control (**MCC** or **MVCC**), is a concurrency control method commonly used by database management systems to provide concurrent access to the database and in programming languages to implement transactional memory.[1]

If someone is reading from a database at the same time as someone else is writing to it, it is possible that the reader will see a half-written or inconsistent piece of data. There are several ways of solving this problem, known as concurrency control methods. The simplest way is to make all readers wait until the writer is done, which is known as a lock. This can be very slow, so MVCC takes a different approach: each user connected to the database sees a *snapshot* of the database at a particular instant in time. Any changes made by a writer will not be seen by other users of the database until the changes have been completed (or, in database terms: until the transaction has been committed.)

When an MVCC database needs to update an item of data, it will not overwrite the old data with new data, but instead mark the old data as obsolete and add the newer *version* elsewhere. Thus there are multiple versions stored, but only one is the latest. This allows readers to access the data that was there when they began reading, even if it was modified or deleted part way through by someone else. It also allows the database to avoid the overhead of filling in holes in memory or disk structures but requires (generally) the system to periodically sweep through and delete the old, obsolete data objects. For a document-oriented database it also allows the system to optimize documents by writing entire documents onto contiguous sections of disk—when updated, the entire document can be re-written rather than bits and pieces cut out or maintained in a linked, non-contiguous database structure.

MVCC provides *point in time* consistent views. Read transactions under MVCC typically use a timestamp or transaction ID to determine what state of the DB to read, and read these *versions* of the data. This avoids managing locks for read transactions because writes can be isolated by virtue of the old versions being maintained, rather than through a process of locks or mutexes. Writes affect a future *version* but at the transaction ID that the read is working at, everything is guaranteed to be consistent because the writes are occurring at a later transaction ID.

Implementation

MVCC uses timestamps or increasing transaction IDs to achieve transactional consistency. MVCC ensures a transaction never has to wait for a database object by maintaining several versions of an object. Each version would have a write timestamp and it would let a transaction (T_i) read the most recent version of an object which precedes the transaction timestamp ($TS(T_i)$).

If a transaction (T_i) wants to write to an object, and if there is another transaction (T_k), the timestamp of T_i must precede the timestamp of T_k (i.e., $TS(T_i) < TS(T_k)$) for the object write operation to succeed. Which is to say a write cannot complete if there are outstanding transactions with an earlier timestamp.

Every object would also have a read timestamp, and if a transaction T_i wanted to write to object P, and the timestamp of that transaction is earlier than the object's read timestamp ($TS(T_i) < RTS(P)$), the transaction T_i is aborted and restarted. Otherwise, T_i creates a new version of P and sets the read/write timestamps of P to the timestamp of the transaction $TS(T_i)$.

The obvious drawback to this system is the cost of storing multiple versions of objects in the database. On the other hand reads are never blocked, which can be important for workloads mostly involving reading values from the database. MVCC is particularly adept at implementing true snapshot isolation, something which other methods of concurrency control frequently do either incompletely or with high performance costs.

Anomalies

MVCC fails to achieve true snapshot isolation contrary to what the original paper was assuming. Under some circumstances some anomalies can arise called *skew write* and *read-read anomaly*. Those anomalies can be fixed using Serializable Snapshot Isolation and Precisely Serializable Snapshot Isolation at the expense of increasing the number of aborted transactions.

Examples

Concurrent read-write

At Time = 1, the state of a database could be:

Time	Object 1	Object 2
1	"Hello" by T1	
0	"Foo" by T0	"Bar" by T0

T0 wrote Object 1="Foo" and Object 2="Bar". After that T1 wrote Object 1="Hello" leaving Object 2 at its original value. The new value of Object 1 will supersede the value at 0 for all transaction that starts after T1 commits at which point version 0 of Object 1 can be garbage collected.

If a long running transaction T2 starts a read operation of Object 2 and Object 1 after T1 committed and there is a concurrent update transaction T3 which deletes Object 2 and adds Object 3="Foo-Bar", the database state will look like at time 2:

Time	Object 1	Object 2	Object 3
2		(deleted) by T3	"Foo-Bar" by T3
1	"Hello" by T1		
0	"Foo" by T0	"Bar" by T0	

There is a new version as of time 2 of Object 2 which is marked as deleted and a new Object 3. Since T2 and T3 run concurrently T2 sees another the version of the database before 2 i.e. before T3 committed writes, as such T2 reads Object 2="Bar" and Object 1="Hello". This is how MVCC allows snapshot isolation reads in almost every cases without any locks.

History

Multiversion concurrency control is described in some detail in the 1981 paper "Concurrency Control in Distributed Database Systems" by Philip Bernstein and Nathan Goodman, then employed by the Computer Corporation of America. Bernstein and Goodman's paper cites a 1978 dissertation by David P. Reed which quite clearly describes MVCC and claims it as an original work.

The first shipping, commercial database software product featuring MVCC was Digital's VAX Rdb/ELN. The second was InterBase, which is still an active, commercial product.

Databases with MVCC

- Altibase
- ArangoDB[2]
- Berkeley DB[3]
- Bigdata[4]
- Cloudant
- Clustrix[5]
- CouchDB
- IBM DB2 – since IBM DB2 9.7 LUW ("Cobra") under CS isolation level - in *currently committed* mode[6]
- IBM Cognos TM1 – in versions 9.5.2 and up.[7]
- Drizzle
- eXtremeDB
- Firebird[8]
- FLAIM
- GE Smallworld Version Managed Data Store
- H2 Database Engine – experimental since version 1.0.57 (2007-08-25)[9]
- Hawtdb [10]
- HBase (Apache HBase [11])
- HSQLDB – starting with version 2.0
- HypergraphDB [12] is a Typed Hypergraph Database. Hypergraphs are an extension of Graph, ObjectOriented, and list based data structures.
- InfiniDB[13]
- Ingres[14]
- InterBase – all versions
- MariaDB (MySQL fork) when used with XtraDB [15] (developed by Percona Inc.)(XtraDB is a storage engine that is an InnoDB fork and that is included in MariaDB sources and binaries)[16] or PBXT [17] (developed by PrimeBase Technologies).[18][19]
- MarkLogic Server - a bit of this is described in[20]
- MemSQL
- MDB [21]
- Meronymy SPARQL Database Server
- Microsoft SQL Server – when using READ_COMMITTED_SNAPSHOT, starting with SQL Server 2005[22]
- MySQL when used with InnoDB,[23][24] Falcon,[25] or Archive storage engines.
- NuoDB [26] - Elastic Cloud Database [27]
- Netezza
- ObjectStore
- Oracle database – all versions since Oracle 4[28]
- OrientDB[29]
- PostgreSQL[30]
- Rdb/ELN
- RDM Embedded[31]
- REAL Server
- RethinkDB[32]
- SAP HANA
- ScimoreDB
- sones GraphDB
- Sybase SQL Anywhere

- Sybase IQ
- ThinkSQL
- Tibero – all versions since Tibero 3
- Zope Object Database[33]

Other software with MVCC

- JBoss Cache – v 3.0[34]
- Ehcache – v 1.6.0-beta4[35][36]
- Clojure – language software transactional memory
- pojo-mvcc – a lightweight MVCC implementation written in Java[37]
- JVSTM [38] – Software Transactional memory that implements the concept of Versioned Boxes [39] proposed by João Cachopo and António Rito Silva, members of the Software Engineering Group - INESC-ID [40]

Version control systems

Any version control system that has the internal notion of a version (e.g. Subversion, Git, probably almost any current VCS with the notable exception of CVS) will provide explicit MVCC (you only ever access data but by its version identifier).

Among the VCSes that don't provide MVCC at the repository level, most still work with the notion of a *working copy*, which is a file tree checked out from the repository, edited without using the VCS itself and checked in after edition. This working copy provides MVCC while it is checked out.

Optimistic concurrency control

Optimistic concurrency control (**OCC**) is a concurrency control method applied to transactional systems such as relational database management systems and software transactional memory. OCC assumes that multiple transactions can frequently complete without interfering with each other. While running, transactions use data resources without acquiring locks on those resources. Before committing, each transaction verifies that no other transaction has modified the data it has read. If the check reveals conflicting modifications, the committing transaction rolls back and can be restarted. Optimistic concurrency control was first proposed by H.T. Kung.

OCC is generally used in environments with low data contention. When conflicts are rare, transactions can complete without the expense of managing locks and without having transactions wait for other transactions' locks to clear, leading to higher throughput than other concurrency control methods. However, if contention for data resources is frequent, the cost of repeatedly restarting transactions hurts performance significantly; it is commonly thought that other concurrency control methods have better performance under these conditions. However, locking-based ("pessimistic") methods also can deliver poor performance because locking can drastically limit effective concurrency even when deadlocks are avoided.

OCC phases

More specifically, OCC transactions involve these phases:

- **Begin**: Record a timestamp marking the transaction's beginning.
- **Modify**: Read database values, and tentatively write changes.
- **Validate**: Check whether other transactions have modified data that this transaction has used (read or written). This includes transactions that completed after this transaction's start time, and optionally, transactions that are still active at validation time.
- **Commit/Rollback**: If there is no conflict, make all changes take effect. If there is a conflict, resolve it, typically by aborting the transaction, although other resolution schemes are possible. Care must be taken to avoid a

TOCTTOU bug, particularly if this phase and the previous one are not performed as a single atomic operation.

Web usage

The stateless nature of HTTP makes locking infeasible for web user interfaces. It's common for a user to start editing a record, then leave without following a "cancel" or "logout" link. If locking is used, other users who attempt to edit the same record must wait until the first user's lock times out.

HTTP does provide a form of built-in OCC: The GET method returns an ETag for a resource and subsequent PUTs use the ETag value in the If-Match headers; while the first PUT will succeed, the second will not, as the value in If-Match is based on the first version of the resource.

Some database management systems offer OCC natively - without requiring special application code. For others, the application can implement an OCC layer outside of the database, and avoid waiting or silently overwriting records. In such cases, the form includes a hidden field with the record's original content, a timestamp, a sequence number, or an opaque token. On submit, this is compared against the database. If it differs, the conflict resolution algorithm is invoked.

Examples

- MediaWiki's edit pages use OCC.[1]
- Bugzilla uses OCC; edit conflicts are called "mid-air collisions".
- The Ruby on Rails framework has an API for OCC.
- The Grails framework uses OCC in its default conventions.
- Microsoft's Entity Framework (including Code-First) has built-in support for OCC based on a binary timestamp value.[2]
- Mimer SQL is a DBMS that only implements optimistic concurrency control.
- Google App Engine data store uses OCC.
- The ElasticSearch search engine supports OCC via the version attribute.
- The MonetDB column-oriented database management system's transaction management scheme is based on OCC.
- Most implementations of software transactional memory use optimistic locking.

Autocommit

In the context of data management, **autocommit** is a mode of operation of a database connection. Each individual database interaction (i.e., each SQL statement) submitted through the database connection in autocommit mode will be executed in its own transaction that is implicitly committed. A SQL statement executed in autocommit mode cannot be rolled back.

Autocommit mode, in theory, incurs per-statement transaction overhead, having often undesirable performance or resource utilization impact. Nonetheless, in systems such as Microsoft SQL Server, as well as connection technologies such as ODBC and Microsoft OLE DB, autocommit mode is the default for all statements that change data, in order to ensure that individual statements will conform to the ACID (atomicity-consistency-isolation-durability) properties of transactions.[1]

The alternative to autocommit mode (non-autocommit) means that the SQL client application itself is responsible for issuing transaction initiation (*start transaction*) and termination (*commit* or *rollback*) commands. Non-autocommit mode enables grouping of multiple data manipulation SQL commands into a single atomic transaction.

Transaction log

In the field of databases in computer science, a **transaction log** (also **transaction journal**, **database log**, **binary log** or **audit trail**) is a history of actions executed by a database management system to guarantee ACID properties over crashes or hardware failures. Physically, a log is a file of updates done to the database, stored in stable storage.

If, after a start, the database is found in an inconsistent state or not been shut down properly, the database management system reviews the database logs for uncommitted transactions and rolls back the changes made by these transactions. Additionally, all transactions that are already committed but whose changes were not yet materialized in the database are re-applied. Both are done to ensure atomicity and durability of transactions.

This term is not to be confused with other, human-readable logs that a database management system usually provides.

Anatomy of a general database log

A database log record is made up of:

- *Log Sequence Number*: A unique id for a log record. With LSNs, logs can be recovered in constant time. Most logs' LSNs are assigned in monotonically increasing order, which is useful in recovery algorithms, like ARIES.
- *Prev LSN*: A link to the last log record. This implies database logs are constructed in linked list form.
- *Transaction ID number*: A reference to the database transaction generating the log record.
- *Type*: Describes the type of database log record.
- Information about the actual changes that triggered the log record to be written.

Types of database log records

All log records include the general log attributes above, and also other attributes depending on their type (which is recorded in the *Type* attribute, as above).

- **Update Log Record** notes an update (change) to the database. It includes this extra information:
  - *PageID*: A reference to the Page ID of the modified page.
  - *Length and Offset*: Length in bytes and offset of the page are usually included.
  - *Before and After Images*: Includes the value of the bytes of page before and after the page change. Some databases may have logs which include one or both images.
- **Compensation Log Record** notes the rollback of a particular change to the database. Each correspond with exactly one other Update Log Record (although the corresponding update log record is not typically stored in the Compensation Log Record). It includes this extra information:
  - *undoNextLSN*: This field contains the LSN of the next log record that is to be undone for transaction that wrote the last Update Log.
- **Commit Record** notes a decision to commit a transaction.
- **Abort Record** notes a decision to abort and hence roll back a transaction.
- **Checkpoint Record** notes that a checkpoint has been made. These are used to speed up recovery. They record information that eliminates the need to read a long way into the log's past. This varies according to checkpoint algorithm. If all dirty pages are flushed while creating the checkpoint (as in PostgreSQL), it might contain:
  - *redoLSN*: This is a reference to the first log record that corresponds to a dirty page. i.e. the first update that wasn't flushed at checkpoint time. This is where redo must begin on recovery.
  - *undoLSN*: This is a reference to the oldest log record of the oldest in-progress transaction. This is the oldest log record needed to undo all in-progress transactions.
- **Completion Record** notes that all work has been done for this particular transaction. (It has been fully committed or aborted)

Tables

These tables are maintained in memory, and can be efficiently reconstructed (if not exactly, to an equivalent state) from the log and the database:

- **Transaction Table**: The table contains one entry for each active transaction. This includes Transaction ID and lastLSN, where lastLSN describes the LSN of the most recent log record for the transaction.
- **Dirty Page Table**: The table contains one entry for each dirty page that hasn't been written to disk. The entry contains recLSN, where recLSN is the LSN of the first log record that caused the page to be dirty.
- **Transaction Log**: A DBMS uses a transaction log to keep track of all transactions that updates the database. The information stored in this log is used by DBMS for a recovery requirement triggered by 'Roll Back' statement.

Savepoint

A **savepoint** is a way of implementing subtransactions (also known as nested transactions) within a relational database management system by indicating a point within a transaction that can be "rolled back to" without affecting any work done in the transaction before the savepoint was created. Multiple savepoints can exist within a single transaction. Savepoints are useful for implementing complex error recovery in database applications — if an error occurs in the midst of a multiple-statement transaction, the application may be able to recover from the error (by rolling back to a savepoint) without needing to abort the entire transaction.

A savepoint can be declared by issuing a `SAVEPOINT` *`name`* statement. All changes made after a savepoint has been declared can be undone by issuing a `ROLLBACK TO SAVEPOINT` *`name`* command. Issuing `RELEASE SAVEPOINT` *`name`* will cause the named savepoint to be discarded, but will not otherwise affect anything. Issuing the commands `ROLLBACK` or `COMMIT` will also discard any savepoints created since the start of the main transaction.[1]

Savepoints are supported in some form or other in database systems like PostgreSQL, Oracle, Microsoft SQL Server, MySQL, DB2, SQLite (since 3.6.8), Firebird and Informix (since version 11.50xC3). Savepoints are also defined in the SQL standard.

[1] http://docs.oracle.com/cd/B19306_01/appdev.102/b14261/savepoint_statement.htm

No-force

A **no-force** policy is used in transaction control in database theory. The term no-force refers to the disk pages related to the actual database object being modified.

With a no-force policy, when a transaction commits, the changes made to the actual objects are not required to be written to disk in-place (*forced*).

A record of the changes must still be preserved at commit time to ensure that the transaction is durable. This record is typically written to a sequential transaction log, with the actual changes to the database objects being changes which can be written at a later time.

For frequently changed objects, a no-force policy allows updates to be merged and so reduce the number of write operations to the actual database object. A no-force policy also reduces the seek time required for a commit by having mostly sequential write operations to the transaction log, rather than requiring the disk to seek to many distinct database objects during a commit.

Non-blocking algorithm

In computer science, a **non-blocking algorithm** ensures that threads competing for a shared resource do not have their execution indefinitely postponed by mutual exclusion. A non-blocking algorithm is **lock-free** if there is guaranteed system-wide progress; **wait-free** if there is also guaranteed per-thread progress.

Literature up to the turn of the 21st century used "non-blocking" synonymously with lock-free. However, since 2003, the term has been weakened to only prevent progress-blocking interactions with a preemptive scheduler. In modern usage, therefore, an algorithm is *non-blocking* if the suspension of one or more threads will not stop the potential progress of the remaining threads. They are designed to avoid requiring a critical section. Often, these algorithms allow multiple processes to make progress on a problem without ever blocking each other. For some operations, these algorithms provide an alternative to locking mechanisms.

Motivation

The traditional approach to multi-threaded programming is to use locks to synchronize access to shared resources. Synchronization primitives such as mutexes, semaphores, and critical sections are all mechanisms by which a programmer can ensure that certain sections of code do not execute concurrently, if doing so would corrupt shared memory structures. If one thread attempts to acquire a lock that is already held by another thread, the thread will block until the lock is free.

Blocking a thread is undesirable for many reasons. An obvious reason is that while the thread is blocked, it cannot accomplish anything. If the blocked thread was performing a high-priority or real-time task, it would be highly undesirable to halt its progress. Other problems are less obvious. Certain interactions between locks can lead to error conditions such as deadlock, livelock, and priority inversion. Using locks also involves a trade-off between coarse-grained locking, which can significantly reduce opportunities for parallelism, and fine-grained locking, which requires more careful design, increases locking overhead and is more prone to bugs.

Non-blocking algorithms are also safe for use in interrupt handlers: even though the preempted thread cannot be resumed, progress is still possible without it. In contrast, global data structures protected by mutual exclusion cannot safely be accessed in a handler, as the preempted thread may be the one holding the lock.

Implementation

With few exceptions, non-blocking algorithms use atomic read-modify-write primitives that the hardware must provide, the most notable of which is compare and swap (CAS). Critical sections are almost always implemented using standard interfaces over these primitives. Until recently, all non-blocking algorithms had to be written "natively" with the underlying primitives to achieve acceptable performance. However, the emerging field of software transactional memory promises standard abstractions for writing efficient non-blocking code.

Much research has also been done in providing basic data structures such as stacks, queues, sets, and hash tables. These allow programs to easily exchange data between threads asynchronously.

Additionally, some data structures are weak enough to be implemented without special atomic primitives. These exceptions include:

- single-reader single-writer ring buffer FIFO
- Read-copy-update with a single writer and any number of readers. (The readers are wait-free; the writer is usually lock-free, until it needs to reclaim memory).
- Read-copy-update with multiple writers and any number of readers. (The readers are wait-free; multiple writers generally serialize with a lock and are not obstruction-free).

Wait-freedom

Wait-freedom is the strongest non-blocking guarantee of progress, combining guaranteed system-wide throughput with starvation-freedom. An algorithm is wait-free if every operation has a bound on the number of steps the algorithm will take before the operation completes. This property is critical for real-time systems and is always nice to have as long as the performance cost is not too high.

It was shown in the 1980s that all algorithms can be implemented wait-free, and many transformations from serial code, called *universal constructions*, have been demonstrated. However, the resulting performance does not in general match even naïve blocking designs. Several papers have since improved the performance of universal constructions, but still, their performance is far below blocking designs.

Several papers have investigated the difficulty of creating wait-free algorithms. For example, it has been shown that the widely available atomic *conditional* primitives, CAS and LL/SC, cannot provide starvation-free implementations of many common data structures without memory costs growing linearly in the number of threads. But in practice these lower bounds do not present a real barrier as spending a word per thread in the shared memory is not considered too costly for practical systems.

Until 2011, wait-free algorithms were rare, both in research and in practice. However, in 2011 Kogan and Petrank presented a wait-free queue building on the CAS primitive, generally available on common hardware. Their construction expands the lock-free queue of Michael and Scott, which is an efficient queue often used in practice. A follow-up paper by Kogan and Petrank provided a methodology for making wait-free algorithms fast and used this methodology to make the wait-free queue practically as fast as its lock-free counterpart.

Lock-freedom

Lock-freedom allows individual threads to starve but guarantees system-wide throughput. An algorithm is lock-free if it satisfies that when the program threads are run sufficiently long at least one of the threads makes progress (for some sensible definition of progress). All wait-free algorithms are lock-free.

In general, a lock-free algorithm can run in four phases: completing one's own operation, assisting an obstructing operation, aborting an obstructing operation, and waiting. Completing one's own operation is complicated by the possibility of concurrent assistance and abortion, but is invariably the fastest path to completion.

The decision about when to assist, abort or wait when an obstruction is met is the responsibility of a *contention manager*. This may be very simple (assist higher priority operations, abort lower priority ones), or may be more optimized to achieve better throughput, or lower the latency of prioritized operations.

Correct concurrent assistance is typically the most complex part of a lock-free algorithm, and often very costly to execute: not only does the assisting thread slow down, but thanks to the mechanics of shared memory, the thread being assisted will be slowed, too, if it is still running.

Obstruction-freedom

Obstruction-freedom is possibly the weakest natural non-blocking progress guarantee. An algorithm is obstruction-free if at any point, a single thread executed in isolation (i.e., with all obstructing threads suspended) for a bounded number of steps will complete its operation. All lock-free algorithms are obstruction-free.

Obstruction-freedom demands only that any partially completed operation can be aborted and the changes made rolled back. Dropping concurrent assistance can often result in much simpler algorithms that are easier to validate. Preventing the system from continually live-locking is the task of a contention manager.

Obstruction-freedom is also called optimistic concurrency control.

Some obstruction-free algorithms use a pair of "consistency markers" in the data structure. Processes reading the data structure first read one consistency marker, then read the relevant data into an internal buffer, then read the other

marker, and then compare the markers. The data is consistent if the two markers are identical. Markers may be non-identical when the read is interrupted by another process updating the data structure. In such a case, the process discards the data in the internal buffer and tries again.

Data recovery

Data Recovery is the process of salvaging data from damaged, failed, corrupted, or inaccessible secondary storage media when it cannot be accessed normally. Often the data are being salvaged from storage media such as internal or external hard disk drives, solid-state drives (SSD), USB flash drive, storage tapes, CDs, DVDs, RAID, and other electronics. Recovery may be required due to physical damage to the storage device or logical damage to the file system that prevents it from being mounted by the host operating system (OS).

The most common "Data Recovery" scenario involves an operating system failure (typically on a single-disk, single-partition, single-OS system), in which case the goal is simply to copy all wanted files to another disk. This can be easily accomplished using a Live CD, many of which provide a means to mount the system drive and backup disks or removable media, and to move the files from the system disk to the backup media with a file manager or optical disc authoring software. Such cases can often be mitigated by disk partitioning and consistently storing valuable data files (or copies of them) on a different partition from the replaceable OS system files.

Another scenario involves a disk-level failure, such as a compromised file system or disk partition, or a hard disk failure. In any of these cases, the data cannot be easily read. Depending on the situation, solutions involve repairing the file system, partition table or master boot record, or hard disk recovery techniques ranging from software-based recovery of corrupted data, hardware-software based recovery of damaged service areas (also known as the hard drive's "firmware"), to hardware replacement on a physically damaged disk. If hard disk recovery is necessary, the disk itself has typically failed permanently, and the focus is rather on a one-time recovery, salvaging whatever data can be read.

In a third scenario, files have been "deleted" from a storage medium. Typically, the contents of deleted files are not removed immediately from the drive; instead, references to them in the directory structure are removed, and the space they occupy is made available for later overwriting. In the meantime, the original file contents remain, often in a number of disconnected fragments, and may be recoverable.

The term "data recovery" is also used in the context of forensic applications or espionage, where data which has been encrypted or hidden, rather than damaged, is recovered.

Physical damage

A wide variety of failures can cause physical damage to storage media. CD-ROMs can have their metallic substrate or dye layer scratched off; hard disks can suffer any of several mechanical failures, such as head crashes and failed motors; tapes can simply break. Physical damage always causes at least some data loss, and in many cases the logical structures of the file system are damaged as well. Any logical damage must be dealt with before files can be salvaged from the failed media.

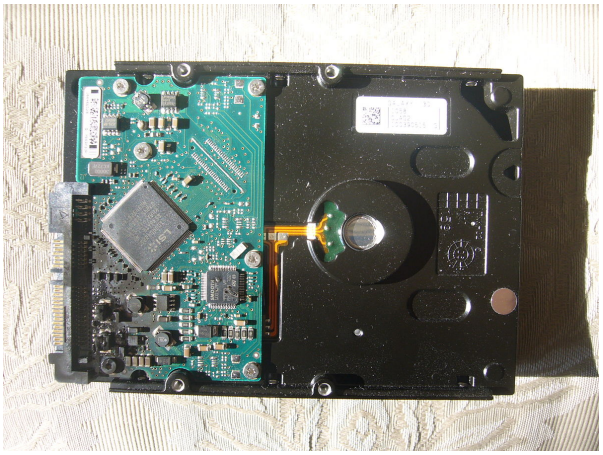
Most physical damage cannot be repaired by end users. For example, opening a hard disk drive in a normal environment can allow airborne dust to settle on the platter and become caught between the platter and the read/write head, causing new head crashes that further damage the platter and thus compromise the recovery process. Furthermore, end users generally do not have the hardware or technical expertise required to make these repairs. Consequently, data recovery companies are often employed to salvage important data with the more reputable ones

using class 100, dust- & static-free cleanrooms.

Recovery techniques

Recovering data from physically damaged hardware can involve multiple techniques. Some damage can be repaired by replacing parts in the hard disk. This alone may make the disk usable, but there may still be logical damage. A specialized disk-imaging procedure is used to recover every readable bit from the surface. Once this image is acquired and saved on a reliable medium, the image can be safely analyzed for logical damage and will possibly allow much of the original file system to be reconstructed.

Hardware repair



Media that has suffered a catastrophic electronic failure requires data recovery in order to salvage its contents.

A common misconception is that a damaged printed circuit board (PCB) may be replaced during recovery procedures by an identical PCB from a healthy drive. While this may work in rare circumstances on hard drives manufactured before 2003, it will not work on newer hard drives. Each hard drive has what is called a System Area. This portion of the drive, which is not accessible to the end user, contains adaptive data that helps the drive operate within normal parameters. One function of the System Area is to log defective sectors within the drive; essentially telling the hard drive where it can and cannot write data. The sector lists are also stored on various chips attached to the PCB, and they are unique to each hard drive. If the data on the PCB does not match what is stored on the platter, then the drive will not calibrate properly.[1] In most cases the hard drive heads will click, because they are unable to find the data matching what is stored on the PCB.

Logical damage

The term "logical damage" refers to situations in which the error is not a problem in the hardware and requires software-level solutions.

Corrupt partitions and filesystems, media errors

In some cases, data on a hard drive can be unreadable due to damage to the partition table or filesystem, or to (intermittent) media errors. In the majority of these cases, at least a portion of the original data can be recovered by repairing the damaged partition table or filesystem using specialized data recovery software such as Testdisk; software like dd rescue can image media despite intermittent errors, and image raw data when there is partition table or filesystem damage. This type of data recovery can be performed by people without expertise in drive hardware, as it requires no special physical equipment or access to platters. Sometimes data can be recovered using relatively simple methods and tools; more serious cases can require expert intervention, particularly if parts of files are irrecoverable. Data carving is the recovery of parts of damaged files using knowledge of their structure.

Result of a failed data recovery from a hard disk drive.

Overwritten data

When data has been physically overwritten on a hard disk drive it is generally assumed that the previous data is no longer possible to recover. In 1996, Peter Gutmann, a computer scientist, presented a paper that suggested overwritten data could be recovered through the use of magnetic force microscope.[2] In 2001, he presented another paper on a similar topic.[3] Substantial criticism has followed, primarily dealing with the lack of any concrete examples of significant amounts of overwritten data being recovered. Although Gutmann's theory may be correct, there is no practical evidence that overwritten data can be recovered, while research has shown to support that overwritten data cannot be recovered.Wikipedia:Citing sources To guard against this type of data recovery, Gutmann and Colin Plumb designed a method of irreversibly scrubbing data, known as the Gutmann method and used by several disk-scrubbing software packages.

Solid-state drives (SSD) overwrite data differently from hard disk drives (HDD) which makes at least some of their data easier to recover. Most SSDs use flash memory to store data in pages and blocks, referenced by logical block addresses (LBA) which are managed by the flash translation layer (FTL). When the FTL modifies a sector it writes the new data to another location and updates the map so the new data appears at the target LBA. This leaves the pre-modification data in place, with possibly many generations, and recoverable by data recovery software.

Remote data recovery

It is not always necessary for experts to have physical access to the damaged drive; where data can be recovered by software techniques, they can often be used remotely, with an expert using a computer at another location linked by an Internet or other connection to equipment at the fault site.

Remote recovery requires a stable connection of adequate bandwidth. However, it is not applicable where access to the hardware is required, as for cases of physical damage.

Four phases

It is important to understand the four phases of data recovery. Each phase stands for different level and range of data recovery capabilities, each phase requires different hdd repair tools and data recovery tools to work with and each phase must be treated properly to make sure the maximum data is finally to be recovered.

- Phase 1: Repair the hard drive
- Phase 2: Image the drive to a new drive.
- Phase 3: Logical recovery of files, partition, MBR, and MFT.
- Phase 4: Repair the damaged files that were retrieved.

Point-in-time recovery

Point-in-time recovery (PITR) in the context of computers is a system whereby a set of data or a particular setting can be restored or recovered from a time in the past. An example of this is Windows XP's feature of being able to restore operating system settings from a past date (before data corruption occurred, for example), or PostgreSQL's feature of being able to view a database table and its data as it was at a particular date in the past. Also, Time Machine for Mac OS X is an example of Point-in-time recovery.

A database with the PITR feature can be restored or recovered to the state that it had at any time since PITR logging was started for that database.

The PostgreSQL database implements Continuous Archiving and Point-In-Time Recovery [1]. In PostgreSQL, Write-ahead logging (WAL) must be enabled for a particular database, in order for PITR to be used on that database; any time after WAL is enabled for a database, that database may be restored to any later time.

Redo log

In the Oracle RDBMS environment, **redo logs** comprise files in a proprietary format which log a history of all changes made to the database. Each redo log file consists of redo records. A redo record, also called a redo entry, holds a group of Change vectors, each of which describes or represents a change made to a single block in the database.

For example, if a user `UPDATE`s a salary-value in a table containing employee-related data, the DBMS generates a redo record containing change-vectors that describe changes to the data segment block for the table. And if the user then `COMMIT`s the update, Oracle generates another redo record and assigns the change a "system change number" (SCN).

Whenever something changes in a datafile, Oracle records the change in the redo log. The name *redo log* indicates its purpose: When the database crashes, the RDBMS can redo (re-process) all changes on datafiles which will take the database data back to the state it was when the last redo record was written. DBAs use the views `V$LOG`, `V$LOGFILE`, `V$LOG_HISTORY` and `V$THREAD` to find information about the redo log of the database. Each redo log file belongs to exactly one group (of which at least two must exist). Exactly one of these groups is the CURRENT group (can be queried using the column status of v$log). Oracle uses that current group to write the redo log entries. When the group is full, a **log switch** occurs, making another group the current one. Each log switch causes checkpoint, however, the converse is not true: a checkpoint does not cause a redo log switch. One can also manually cause a redo-log switch using the `ALTER SYSTEM SWITCH LOGFILE` command.

Usage

Before a user receives a "Commit complete" message, the system must first successfully write the new or changed data to a redo log file..

All changes included in the transaction are first written into the log buffer. Using memory in this way for the initial capture aims to reduce disk IO. Of course, when a transaction commits, the redo log buffer must be flushed to disk, because otherwise the recovery for that commit could not be guaranteed. It is LGWR (Log Writer) that does that flushing.

If a database crashes, the recovery process has to apply all transactions, both uncommitted as well as committed, to the data-files on disk, using the information in the redo log files. Oracle must re-do all redo-log transactions that have both a begin and a commit entry, and it must undo all transactions that have a begin entry but no commit entry. (Re-doing a transaction in this context simply means applying the information in the redo log files to the database; the system does not re-run the transaction itself.) The system thus re-creates committed transactions by applying the “after image” records in the redo log files to the database, and undoes incomplete transactions by using the “before image” records in the undo tablespace.

Change data capture can read the redo logs.

Implications

Given the verbosity of the logging, Oracle Corporation provides methods for archiving redo logs (archive-logs), and this in turn can feed into data backup solutions and standby databases.

The existence of a detailed series of individually logged transactions and actions provides the basis of several data-management enhancements such as Oracle Flashback, log-mining and point-in-time recovery.

For database tuning purposes, efficiently coping with redo logs requires plentiful and fast-access disk.

Extreme transaction processing

In Computer Science, **Extreme Transaction Processing** (XTP) is an exceptionally demanding form of transaction processing. Transactions of most high-end (more than 10,000 concurrent accesses or 500 transaction per second) or ultra-high-end (more than 100,000 concurrent accesses or 5,000 transaction per second) requirements or more would require this form of processing.[1]

Definition

Gartner defines XTP as an application style aimed at supporting the design, development, deployment, management and maintenance of distributed TP applications characterized by exceptionally demanding performance, scalability, availability, security, manageability and dependability requirements.[2][3][4]

XTP applications focuses on delivering high and consistent performance in a linearly scalable and highly available system.[5]

Major Solutions

Major solutions promising XTP are :-

1. Extreme Scale
2. Oracle Coherence
3. Red Hat's JBoss Data Grid [6], based on the open source Infinispan [7] project
4. GigaSpaces [8]
5. GemFire [9]

In-database processing

In-database processing, sometimes referred to as in-database analytics, refers to the integration of data analytics into data warehousing functionality. Today, many large databases, such as those used for credit card fraud detection and investment bank risk management, use this technology because it provides significant performance improvements over traditional methods.

History

Traditional approaches to data analysis require data to be moved out of the database into a separate analytics environment for processing, and then back to the database. (SPSS from IBM are examples of tools that still do this today). Doing the analysis in the database, where the data resides, eliminates the costs, time and security issues associated with the old approach by doing the processing in the data warehouse itself.

Though in-database capabilities were first commercially offered in the mid-1990s, as object-related database systems from vendors including IBM, Illustra/Informix (now IBM) and Oracle, the technology did not begin to catch on until the mid-2000s.

At that point, the need for in-database processing had become more pressing as the amount of data available to collect and analyze continues to grow exponentially (due largely to the rise of the Internet), from megabytes to gigabytes, terabytes and petabytes. This “big data” is one of the primary reasons it has become important to collect, process and analyze data efficiently and accurately.

Also, the speed of business has accelerated to the point where a performance gain of nanoseconds can make a difference in some industries. Additionally, as more people and industries use data to answer important questions, the questions they ask become more complex, demanding more sophisticated tools and more precise results.

All of these factors in combination have created the need for in-database processing. The introduction of the column-oriented database, specifically designed for analytics, data warehousing and reporting, has helped make the technology possible.

Types

There are three main types of in-database processing: translating a model into SQL code, loading C or C++ libraries into the database process space as a built-in user-defined function (UDF), and out-of-process libraries typically written in C, C++ or JAVA and registering them in the database as a built-in UDFs in a SQL statement.

Translating Models into SQL Code

In this type of in-database processing, a predictive model is converted from its source language into SQL that can run in the database usually in a stored procedure. Many analytic model-building tools have the ability to export their models in either in SQL or PMML (Predictive Modeling Markup Language). Once the SQL is loaded into a stored procedure, values can be passed in through parameters and the model is executed natively in the database. Tools that can use this approach include SAS, R and KXEN.

Loading C or C++ Libraries into the database process space

With C or C++ UDF libraries that run in process, the functions are typically registered as built-in functions within the database server and called like any other built-in function in a SQL statement. Running in process allows the function to have full access to the database server’s memory, parallelism and processing management capabilities. Because of this, the functions must be well-behaved so as not to negatively impact the database or the engine. This type of UDF gives the highest performance out of any method for OLAP, mathematical, statistical, univariate

distributions and data mining algorithms.

Out-of-Process

Out-of-Process UDFs are typically written in C, C++ or JAVA. By running out of process, they do not run the same risk to the database or the engine as they run in their own process space with their own resources. Here, they wouldn't be expected to have the same performance as an in-process UDF. They are still typically registered in the database engine and called through standard SQL, usually in a stored procedure. Out-of-process UDFs are a safe way to extend the capabilities of a database server and are an ideal way to add custom data mining libraries.

Uses

In-database processing makes data analysis more accessible and relevant for high-throughput, real-time applications including fraud detection, credit scoring, risk management, transaction processing, pricing and margin analysis, usage-based micro-segmenting, behavioral ad targeting and recommendation engines, such as those used by customer service organizations to determine next-best actions.

Vendors

In-database processing is performed and promoted as a feature by many of the major data warehousing vendors, including Teradata (and acquired Aster Data Systems), IBM Netezza, EMC Greenplum, Sybase, ParAccel, SAS, and EXASOL. Fuzzy Logix offers libraries of in-database models used for mathematical, statistical, data mining, simulation and classification modelling as well as financial models for equity, fixed income, interest rate and portfolio optimization.

Related Technologies

In-database processing is one of several technologies focused on improving data warehousing performance. Others include parallel computing, shared everything architectures, shared nothing architectures and massive parallel processing. It is an important step towards improving predictive analytics capabilities.[1]

Locks with ordered sharing

In databases and transaction processing the term **Locks with ordered sharing** comprises several variants of the *Two phase locking* (2PL) concurrency control protocol generated by changing the blocking semantics of locks upon conflicts. One variant is identical to Strict commitment ordering (SCO).

Nested transaction

A **nested transaction** is a database transaction that is started by an instruction within the scope of an already started transaction.

Nested transactions are implemented differently in different databases. However, they have in common that the changes are not made visible to any unrelated transactions until the outermost transaction has committed. This means that a commit in an inner transaction does not necessary persist updates to the database.

In some databases, changes made by the nested transaction are not seen by the 'host' transaction until the nested transaction is committed. According to some,Wikipedia:Avoid weasel words this follows from the isolation property of transactions.

The capability to handle nested transactions properly is a prerequisite for true component based application architectures. In a component-based encapsulated architecture, nested transactions can occur without the programmer knowing it. A component function may or may not contain a database transaction (this is the encapsulated secret of the component. See Information hiding). If a call to such a component function is made inside a BEGIN - COMMIT bracket, nested transactions occur. Since popular databases like MySQL do not allow nesting BEGIN - COMMIT brackets, a framework or a transaction monitor is needed to handle this. When we speak about nested transactions, it should be made clear that this feature is DBMS dependent and is not available for all databases.

Theory for nested transactions is similar to the theory for flat transactions, and was introduced in the following paper:

- Resende, R.F.; El Abbadi, A. (1994-05-25). "On the serializability theorem for nested transactions". *Information Processing Letters* **50** (4): 177–183. doi:10.1016/0020-0190(94)00033-6 [1].

The banking industry usually processes financial transactions using **Open Nested Transactions**, which is a looser variant of the nested transaction model that provides higher performance while accepting the accompanying trade-offs of inconsistency. Open Nested Transactions are discussed in the following paper:

- Weikum, Gerhard; Hans-J. Schek (1992). "Concepts and Applications of Multilevel Transactions and Open Nested Transactions" [2]. *Database Transaction Models for Advanced Applications* (Morgan Kaufmann): 515–553. ISBN 1-55860-214-3. Retrieved 2007-11-13.

Transaction processing system

Transaction processing is a style of computing that divides work into individual, indivisible operations, called transactions. A **transaction processing system (TPS)** or **transaction server** is a software system, or software/hardware combination, that supports transaction processing.

History

The first transaction processing systems was American Airlines SABRE system[*citation needed*], which became operational in 1960. Designed to process up to 83,000 transactions a day, the system ran on two IBM 7090 computers. SABRE was migrated to IBM System/360 computers in 1972, and became an IBM product first as *Airline control Program (ACP)* and later as *Transaction Processing Facility (TPF)*. In addition to airlines TPF is used by large banks, credit card companies, and hotel chains.

The Hewlett-Packard NonStop system (formerly Tandem NonStop) was a hardware and software system designed for *Online Transaction Processing (OLTP)* introduced in 1976. The systems were designed for transaction processing and provided an extreme level of availability and data integrity.

List of transaction processing systems

- IBM Transaction Processing Facility (TPF) - 1960. Unlike most other transaction processing systems TPF is a dedicated operating system for transaction processing on IBM System z mainframes. Originally Airline Control Program (ACP).
- IBM Information Management System (IMS) - 1966. A joint hierarchical database and information management system with extensive transaction processing capabilities. Runs on OS/360 and successors.
- IBM Customer Information Control System (CICS) - 1969. A transaction manager designed for rapid, high-volume online processing, CICS originally used standard system datasets, but now has a connection to IBM's DB/2 relational database system. Runs on OS/360 and successors and DOS/360 and successors, IBM AIX, VM, and OS/2. Non-mainframe versions are called *TXSeries*.
- Tuxedo - 1980s. Transactions for Unix, Extended for Distributed Operations developed by AT&T Corporation, now owned by Oracle Corporation. Tuxedo is a cross-platform TPS.
- UNIVAC Transaction Interface Package (TIP) - 1970s. A transaction processing monitor for UNIVAC 1100/2200 series computers.
- Burroughs Corporation supported transaction processing capabilities in its MCP operating systems. As of 2012 UNISYS ClearPath Enterprise Servers include Transaction Server, "an extremely flexible, high-performance message and application control system."
- Digital Equipment Corporation (DEC) Application Control and Management System (ACMS) - 1985. "Provides an environment for creating and controlling online transaction processing (OLTP) applications on the VMS operating system." Runs on VAX/VMS systems.

- Digital Equipment Corporation (DEC) Message Control System (MCS-10) for PDP-10 TOPS-10 systems.
- Honeywell Multics Transaction Processing. Feature (TP) - 1979.
- Transaction Management eXecutive (TMX) was NCR Corporation's proprietary transaction processing system running on NCR Tower 5000-series systems. This system was used mainly by financial institutions in the 1980s and 1990s.
- Hewlett-Packard NonStop system - 1976. NonStop is an integrated hardware and software system specifically designed for transaction processing. Originally from Tandem Computers.
- Transarc Encina - 1991. Transarc was purchased by IBM in 1994. Encina was discontinued as a product and folded into IBM's *TXSeries*. Encina support was discontinued in 2006.

Processing types

Transaction processing is distinct from other computer processing models — batch processing, time-sharing, and real-time processing.

Batch processing

Batch processing is execution of a series of programs (*jobs*) on a computer without manual intervention. Several transactions, called a *batch* are collected and processed at the same time. The results of each transaction are not immediately available when the transaction is being entered;[1] there is a time delay.

Real-time processing

"Real time systems attempt to guarantee an appropriate response to a stimulus or request quickly enough to affect the conditions that caused the stimulus." Each transaction in real-time processing is unique; it is not part of a group of transactions.

Time-sharing

Time sharing is the sharing of a computer system among multiple users, usually giving each user the illusion that they have exclusive control of the system. The users may be working on the same project or different projects, but there are usually few restrictions on the type of work each user is doing.

Transaction processing

Transaction processing systems also attempt to provide predictable response times to requests, although this is not as critical as for real-time systems. Rather than allowing the user to run arbitrary programs as time-sharing, transaction processing allows only predefined, structured transactions. Each transaction is usually short duration and the processing activity for each transaction is programmed in advance.

Transaction processing system features

The following features are considered important in evaluating transaction processing systems.

Performance

Fast performance with a rapid response time is critical. Transaction processing systems are usually measured by the number of transactions they can process in a given period of time.

Continuous availability

The system must be available during the time period when the users are entering transactions. Many organizations rely heavily on their TPS; a breakdown will disrupt operations or even stop the business.

Data integrity

The system must be able to handle hardware or software problems without corrupting data. Multiple users must be protected from attempting to change the same piece of data at the same time, for example two operators cannot sell the same seat on an airplane.

Ease of use

Often users of transaction processing systems are casual users. The system should be simple for them to understand, protect them from data-entry errors as much as possible, and allow them to easily correct their errors.

Modular growth

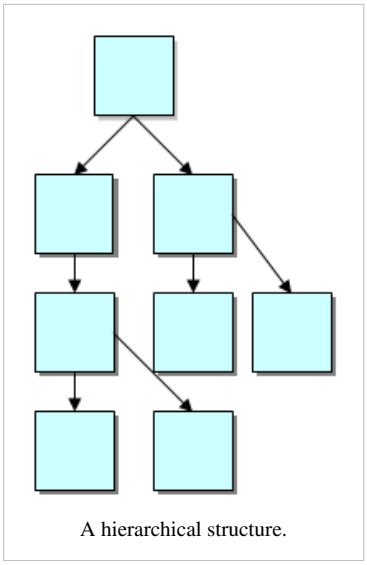
The system should be capable of growth at incremental costs, rather than requiring a complete replacement. It should be possible to add, replace, or update hardware and software components without shutting down the system.

Databases and files

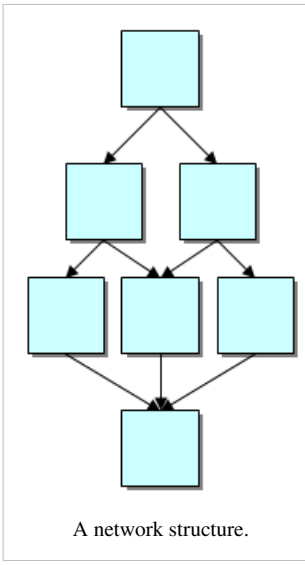
A database is an organized collection of data. Databases offer fast retrieval times for non-structured requests as in a typical transaction processing application.

Databases may be constructed using hierarchical, network, or relational structures.

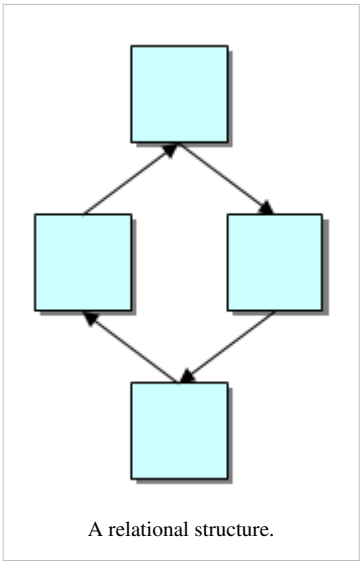
- Hierarchical structure: organizes data in a series of levels. Its top to bottom like structure consists of nodes and branches; each child node has branches and is only linked to one higher level parent node.
- Network structure: network structures also organizes data using nodes and branches. But, unlike hierarchical, each child node can be linked to multiple, higher parent nodes.
- Relational structure: a relational database organizes its data in a series of related tables. This gives flexibility as relationships between the tables are built.



A hierarchical structure.



A network structure.



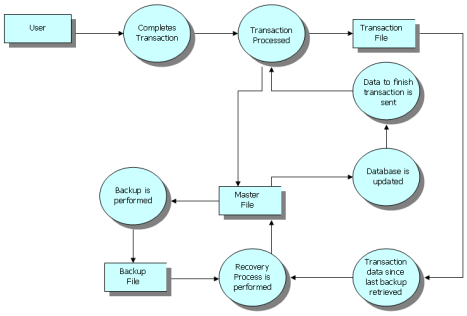
A relational structure.

The following features are desirable in a database system used in transaction processing systems:

- **Good data placement**: The database should be designed to access patterns of data from many simultaneous users.
- **Short transactions**: Short transactions enables quick processing. This avoids concurrency and paces the systems.
- **Real-time backup**: Backup should be scheduled between low times of activity to prevent lag of the server.
- **High normalization**: This lowers redundant information to increase the speed and improve concurrency, this also improves backups.
- **Archiving of historical data**: Uncommonly used data are moved into other databases or backed up tables. This keeps tables small and also improves backup times.
- **Good hardware configuration**: Hardware must be able to handle many users and provide quick response times.

Backup procedures

Since business organizations have become very dependent on TPSs, a breakdown in their TPS may stop the business' regular routines and thus stopping its operation for a certain amount of time. In order to prevent data loss and minimize disruptions when a TPS breaks down a well-designed backup and recovery procedure is put into use. The recovery process can rebuild the system when it goes down.



A Dataflow Diagram of backup and recovery procedures.

Recovery process

A TPS may fail for many reasons. These reasons could include a system failure, human errors, hardware failure, incorrect or invalid data, computer viruses, software application errors or natural or man-made disasters. As it's not possible to prevent all TPS failures, a TPS must be able to cope with failures. The TPS must be able to detect and correct errors when they occur. A TPS will go through a recovery of the database to cope when the system fails, it involves the backup, journal, checkpoint, and recovery manager:

- Journal: A journal maintains an audit trail of transactions and database changes. Transaction logs and Database change logs are used, a transaction log records all the essential data for each transactions, including data values, time of transaction and terminal number. A database change log contains before and after copies of records that

have been modified by transactions.

- Checkpoint: *The purpose of checkpointing* is to provide a snapshot of the data within the database. A checkpoint, in general, is any identifier or other reference that identifies the state of the database at a point in time. Modifications to database pages are performed in memory and are not necessarily written to disk after every update. Therefore, periodically, the database system must perform a checkpoint to write these updates which are held in-memory to the storage disk. Writing these updates to storage disk creates a point in time in which the database system can apply changes contained in a transaction log during recovery after an unexpected shut down or crash of the database system.

If a checkpoint is interrupted and a recovery is required, then the database system must start recovery from a previous successful checkpoint. *Checkpointing can be either transaction-consistent or non-transaction-consistent* (called also fuzzy checkpointing). *Transaction-consistent checkpointing* produces a persistent database image that is sufficient to recover the database to the state that was externally perceived at the moment of starting the checkpointing. *A non-transaction-consistent checkpointing* results in a persistent database image that is insufficient to perform a recovery of the database state. To perform the database recovery, additional information is needed, typically contained in transaction logs. Transaction consistent checkpointing refers to a consistent database, which doesn't necessarily include all the latest committed transactions, but all modifications made by transactions, that were committed at the time checkpoint creation was started, are fully present. A non-consistent transaction refers to a checkpoint which is not necessarily a consistent database, and can't be recovered to one without all log records generated for open transactions included in the checkpoint. Depending on the type of database management system implemented *a checkpoint may incorporate indexes or storage pages (user data), indexes and storage pages*. If no indexes are incorporated into the checkpoint, indexes must be created when the database is restored from the checkpoint image.

- Recovery Manager: A recovery manager is a program which restores the database to a correct condition which can restart the transaction processing.

Depending on how the system failed, there can be two different recovery procedures used. Generally, the procedures involves restoring data that has been collected from a backup device and then running the transaction processing again. Two types of recovery are *backward recovery* and *forward recovery*:

- Backward recovery: used to undo unwanted changes to the database. It reverses the changes made by transactions which have been aborted.
- Forward recovery: it starts with a backup copy of the database. The transaction will then reprocess according to the transaction journal that occurred between the time the backup was made and the present time.

Types of back-up procedures

There are two main types of Back-up Procedures: **Grandfather-father-son** and **Partial backups**:

Grandfather-father-son

This procedure refers to at least three generations of backup master files. thus, the most recent backup is the son, the oldest backup is the grandfather. It's commonly used for a *batch transaction processing system* with a magnetic tape. If the system fails during a batch run, the master file is recreated by using the son backup and then restarting the batch. However if the son backup fails, is corrupted or destroyed, then the previous generation of backup (the father) is used. Likewise, if that fails, then the generation of backup previous to the father (i.e. the grandfather) is required. Of course the older the generation, the more the data may be out of date. Organizations can have many generations of backup.

Partial backups

This only occurs when parts of the master file are backed up. The master file is usually backed up to magnetic tape at regular times, this could be daily, weekly or monthly. Completed transactions since the last backup are stored separately and are called **journals**, or **journal files**. The master file can be recreated from the journal files on the backup tape if the system is to fail.

Updating in a batch

This is used when transactions are recorded on paper (such as bills and invoices) or when it's being stored on a magnetic tape. Transactions will be collected and updated as a batch when it's convenient or economical to process them. Historically, this was the most common method as the information technology did not exist to allow real-time processing.

The two stages in batch processing are:

- Collecting and storage of the transaction data into a transaction file - this involves sorting the data into sequential order.
- Processing the data by updating the master file - which can be difficult, this may involve data additions, updates and deletions which may require being performed in a certain order. If an error occurs, then the entire batch fails.

Updating in batch requires sequential access - since it uses a magnetic tape this is the only way to access data. A batch will start at the beginning of the tape, then reading it from the order it was stored; it's very time-consuming to locate specific transactions.

The information technology used includes a secondary storage medium which can store large quantities of data inexpensively (thus the common choice of a magnetic tape). The software used to collect data does not have to be online - it doesn't even need a user interface.

Updating in real-time

This is the immediate processing of data. It provides instant confirmation of a transaction. It may involve a large number of users who are simultaneously performing transactions which change data. Because of advances in technology (such as the increase in the speed of data transmission and larger bandwidth), real-time updating is possible.

Steps in a real-time update involve the sending of a transaction data to an online database in a master file. The person providing information is usually able to help with error correction and receives confirmation of the transaction completion.

Updating in real-time uses direct access of data. This occurs when data are accessed without accessing previous data items. The storage device stores data in a particular location based on a mathematical procedure. This will then be calculated to find an approximate location of the data. If data are not found at this location, it will search through successive locations until it's found.

The information technology used could be a secondary storage medium that can store large amounts of data and provide quick access (thus the common choice of a magnetic disk).

Processing types

Transaction processing is distinct from other computer processing models — batch processing, time-sharing, and real-time processing.

Batch processing

Batch processing is execution of a series of programs (*jobs*) on a computer without manual intervention. Several transactions, called a *batch* are collected and processed at the same time. The results of each transaction are not immediately available when the transaction is being entered;[1] there is a time delay.

Real-time processing

"Real time systems attempt to guarantee an appropriate response to a stimulus or request quickly enough to affect the conditions that caused the stimulus." Each transaction in real-time processing is unique; it is not part of a group of transactions.

Time-sharing

Time sharing is the sharing of a computer system among multiple users, usually giving each user the illusion that they have exclusive control of the system. The users may be working on the same project or different projects, but there are usually few restrictions on the type of work each user is doing.

Transaction processing

Transaction processing systems also attempt to provide predictable response times to requests, although this is not as critical as for real-time systems. Rather than allowing the user to run arbitrary programs as time-sharing, transaction processing allows only predefined, structured transactions. Each transaction is usually short duration and the processing activity for each transaction is programmed in advance.

Transaction processing system features

The following features are considered important in evaluating transaction processing systems.

Performance

Fast performance with a rapid response time is critical. Transaction processing systems are usually measured by the number of transactions they can process in a given period of time.

Continuous availability

The system must be available during the time period when the users are entering transactions. Many organizations rely heavily on their TPS; a breakdown will disrupt operations or even stop the business.

Data integrity

The system must be able to handle hardware or software problems without corrupting data. Multiple users must be protected from attempting to change the same piece of data at the same time, for example two operators cannot sell the same seat on an airplane.

Ease of use

Often users of transaction processing systems are casual users. The system should be simple for them to understand, protect them from data-entry errors as much as possible, and allow them to easily correct their errors.

Modular growth

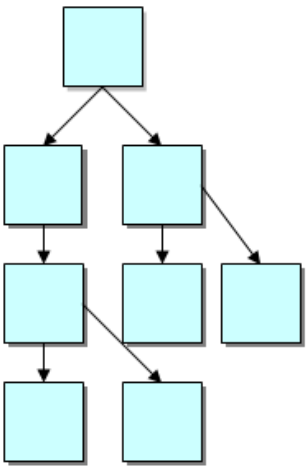
The system should be capable of growth at incremental costs, rather than requiring a complete replacement. It should be possible to add, replace, or update hardware and software components without shutting down the system.

Databases and files

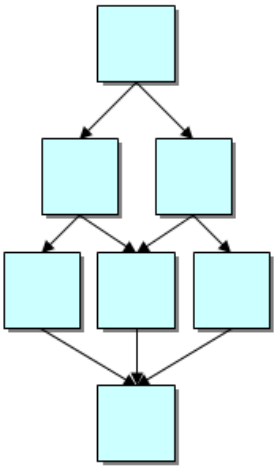
A database is an organized collection of data. Databases offer fast retrieval times for non-structured requests as in a typical transaction processing application.

Databases may be constructed using hierarchical, network, or relational structures.

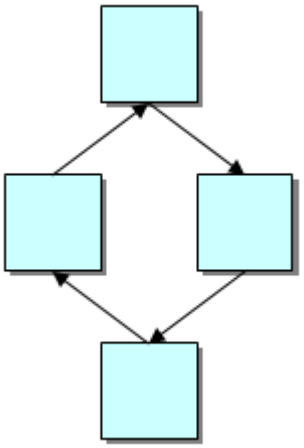
- Hierarchical structure: organizes data in a series of levels. Its top to bottom like structure consists of nodes and branches; each child node has branches and is only linked to one higher level parent node.
- Network structure: network structures also organizes data using nodes and branches. But, unlike hierarchical, each child node can be linked to multiple, higher parent nodes.
- Relational structure: a relational database organizes its data in a series of related tables. This gives flexibility as relationships between the tables are built.



A hierarchical structure.



A network structure.



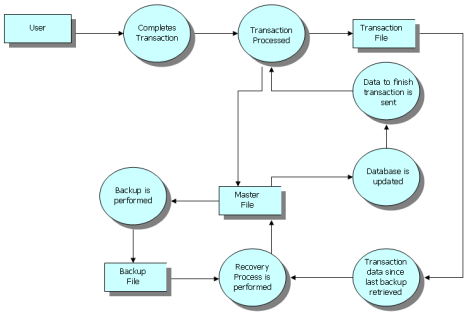
A relational structure.

The following features are desirable in a database system used in transaction processing systems:

- **Good data placement**: The database should be designed to access patterns of data from many simultaneous users.
- **Short transactions**: Short transactions enables quick processing. This avoids concurrency and paces the systems.
- **Real-time backup**: Backup should be scheduled between low times of activity to prevent lag of the server.
- **High normalization**: This lowers redundant information to increase the speed and improve concurrency, this also improves backups.
- **Archiving of historical data**: Uncommonly used data are moved into other databases or backed up tables. This keeps tables small and also improves backup times.
- **Good hardware configuration**: Hardware must be able to handle many users and provide quick response times.

Backup procedures

Since business organizations have become very dependent on TPSs, a breakdown in their TPS may stop the business' regular routines and thus stopping its operation for a certain amount of time. In order to prevent data loss and minimize disruptions when a TPS breaks down a well-designed backup and recovery procedure is put into use. The recovery process can rebuild the system when it goes down.



A Dataflow Diagram of backup and recovery procedures.

Recovery process

A TPS may fail for many reasons. These reasons could include a system failure, human errors, hardware failure, incorrect or invalid data, computer viruses, software application errors or natural or man-made disasters. As it's not possible to prevent all TPS failures, a TPS must be able to cope with failures. The TPS must be able to detect and correct errors when they occur. A TPS will go through a recovery of the database to cope when the system fails, it involves the backup, journal, checkpoint, and recovery manager:

- Journal: A journal maintains an audit trail of transactions and database changes. Transaction logs and Database change logs are used, a transaction log records all the essential data for each transactions, including data values, time of transaction and terminal number. A database change log contains before and after copies of records that

have been modified by transactions.

- Checkpoint: *The purpose of checkpointing* is to provide a snapshot of the data within the database. A checkpoint, in general, is any identifier or other reference that identifies the state of the database at a point in time. Modifications to database pages are performed in memory and are not necessarily written to disk after every update. Therefore, periodically, the database system must perform a checkpoint to write these updates which are held in-memory to the storage disk. Writing these updates to storage disk creates a point in time in which the database system can apply changes contained in a transaction log during recovery after an unexpected shut down or crash of the database system.

If a checkpoint is interrupted and a recovery is required, then the database system must start recovery from a previous successful checkpoint. *Checkpointing can be either transaction-consistent or non-transaction-consistent* (called also fuzzy checkpointing). *Transaction-consistent checkpointing* produces a persistent database image that is sufficient to recover the database to the state that was externally perceived at the moment of starting the checkpointing. *A non-transaction-consistent checkpointing* results in a persistent database image that is insufficient to perform a recovery of the database state. To perform the database recovery, additional information is needed, typically contained in transaction logs. Transaction consistent checkpointing refers to a consistent database, which doesn't necessarily include all the latest committed transactions, but all modifications made by transactions, that were committed at the time checkpoint creation was started, are fully present. A non-consistent transaction refers to a checkpoint which is not necessarily a consistent database, and can't be recovered to one without all log records generated for open transactions included in the checkpoint. Depending on the type of database management system implemented *a checkpoint may incorporate indexes or storage pages (user data), indexes and storage pages*. If no indexes are incorporated into the checkpoint, indexes must be created when the database is restored from the checkpoint image.

- Recovery Manager: A recovery manager is a program which restores the database to a correct condition which can restart the transaction processing.

Depending on how the system failed, there can be two different recovery procedures used. Generally, the procedures involves restoring data that has been collected from a backup device and then running the transaction processing again. Two types of recovery are *backward recovery* and *forward recovery*:

- Backward recovery: used to undo unwanted changes to the database. It reverses the changes made by transactions which have been aborted.
- Forward recovery: it starts with a backup copy of the database. The transaction will then reprocess according to the transaction journal that occurred between the time the backup was made and the present time.

Types of back-up procedures

There are two main types of Back-up Procedures: **Grandfather-father-son** and **Partial backups**:

Grandfather-father-son

This procedure refers to at least three generations of backup master files. thus, the most recent backup is the son, the oldest backup is the grandfather. It's commonly used for a *batch transaction processing system* with a magnetic tape. If the system fails during a batch run, the master file is recreated by using the son backup and then restarting the batch. However if the son backup fails, is corrupted or destroyed, then the previous generation of backup (the father) is used. Likewise, if that fails, then the generation of backup previous to the father (i.e. the grandfather) is required. Of course the older the generation, the more the data may be out of date. Organizations can have many generations of backup.

Partial backups

This only occurs when parts of the master file are backed up. The master file is usually backed up to magnetic tape at regular times, this could be daily, weekly or monthly. Completed transactions since the last backup are stored separately and are called **journals**, or **journal files**. The master file can be recreated from the journal files on the backup tape if the system is to fail.

Updating in a batch

This is used when transactions are recorded on paper (such as bills and invoices) or when it's being stored on a magnetic tape. Transactions will be collected and updated as a batch when it's convenient or economical to process them. Historically, this was the most common method as the information technology did not exist to allow real-time processing.

The two stages in batch processing are:

- Collecting and storage of the transaction data into a transaction file - this involves sorting the data into sequential order.
- Processing the data by updating the master file - which can be difficult, this may involve data additions, updates and deletions which may require being performed in a certain order. If an error occurs, then the entire batch fails.

Updating in batch requires sequential access - since it uses a magnetic tape this is the only way to access data. A batch will start at the beginning of the tape, then reading it from the order it was stored; it's very time-consuming to locate specific transactions.

The information technology used includes a secondary storage medium which can store large quantities of data inexpensively (thus the common choice of a magnetic tape). The software used to collect data does not have to be online - it doesn't even need a user interface.

Updating in real-time

This is the immediate processing of data. It provides instant confirmation of a transaction. It may involve a large number of users who are simultaneously performing transactions which change data. Because of advances in technology (such as the increase in the speed of data transmission and larger bandwidth), real-time updating is possible.

Steps in a real-time update involve the sending of a transaction data to an online database in a master file. The person providing information is usually able to help with error correction and receives confirmation of the transaction completion.

Updating in real-time uses direct access of data. This occurs when data are accessed without accessing previous data items. The storage device stores data in a particular location based on a mathematical procedure. This will then be calculated to find an approximate location of the data. If data are not found at this location, it will search through successive locations until it's found.

The information technology used could be a secondary storage medium that can store large amounts of data and provide quick access (thus the common choice of a magnetic disk).

Processing types

Transaction processing is distinct from other computer processing models — batch processing, time-sharing, and real-time processing.

Batch processing

Batch processing is execution of a series of programs (*jobs*) on a computer without manual intervention. Several transactions, called a *batch* are collected and processed at the same time. The results of each transaction are not immediately available when the transaction is being entered;[1] there is a time delay.

Real-time processing

"Real time systems attempt to guarantee an appropriate response to a stimulus or request quickly enough to affect the conditions that caused the stimulus." Each transaction in real-time processing is unique; it is not part of a group of transactions.

Time-sharing

Time sharing is the sharing of a computer system among multiple users, usually giving each user the illusion that they have exclusive control of the system. The users may be working on the same project or different projects, but there are usually few restrictions on the type of work each user is doing.

Transaction processing

Transaction processing systems also attempt to provide predictable response times to requests, although this is not as critical as for real-time systems. Rather than allowing the user to run arbitrary programs as time-sharing, transaction processing allows only predefined, structured transactions. Each transaction is usually short duration and the processing activity for each transaction is programmed in advance.

Transaction processing system features

The following features are considered important in evaluating transaction processing systems.

Performance

Fast performance with a rapid response time is critical. Transaction processing systems are usually measured by the number of transactions they can process in a given period of time.

Continuous availability

The system must be available during the time period when the users are entering transactions. Many organizations rely heavily on their TPS; a breakdown will disrupt operations or even stop the business.

Data integrity

The system must be able to handle hardware or software problems without corrupting data. Multiple users must be protected from attempting to change the same piece of data at the same time, for example two operators cannot sell the same seat on an airplane.

Ease of use

Often users of transaction processing systems are casual users. The system should be simple for them to understand, protect them from data-entry errors as much as possible, and allow them to easily correct their errors.

Modular growth

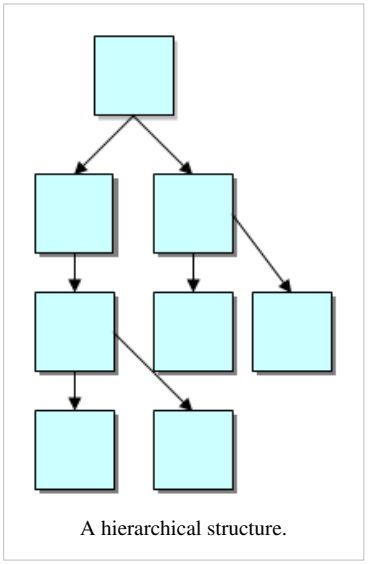
The system should be capable of growth at incremental costs, rather than requiring a complete replacement. It should be possible to add, replace, or update hardware and software components without shutting down the system.

Databases and files

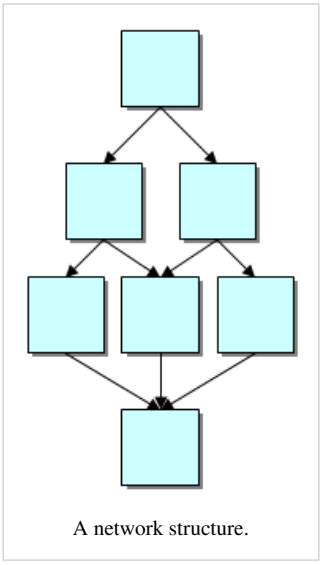
A database is an organized collection of data. Databases offer fast retrieval times for non-structured requests as in a typical transaction processing application.

Databases may be constructed using hierarchical, network, or relational structures.

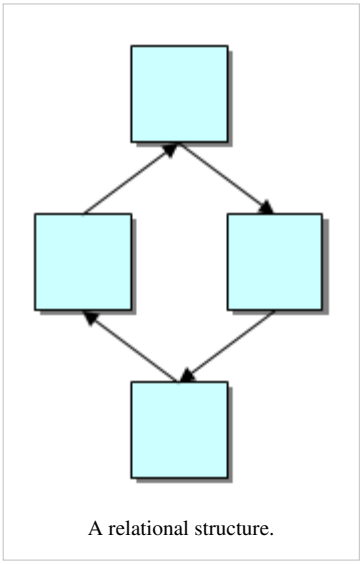
- Hierarchical structure: organizes data in a series of levels. Its top to bottom like structure consists of nodes and branches; each child node has branches and is only linked to one higher level parent node.
- Network structure: network structures also organizes data using nodes and branches. But, unlike hierarchical, each child node can be linked to multiple, higher parent nodes.
- Relational structure: a relational database organizes its data in a series of related tables. This gives flexibility as relationships between the tables are built.



A hierarchical structure.



A network structure.



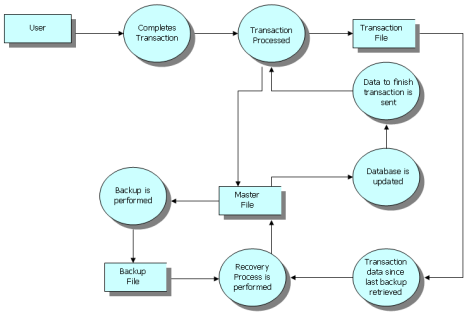
A relational structure.

The following features are desirable in a database system used in transaction processing systems:

- **Good data placement**: The database should be designed to access patterns of data from many simultaneous users.
- **Short transactions**: Short transactions enables quick processing. This avoids concurrency and paces the systems.
- **Real-time backup**: Backup should be scheduled between low times of activity to prevent lag of the server.
- **High normalization**: This lowers redundant information to increase the speed and improve concurrency, this also improves backups.
- **Archiving of historical data**: Uncommonly used data are moved into other databases or backed up tables. This keeps tables small and also improves backup times.
- **Good hardware configuration**: Hardware must be able to handle many users and provide quick response times.

Backup procedures

Since business organizations have become very dependent on TPSs, a breakdown in their TPS may stop the business' regular routines and thus stopping its operation for a certain amount of time. In order to prevent data loss and minimize disruptions when a TPS breaks down a well-designed backup and recovery procedure is put into use. The recovery process can rebuild the system when it goes down.



A Dataflow Diagram of backup and recovery procedures.

Recovery process

A TPS may fail for many reasons. These reasons could include a system failure, human errors, hardware failure, incorrect or invalid data, computer viruses, software application errors or natural or man-made disasters. As it's not possible to prevent all TPS failures, a TPS must be able to cope with failures. The TPS must be able to detect and correct errors when they occur. A TPS will go through a recovery of the database to cope when the system fails, it involves the backup, journal, checkpoint, and recovery manager:

- Journal: A journal maintains an audit trail of transactions and database changes. Transaction logs and Database change logs are used, a transaction log records all the essential data for each transactions, including data values, time of transaction and terminal number. A database change log contains before and after copies of records that have been modified by transactions.
- Checkpoint: *The purpose of checkpointing* is to provide a snapshot of the data within the database. A checkpoint, in general, is any identifier or other reference that identifies the state of the database at a point in time. Modifications to database pages are performed in memory and are not necessarily written to disk after every update. Therefore, periodically, the database system must perform a checkpoint to write these updates which are held in-memory to the storage disk. Writing these updates to storage disk creates a point in time in which the database system can apply changes contained in a transaction log during recovery after an unexpected shut down or crash of the database system.

If a checkpoint is interrupted and a recovery is required, then the database system must start recovery from a previous successful checkpoint. *Checkpointing can be either transaction-consistent or non-transaction-consistent* (called also fuzzy checkpointing). *Transaction-consistent checkpointing* produces a persistent database image that is sufficient to recover the database to the state that was externally perceived at the moment of starting the checkpointing. *A non-transaction-consistent checkpointing* results in a persistent database image that is insufficient to perform a recovery of the database state. To perform the database recovery, additional information is needed, typically contained in transaction logs. Transaction consistent checkpointing refers to a consistent database, which doesn't necessarily include all the latest committed transactions, but all modifications made by transactions, that were committed at the time checkpoint creation was started, are fully present. A non-consistent transaction refers to a checkpoint which is not necessarily a consistent database, and can't be recovered to one without all log records generated for open transactions included in the checkpoint. Depending on the type of database management system implemented *a checkpoint may incorporate indexes or storage pages (user data), indexes and storage pages*. If no indexes are incorporated into the checkpoint, indexes must be created when the database is restored from the checkpoint image.

- Recovery Manager: A recovery manager is a program which restores the database to a correct condition which can restart the transaction processing.

Depending on how the system failed, there can be two different recovery procedures used. Generally, the procedures involves restoring data that has been collected from a backup device and then running the transaction processing

again. Two types of recovery are *backward recovery* and *forward recovery*:

- Backward recovery: used to undo unwanted changes to the database. It reverses the changes made by transactions which have been aborted.
- Forward recovery: it starts with a backup copy of the database. The transaction will then reprocess according to the transaction journal that occurred between the time the backup was made and the present time.

Types of back-up procedures

There are two main types of Back-up Procedures: **Grandfather-father-son** and **Partial backups**:

Grandfather-father-son

This procedure refers to at least three generations of backup master files. thus, the most recent backup is the son, the oldest backup is the grandfather. It's commonly used for a *batch transaction processing system* with a magnetic tape. If the system fails during a batch run, the master file is recreated by using the son backup and then restarting the batch. However if the son backup fails, is corrupted or destroyed, then the previous generation of backup (the father) is used. Likewise, if that fails, then the generation of backup previous to the father (i.e. the grandfather) is required. Of course the older the generation, the more the data may be out of date. Organizations can have many generations of backup.

Partial backups

This only occurs when parts of the master file are backed up. The master file is usually backed up to magnetic tape at regular times, this could be daily, weekly or monthly. Completed transactions since the last backup are stored separately and are called **journals**, or **journal files**. The master file can be recreated from the journal files on the backup tape if the system is to fail.

Updating in a batch

This is used when transactions are recorded on paper (such as bills and invoices) or when it's being stored on a magnetic tape. Transactions will be collected and updated as a batch when it's convenient or economical to process them. Historically, this was the most common method as the information technology did not exist to allow real-time processing.

The two stages in batch processing are:

- Collecting and storage of the transaction data into a transaction file - this involves sorting the data into sequential order.
- Processing the data by updating the master file - which can be difficult, this may involve data additions, updates and deletions which may require being performed in a certain order. If an error occurs, then the entire batch fails.

Updating in batch requires sequential access - since it uses a magnetic tape this is the only way to access data. A batch will start at the beginning of the tape, then reading it from the order it was stored; it's very time-consuming to locate specific transactions.

The information technology used includes a secondary storage medium which can store large quantities of data inexpensively (thus the common choice of a magnetic tape). The software used to collect data does not have to be online - it doesn't even need a user interface.

Updating in real-time

This is the immediate processing of data. It provides instant confirmation of a transaction. It may involve a large number of users who are simultaneously performing transactions which change data. Because of advances in technology (such as the increase in the speed of data transmission and larger bandwidth), real-time updating is possible.

Steps in a real-time update involve the sending of a transaction data to an online database in a master file. The person providing information is usually able to help with error correction and receives confirmation of the transaction completion.

Updating in real-time uses direct access of data. This occurs when data are accessed without accessing previous data items. The storage device stores data in a particular location based on a mathematical procedure. This will then be calculated to find an approximate location of the data. If data are not found at this location, it will search through successive locations until it's found.

The information technology used could be a secondary storage medium that can store large amounts of data and provide quick access (thus the common choice of a magnetic disk).

Priority inversion

In computer science, **priority inversion** is a problematic scenario in scheduling in which a high priority task is indirectly preempted by a medium priority task effectively "inverting" the relative priorities of the two tasks.

This violates the priority model that high priority tasks can only be prevented from running by higher priority tasks and briefly by low priority tasks which will quickly complete their use of a resource shared by the high and low priority tasks.

Example of a priority inversion

Consider two tasks H and L, of high and low priority respectively, either of which can acquire exclusive use of a shared resource R. If H attempts to acquire R after L has acquired it, then H becomes unrunnable until L relinquishes the resource. The use of the shared exclusive-use resource when properly designed is such that L relinquishes R promptly enough that H's priority use is not hindered excessively. In spite of the good design of these two cooperating tasks, the surprising behavior, priority inversion, occurs when any third task M of medium priority becomes runnable during L's use of R. Once H becomes unrunnable, M is the highest priority runnable task, thus it runs and while it does L cannot relinquish R. So in this scenario, the medium priority task preempts the high priority task, resulting in a priority inversion.

Consequences

In some cases, priority inversion can occur without causing immediate harm—the delayed execution of the high priority task goes unnoticed, and eventually the low priority task releases the shared resource. However, there are also many situations in which priority inversion can cause serious problems. If the high priority task is left starved of the resources, it might lead to a system malfunction or the triggering of pre-defined corrective measures, such as a watch dog timer resetting the entire system. The trouble experienced by the Mars lander "Mars Pathfinder"[1][2] is a classic example of problems caused by priority inversion in realtime systems.

Priority inversion can also reduce the perceived performance of the system. Low priority tasks usually have a low priority because it is not important for them to finish promptly (for example, they might be a batch job or another non-interactive activity). Similarly, a high priority task has a high priority because it is more likely to be subject to strict time constraints—it may be providing data to an interactive user, or acting subject to realtime response guarantees. Because priority inversion results in the execution of a lower priority task blocking the high priority task, it can lead to reduced system responsiveness, or even the violation of response time guarantees.

A similar problem called deadline interchange can occur within earliest deadline first scheduling (EDF).

Solutions

The existence of this problem has been known since the 1970s. Lampson and Redell published one of the first papers to point out the priority inversion problem. Systems such as the UNIX kernel were already addressing the problem with the splx() primitive. There is no fool-proof method to predict the situation. There are however many existing solutions, of which the most common ones are:

Disabling all interrupts to protect critical sections

> When disabled interrupts are used to prevent priority inversion, there are only two priorities: *preemptible*, and *interrupts disabled.* With no third priority, inversion is impossible. Since there's only one piece of lock data (the interrupt-enable bit), misordering locking is impossible, and so deadlocks cannot occur. Since the critical regions always run to completion, hangs do not occur. Note that this only works if all interrupts are disabled. If only a particular hardware device's interrupt is disabled, priority inversion is reintroduced by the hardware's prioritization of interrupts. In early versions of UNIX, a series of primitives named splx(0) ... splx(7) disabled all interrupts up through the given priority. By properly choosing the highest priority of any interrupt that ever entered the critical section, the priority inversion problem could be solved without locking out all of the interrupts. Ceilings were assigned in rate-monotonic order, i.e. the slower devices had lower priorities.
>
> In multiple CPU systems, a simple variation, "single shared-flag locking" is used. This scheme provides a single flag in shared memory that is used by all CPUs to lock all inter-processor critical sections with a busy-wait. Interprocessor communications are expensive and slow on most multiple CPU systems. Therefore, most such systems are designed to minimize shared resources. As a result, this scheme actually works well on many practical systems. These methods are widely used in simple embedded systems, where they are prized for their reliability, simplicity and low resource use. These schemes also require clever programming to keep the critical sections very brief. Many software engineers consider them impractical in general-purpose computers.

A priority ceiling

> With priority ceilings, the shared mutex process (that runs the operating system code) has a characteristic (high) priority of its own, which is assigned to the task locking the mutex. This works well, provided the other high priority task(s) that tries to access the mutex does not have a priority higher than the ceiling priority.

Priority inheritance

Under the policy of priority inheritance, whenever a high priority task has to wait for some resource shared with an executing low priority task, the low priority task is temporarily assigned the priority of the highest waiting priority task for the duration of its own use of the shared resource, thus keeping medium priority tasks from pre-empting the (originally) low priority task, and thereby affecting the waiting high priority task as well. Once the resource is released, the low priority task continues at its original priority level.

Random boosting

Ready tasks holding locks are randomly boosted in priority until they exit the critical section. This solution is used in Microsoft Windows.

Avoid blocking

Because priority inversion involves a low-priority task blocking a high-priority task, one way to avoid priority inversion is to avoid blocking, for example by using Non-blocking synchronization or Read-copy-update.

Priority ceiling protocol

In real-time computing, the **priority ceiling protocol** is a synchronization protocol for shared resources to avoid unbounded priority inversion and mutual deadlock due to wrong nesting of critical sections. In this protocol each resource is assigned a priority ceiling, which is a priority equal to the highest priority of any task which may lock the resource.

For example, with priority ceilings, the shared mutex process (that runs the operating system code) has a characteristic (high) priority of its own, which is assigned to the task locking the mutex. This works well, provided the other high priority task(s) that tries to access the mutex does not have a priority higher than the ceiling priority.

In the **Immediate Ceiling Priority Protocol** (ICPP) when a task locks the resource its priority is temporarily raised to the priority ceiling of the resource, thus no task that may lock the resource is able to get scheduled. This allows a low priority task to defer execution of higher-priority tasks.

The **Original Ceiling Priority Protocol** (OCPP) has the same worst-case performance, but is subtly different in the implementation which can provide finer grained priority inheritance control mechanism than ICPP. Under this approach, a task can lock a resource only if its dynamic priority is higher than the current system priority. (The dynamic priority of a task is the maximum of its own static priority and any it inherits due to it blocking higher-priority processes. The system current priority is the ceiling of the resource having the highest ceiling among those locked by *other* tasks currently.) Otherwise the task is blocked, and its priority is inherited by the task currently holding the resource that gives the current system priority.

A task will not get scheduled if any resource it may lock actually has been locked by another task, and therefore the priority ceiling protocol prevents deadlocks.

ICPP is called "Ceiling Locking" in Ada, "Priority Protect Protocol" in POSIX and "Priority Ceiling Emulation" in RTSJ. It is also known as "Highest Locker's Priority Protocol" (HLP). [1]

ICPP versus OCPP

The worst-case behaviour of the two ceiling schemes is identical from a scheduling view point. However, there are some differences:[2]

- ICPP is easier to implement than OCPP, as blocking relationships need not be monitored
- ICPP leads to fewer context switches as blocking is prior to first execution
- ICPP requires more priority movements as this happens with all resource usage
- OCPP changes priority only if an actual block has occurred

- How to use priority inheritance (http://www.embedded.com/showArticle.jhtml?articleID=20600062), by Kyle Renwick and Bill Renwick (2004-05-18)

Priority inheritance

In real-time computing, **priority inheritance** is a method for eliminating priority inversion problems. Using this programming method, a process scheduling algorithm will increase the priority of a process to the maximum priority of any process waiting for any resource on which the process has a resource lock.

The basic idea of the priority inheritance protocol is that when a job blocks one or more high-priority jobs, it ignores its original priority assignment and executes its critical section at the highest priority level over all the jobs it blocks. After executing its critical section, the job returns to its original priority level.

Example

Consider three jobs:

Job Name	Priority
H	High
M	Medium
L	Low

Suppose H is blocked by L for some shared resource. The priority inheritance protocol requires that L executes its critical section at the (high) priority of H. As a result, M will be unable to preempt L and will be blocked. That is, the higher-priority job M must wait for the critical section of the lower priority job L to be executed, because L now inherits the priority of H. When L exits its critical section, it regains its original (low) priority and awakens H (which was blocked by L). H, having high priority, immediately preempts L and runs to completion. This enables M and L to resume in succession and run to completion.

Query Optimization and Indexing

Query optimization

Query optimization is a function of many relational database management systems. The **query optimizer** attempts to determine the most efficient way to execute a given query by considering the possible query plans.

Generally, the query optimizer cannot be accessed directly by users: once queries are submitted to database server, and parsed by the parser, they are then passed to the query optimizer where optimization occurs. However, some database engines allow guiding the query optimizer with hints.

A query is a request for information from a database. It can be as simple as "finding the address of a person with SS# 123-45-6789," or more complex like "finding the average salary of all the employed married men in California between the ages 30 to 39, that earn less than their wives." Queries results are generated by accessing relevant database data and manipulating it in a way that yields the requested information. Since database structures are complex, in most cases, and especially for not-very-simple queries, the needed data for a query can be collected from a database by accessing it in different ways, through different data-structures, and in different orders. Each different way typically requires different processing time. Processing times of a same query may have large variance, from a fraction of a second to hours, depending on the way selected. The purpose of query optimization, which is an automated process, is to find the way to process a given query in minimum time. The large possible variance in time justifies performing query optimization, though finding the exact optimal way to execute a query, among all possibilities, is typically very complex, time consuming by itself, may be too costly, and often practically impossible. Thus query optimization typically tries to approximate the optimum by comparing several common-sense alternatives to provide in a reasonable time a "good enough" plan which typically does not deviate much from the best possible result.

General considerations

There is a trade-off between the amount of time spent figuring out the best query plan and the quality of the choice; the optimizer may not choose the best answer on its own. Different qualities of database management systems have different ways of balancing these two. Cost-based query optimizers evaluate the resource footprint of various query plans and use this as the basis for plan selection. These assign an estimated "cost" to each possible query plan, and choose the plan with the smallest cost. Costs are used to estimate the runtime cost of evaluating the query, in terms of the number of I/O operations required, CPU path length, amount of disk buffer space, disk storage service time, and interconnect usage between units of parallelism, and other factors determined from the data dictionary. The set of query plans examined is formed by examining the possible access paths (e.g., primary index access, secondary index access, full file scan) and various relational table join techniques (e.g., merge join, hash join, product join). The search space can become quite large depending on the complexity of the SQL query. There are two types of optimization. These consist of logical optimization—which generates a sequence of relational algebra to solve the query—and physical optimization—which is used to determine the means of carrying out each operation.

Implementation

Most query optimizers represent query plans as a tree of "plan nodes". A plan node encapsulates a single operation that is required to execute the query. The nodes are arranged as a tree, in which intermediate results flow from the bottom of the tree to the top. Each node has zero or more child nodes—those are nodes whose output is fed as input to the parent node. For example, a join node will have two child nodes, which represent the two join operands, whereas a sort node would have a single child node (the input to be sorted). The leaves of the tree are nodes which produce results by scanning the disk, for example by performing an index scan or a sequential scan.

Join ordering

The performance of a query plan is determined largely by the order in which the tables are joined. For example, when joining 3 tables A, B, C of size 10 rows, 10,000 rows, and 1,000,000 rows, respectively, a query plan that joins B and C first can take several orders-of-magnitude more time to execute than one that joins A and C first. Most query optimizers determine join order via a dynamic programming algorithm pioneered by IBM's System R database project [*citation needed*]. This algorithm works in two stages:

1. First, all ways to access each relation in the query are computed. Every relation in the query can be accessed via a sequential scan. If there is an index on a relation that can be used to answer a predicate in the query, an index scan can also be used. For each relation, the optimizer records the cheapest way to scan the relation, as well as the cheapest way to scan the relation that produces records in a particular sorted order.
2. The optimizer then considers combining each pair of relations for which a join condition exists. For each pair, the optimizer will consider the available join algorithms implemented by the DBMS. It will preserve the cheapest way to join each pair of relations, in addition to the cheapest way to join each pair of relations that produces its output according to a particular sort order.
3. Then all three-relation query plans are computed, by joining each two-relation plan produced by the previous phase with the remaining relations in the query.

sort order can avoid a redundant sort operation later on in processing the query. Second, a particular sort order can speed up a subsequent join because it clusters the data in a particular way.

Query planning for nested SQL queries

A SQL query to a modern relational DBMS does more than just selections and joins. In particular, SQL queries often nest several layers of SPJ blocks (Select-Project-Join), by means of group by, exists, and not exists operators. In some cases such nested SQL queries can be flattened into a select-project-join query, but not always. Query plans for nested SQL queries can also be chosen using the same dynamic programming algorithm as used for join ordering, but this can lead to an enormous escalation in query optimization time. So some database management systems use an alternative rule-based approach that uses a query graph model.

Cost estimation

One of the hardest problems in query optimization is to accurately estimate the costs of alternative query plans. Optimizers cost query plans using a mathematical model of query execution costs that relies heavily on estimates of the cardinality, or number of tuples, flowing through each edge in a query plan. Cardinality estimation in turn depends on estimates of the selection factor of predicates in the query. Traditionally, database systems estimate selectivities through fairly detailed statistics on the distribution of values in each column, such as histograms. This technique works well for estimation of selectivities of individual predicates. However many queries have conjunctions of predicates such as `select count(*) from R where R.make='Honda' and R.model='Accord'`. Query predicates are often highly correlated (for example, `model='Accord'` implies `make='Honda'`), and it is very hard to estimate the selectivity of the conjunct in general. Poor cardinality estimates and uncaught correlation are one of the main reasons why query optimizers pick poor query plans. This is

one reason why a database administrator should regularly update the database statistics, especially after major data loads/unloads.

Query optimizer

Query optimization is a function of many relational database management systems. The **query optimizer** attempts to determine the most efficient way to execute a given query by considering the possible query plans.

Generally, the query optimizer cannot be accessed directly by users: once queries are submitted to database server, and parsed by the parser, they are then passed to the query optimizer where optimization occurs. However, some database engines allow guiding the query optimizer with hints.

A query is a request for information from a database. It can be as simple as "finding the address of a person with SS# 123-45-6789," or more complex like "finding the average salary of all the employed married men in California between the ages 30 to 39, that earn less than their wives." Queries results are generated by accessing relevant database data and manipulating it in a way that yields the requested information. Since database structures are complex, in most cases, and especially for not-very-simple queries, the needed data for a query can be collected from a database by accessing it in different ways, through different data-structures, and in different orders. Each different way typically requires different processing time. Processing times of a same query may have large variance, from a fraction of a second to hours, depending on the way selected. The purpose of query optimization, which is an automated process, is to find the way to process a given query in minimum time. The large possible variance in time justifies performing query optimization, though finding the exact optimal way to execute a query, among all possibilities, is typically very complex, time consuming by itself, may be too costly, and often practically impossible. Thus query optimization typically tries to approximate the optimum by comparing several common-sense alternatives to provide in a reasonable time a "good enough" plan which typically does not deviate much from the best possible result.

General considerations

There is a trade-off between the amount of time spent figuring out the best query plan and the quality of the choice; the optimizer may not choose the best answer on its own. Different qualities of database management systems have different ways of balancing these two. Cost-based query optimizers evaluate the resource footprint of various query plans and use this as the basis for plan selection. These assign an estimated "cost" to each possible query plan, and choose the plan with the smallest cost. Costs are used to estimate the runtime cost of evaluating the query, in terms of the number of I/O operations required, CPU path length, amount of disk buffer space, disk storage service time, and interconnect usage between units of parallelism, and other factors determined from the data dictionary. The set of query plans examined is formed by examining the possible access paths (e.g., primary index access, secondary index access, full file scan) and various relational table join techniques (e.g., merge join, hash join, product join). The search space can become quite large depending on the complexity of the SQL query. There are two types of optimization. These consist of logical optimization—which generates a sequence of relational algebra to solve the query—and physical optimization—which is used to determine the means of carrying out each operation.

Implementation

Most query optimizers represent query plans as a tree of "plan nodes". A plan node encapsulates a single operation that is required to execute the query. The nodes are arranged as a tree, in which intermediate results flow from the bottom of the tree to the top. Each node has zero or more child nodes—those are nodes whose output is fed as input to the parent node. For example, a join node will have two child nodes, which represent the two join operands, whereas a sort node would have a single child node (the input to be sorted). The leaves of the tree are nodes which produce results by scanning the disk, for example by performing an index scan or a sequential scan.

Join ordering

The performance of a query plan is determined largely by the order in which the tables are joined. For example, when joining 3 tables A, B, C of size 10 rows, 10,000 rows, and 1,000,000 rows, respectively, a query plan that joins B and C first can take several orders-of-magnitude more time to execute than one that joins A and C first. Most query optimizers determine join order via a dynamic programming algorithm pioneered by IBM's System R database project [*citation needed*]. This algorithm works in two stages:

1. First, all ways to access each relation in the query are computed. Every relation in the query can be accessed via a sequential scan. If there is an index on a relation that can be used to answer a predicate in the query, an index scan can also be used. For each relation, the optimizer records the cheapest way to scan the relation, as well as the cheapest way to scan the relation that produces records in a particular sorted order.
2. The optimizer then considers combining each pair of relations for which a join condition exists. For each pair, the optimizer will consider the available join algorithms implemented by the DBMS. It will preserve the cheapest way to join each pair of relations, in addition to the cheapest way to join each pair of relations that produces its output according to a particular sort order.
3. Then all three-relation query plans are computed, by joining each two-relation plan produced by the previous phase with the remaining relations in the query.

sort order can avoid a redundant sort operation later on in processing the query. Second, a particular sort order can speed up a subsequent join because it clusters the data in a particular way.

Query planning for nested SQL queries

A SQL query to a modern relational DBMS does more than just selections and joins. In particular, SQL queries often nest several layers of SPJ blocks (Select-Project-Join), by means of group by, exists, and not exists operators. In some cases such nested SQL queries can be flattened into a select-project-join query, but not always. Query plans for nested SQL queries can also be chosen using the same dynamic programming algorithm as used for join ordering, but this can lead to an enormous escalation in query optimization time. So some database management systems use an alternative rule-based approach that uses a query graph model.

Cost estimation

One of the hardest problems in query optimization is to accurately estimate the costs of alternative query plans. Optimizers cost query plans using a mathematical model of query execution costs that relies heavily on estimates of the cardinality, or number of tuples, flowing through each edge in a query plan. Cardinality estimation in turn depends on estimates of the selection factor of predicates in the query. Traditionally, database systems estimate selectivities through fairly detailed statistics on the distribution of values in each column, such as histograms. This technique works well for estimation of selectivities of individual predicates. However many queries have conjunctions of predicates such as `select count(*) from R where R.make='Honda' and R.model='Accord'` . Query predicates are often highly correlated (for example, `model='Accord'` implies `make='Honda'`), and it is very hard to estimate the selectivity of the conjunct in general. Poor cardinality estimates and uncaught correlation are one of the main reasons why query optimizers pick poor query plans. This is one reason why a database administrator should regularly update the database statistics, especially after major data loads/unloads.

Query plan

A **query plan** (or **query execution plan**) is an ordered set of steps used to access data in a SQL relational database management system. This is a specific case of the relational model concept of access plans.

Since SQL is declarative, there are typically a large number of alternative ways to execute a given query, with widely varying performance. When a query is submitted to the database, the query optimizer evaluates some of the different, correct possible plans for executing the query and returns what it considers the best alternative. Because query optimizers are imperfect, database users and administrators sometimes need to manually examine and tune the plans produced by the optimizer to get better performance.

Generating query plans

A given database management system may offer one or more mechanisms for returning the plan for a given query. Some packages feature tools which will generate a graphical representation of a query plan. Other tools allow a special mode to be set on the connection to cause the DBMS to return a textual description of the query plan. Another mechanism for retrieving the query plan involves querying a virtual database table after executing the query to be examined. In Oracle, for instance, this can be achieved using the EXPLAIN PLAN statement.

Graphical plans

The SQL Server Management Studio tool which ships with Microsoft SQL Server, for example, shows this graphical plan when executing this two-table join against a sample database:

```
SELECT *
FROM HumanResources.Employee AS e
    INNER JOIN Person.Contact AS c
    ON e.ContactID = c.ContactID
ORDER BY c.LastName
```

The UI allows exploration of various attributes of the operators involved in the query plan, including the operator type, the number of rows each operator consumes or produces, and the expected cost of each operator's work.

Textual plans

The textual plan given for the same query in the screenshot is shown here:

```
StmtText
----
  |--Sort(ORDER BY:([c].[LastName] ASC))
       |--Nested Loops(Inner Join, OUTER REFERENCES:([e].[ContactID],
[Expr1004]) WITH UNORDERED PREFETCH)
            |--Clustered Index
Scan(OBJECT:([AdventureWorks].[HumanResources].[Employee].[PK_Employee_EmployeeID]
 AS [e]))
            |--Clustered Index
Seek(OBJECT:([AdventureWorks].[Person].[Contact].[PK_Contact_ContactID]
 AS [c]),

SEEK:([c].[ContactID]=[AdventureWorks].[HumanResources].[Employee].[ContactID]
 as [e].[ContactID]) ORDERED FORWARD)
```

It indicates that the query engine will do a scan over the primary key index on the Employee table and a matching seek through the primary key index (the ContactID column) on the Contact table to find matching rows. The resulting rows from each side will be shown to a nested loops join operator, sorted, then returned as the result set to the connection.

In order to tune the query, the user must understand the different operators that the database may use, and which ones might be more efficient than others while still providing semantically correct query results.

Database tuning

Reviewing the query plan can present opportunities for new indexes or changes to existing indexes. It can also show that the database is not properly taking advantage of existing indexes (see query optimizer).

Query tuning

The query optimizer will not always choose the best query plan for a given query. In some databases the query plan can be reviewed, problems found, and then the query optimizer given hints on how to improve it. In other databases alternatives to express the same query (other queries that return the same results) can be tried. Some query tools can generate embedded hints in the query, for use by the optimizer.

Some databases like Oracle provide a Plan table for query tuning. This plan table will return the cost and time for executing a Query. In Oracle there are 2 optimization techniques:

1. CBO or Cost Based Optimization
2. RBO or Rule Based Optimization

The RBO is slowly being deprecated. For CBO to be used, all the tables referenced by the query must be analyzed. To analyze a table, a package DBMS_STATS can be made use of.

The others methods for query optimization include:

1. SQL Trace
2. Oracle Trace
3. TKPROF

Index (database)

A **database index** is a data structure that improves the speed of data retrieval operations on a database table at the cost of additional writes and the use of more storage space to maintain the extra copy of data. Indexes are used to quickly locate data without having to search every row in a database table every time a database table is accessed. Indexes can be created using one or more columns of a database table, providing the basis for both rapid random lookups and efficient access of ordered records.

An index is a copy of select columns of data from a table that can be searched very efficiently that also includes a low level disk block address or direct link to the complete row of data it was copied from. Some databases extend the power of indexing by allowing indices to be created on functions or expressions. For example, an index could be created on `upper(last_name)`, which would only store the upper case versions of the last_name field in the index. Another option sometimes supported is the use of "filtered" indices, where index entries are created only for those records that satisfy some conditional expression. A further aspect of flexibility is to permit indexing on user-defined functions, as well as expressions formed from an assortment of built-in functions.

Usage

Support for fast lookup

Most database software includes indexing technology that enables sub-linear time lookup to improve performance, as linear search is inefficient for large databases.

Suppose a database contains N data items and it is desired to retrieve one of them based on the value of one of the fields. A naïve implementation would retrieve and examine each item until a match was not found. A successful lookup would retrieve half the objects on average; an unsuccessful lookup all of them for each attempt. This means that the number of operations in the worst case is O(N) or linear time. Since databases commonly contain millions of objects and since lookup is a common operation, it is often desirable to improve on this performance.

An index is any data structure that improves the performance of lookup. There are many different data structures used for this purpose, and in fact a substantial proportion of the field of computer science is devoted to the design and analysis of index data structures. [*citation needed*] There are complex design trade-offs involving lookup performance, index size, and index update performance. Many index designs exhibit logarithmic (O(log(N))) lookup performance and in some applications it is possible to achieve flat (O(1)) performance.

Policing the database constraints

Indexes are used to police database constraints, such as UNIQUE, EXCLUSION, PRIMARY KEY and FOREIGN KEY. An index may be declared as UNIQUE which creates an implicit constraint on the underlying table. Database systems usually implicitly create an index on a set of columns declared PRIMARY KEY, and some are capable of using an already existing index to police this constraint. Many database systems require that both referencing and referenced sets of columns in a FOREIGN KEY constraint are indexed, thus improving performance of inserts, updates and deletes to the tables participating in the constraint.

Some database systems support EXCLUSION constraint which ensures that for a newly inserted or updated record a certain predicate would hold for no other record. This may be used to implement a UNIQUE constraint (with equality predicate) or more complex constraints, like ensuring that no overlapping time ranges or no intersecting geometry objects would be stored in the table. An index supporting fast searching for records satisfying the predicate is required to police such a constraint.[1]

Index architecture

Non-clustered

The data is present in arbitrary order, but the **logical ordering** is specified by the index. The data rows may be spread throughout the table regardless of the value of the indexed column or expression. The non-clustered index tree contains the index keys in sorted order, with the leaf level of the index containing the pointer to the record (page and the row number in the data page in page-organized engines; row offset in file-organized engines).

In a non-clustered index

- The physical order of the rows is not the same as the index order.
- The indexed columns are typically non-primary key columns used in JOIN, WHERE, and ORDER BY clauses.

There can be more than one non-clustered index on a database table.

Clustered

Clustering alters the data block into a certain distinct order to match the index, resulting in the row data being stored in order. Therefore, only one clustered index can be created on a given database table. Clustered indices can greatly increase overall speed of retrieval, but usually only where the data is accessed sequentially in the same or reverse order of the clustered index, or when a range of items is selected.

Since the physical records are in this sort order on disk, the next row item in the sequence is immediately before or after the last one, and so fewer data block reads are required. The primary feature of a clustered index is therefore the ordering of the physical data rows in accordance with the index blocks that point to them. Some databases separate the data and index blocks into separate files, others put two completely different data blocks within the same physical file(s).

Cluster

When multiple databases and multiple tables are joined, it's referred to as a **cluster** (not to be confused with clustered index described above). The records for the tables sharing the value of a cluster key shall be stored together in the same or nearby data blocks. This may improve the joins of these tables on the cluster key, since the matching records are stored together and less I/O is required to locate them.[2] The data layout in the tables which are parts of the cluster is defined by the cluster configuration. A cluster can be keyed with a B-Tree index or a hash table. The data block in which the table record will be stored is defined by the value of the cluster key.

Column order

The order in which columns are listed in the index definition is important. It is possible to retrieve a set of row identifiers using only the first indexed column. However, it is not possible or efficient (on most databases) to retrieve the set of row identifiers using only the second or greater indexed column.

For example, imagine a phone book that is organized by city first, then by last name, and then by first name. If you are given the city, you can easily extract the list of all phone numbers for that city. However, in this phone book it would be very tedious to find all the phone numbers for a given last name. You would have to look within each city's section for the entries with that last name. Some databases can do this, others just won't use the index.

In the phone book example with an composite index created on the columns (*city, last_name, first_name*), if we search by giving exact values for all the three fields, the search time will be minimal. But if we provide the values for *city* and *first_name* only, the search will use only the *city* field to retrieve all the records matched. And then a sequential lookup will be performed for checking the matching with *first_name*. So, to improve the performance, one must ensure that the index is created on the order of search columns.

Applications and limitations

Indices are useful for many applications but come with some limitations. Consider the following SQL statement: `SELECT first_name FROM people WHERE last_name = 'Smith';`. To process this statement without an index the database software must look at the last_name column on every row in the table (this is known as a full table scan). With an index the database simply follows the B-tree data structure until the Smith entry has been found; this is much less computationally expensive than a full table scan.

Consider this SQL statement: `SELECT email_address FROM customers WHERE email_address LIKE '%@yahoo.com';`. This query would yield an email address for every customer whose email address ends with "@yahoo.com", but even if the email_address column has been indexed the database must perform a full index scan. This is because the index is built with the assumption that words go from left to right. With a wildcard at the beginning of the search-term, the database software is unable to use the underlying B-tree data structure (in other words, the WHERE-clause is *not sargable*). This problem can be solved through the addition of another index created on `reverse(email_address)` and a SQL query like this: `SELECT email_address FROM customers WHERE reverse(email_address) LIKE reverse('%@yahoo.com');`. This puts the wild-card at the right-most part of the query (now moc.oohay@%) which the index on reverse(email_address) can satisfy.

But when the wildcard characters are used on both sides of the search word as "%yahoo.com%", the index available on this field will not be used. Rather only a sequential search will be performed which will take O(N) time. So, index must be available on the columns on which the lookup is performed.

Types of indexes

Bitmap index

A bitmap index is a special kind of index that stores the bulk of its data as bit arrays (bitmaps) and answers most queries by performing bitwise logical operations on these bitmaps. The most commonly used indexes, such as B+trees, are most efficient if the values they index do not repeat or repeat a smaller number of times. In contrast, the bitmap index is designed for cases where the values of a variable repeat very frequently. For example, the gender field in a customer database usually contains two distinct values: male or female. For such variables, the bitmap index can have a significant performance advantage over the commonly used trees.

Dense index

A dense index in databases is a file with pairs of keys and pointers for every record in the data file. Every key in this file is associated with a particular pointer to *a record* in the sorted data file. In clustered indices with duplicate keys, the dense index points *to the first record* with that key.[3]

Sparse index

A sparse index in databases is a file with pairs of keys and pointers for every block in the data file. Every key in this file is associated with a particular pointer *to the block* in the sorted data file. In clustered indices with duplicate keys, the sparse index points *to the lowest search key* in each block.

Reverse index

A reverse key index reverses the key value before entering it in the index. E.g., the value 24538 becomes 83542 in the index. Reversing the key value is particularly useful for indexing data such as sequence numbers, where new key values monotonically increase.

Index implementations

Indices can be implemented using a variety of data structures. Popular indices include balanced trees, B+ trees and hashes.

In Microsoft SQL Server, the leaf node of the clustered index corresponds to the actual data, not simply a pointer to data that resides elsewhere, as is the case with a non-clustered index. Each relation can have a single clustered index and many unclustered indices.

Index concurrency control

An index is typically being accessed concurrently by several transactions and processes, and thus needs concurrency control. While in principle indexes can utilize the common database concurrency control methods, specialized concurrency control methods for indexes exist, which are applied in conjunction with the common methods for a substantial performance gain.

Covering index

In most cases, an index is used to quickly locate the data record(s) from which the required data is read. In other words, the index is only used to locate data records in the table and not to return data.

A covering index is a special case where the index itself contains the required data field(s) and can return the data.

Consider the following table (other fields omitted):

ID	Name	Other Fields
12	Plug	...
13	Lamp	...
14	Fuse	...

To find the Name for ID 13, an index on (ID) will be useful, but the record must still be read to get the Name. However, an index on (ID, Name) contains the required data field and eliminates the need to look up the record.

A covering index can dramatically speed up data retrieval but may itself be large due to the additional keys, which slow down data insertion & update. To reduce such index size, some systems allow non-key fields to be included in the index. Non-key fields are not themselves part of the index ordering but only included at the leaf level, allowing for a covering index with less overall index size.

Standardization

There is no standard about creating indexes because the ISO SQL Standard does not cover physical aspects. Indexes are one of the physical parts of database conception among others like storage (tablespace or filegroups). RDBMS vendors all give a CREATE INDEX syntax with some specific options which depends on functionalities they provide to customers.

Partial index

In databases, a **partial index**, also known as **filtered index** is an index which has some condition applied to it so that it includes a subset of rows in the table.

This allows the index to remain small, even though the table may be rather large, and have extreme selectivity.

Suppose you have a transaction table where entries start out with STATUS = 'A' (active), and then may pass through other statuses ('P' for pending, 'W' for "being worked on") before reaching a final status, 'F', at which point it is no longer likely to be processed again.

In PostgreSQL, a useful partial index might be defined as:

```
create index partial_status on txn_table (status)
where status in ('A', 'P', 'W');
```

This index would not bother storing any of the millions of rows that have reached "final" status, 'F', and would allow queries looking for transactions that still "need work" to efficiently search via this index.

Similarly, a partial index can be used to index only those rows where a column is not null, which will be of benefit when the column usually is null.

```
create index partial_object_update on object_table (updated_on)
where updated_on is not null;
```

This index would allow the following query to read only the updated tuples:

```
select * from object_table
where updated_on is not null
order by updated_on;
```

It is not necessary that the condition be the same as the index criterion; Stonebraker's paper below presents a number of examples with indexes similar to the following:

```
create index partial_salary on employee(age)
where salary > 2100;
```

Support

In SQL Server, this type of index is called a *filtered index*. Partial indexes have been supported in PostgreSQL since version 7.2, released in February 2002. SQLite supports partial indexes since version 3.8.0.

MySQL as of version 5.4 does not support partial indexes. In MySQL, the term "partial index" is sometimes used to refer to prefix indexes, where only a truncated prefix of each value is stored in the index. This is another technique for reducing index size.

- The Case For Partial Indexes (http://db.cs.berkeley.edu/papers/ERL-M89-17.pdf)

Expression index

An **expression index** is a database index that is built on a generic expression, rather than on a list of columns. This allows indexes to be defined for common query conditions that depend on data in a table, but are not actually stored in that table.

A common use for an expression index is to support case-insensitive searching or constraints. For example, if a web site wants to make user names case-insensitive, but still preserve the case as originally entered by the user, a unique index can be created on the upper- or lower-case representation of the user name:

```
CREATE UNIQUE INDEX site_user__user_name_lower ON site_user( lower( user_name ) );
```

That will create a unique index on "lower(user_name)". Any queries that search on "lower(user_name)" could then make use of that index:

```
SELECT user_id FROM site_user WHERE lower(user_name) = lower('Decibel');
```

Reverse index

Database management systems provide multiple types of indexes to improve performance and data integrity across diverse application. Index types include b-trees, bitmaps, and r-trees.

In database management systems, a **reverse key index** strategy reverses the key value before entering it in the index.[1] E.g., the value 24538 becomes 83542 in the index. Reversing the key value is particularly useful for indexing data such as sequence numbers, where each new key value is greater than the prior value, i.e., values monotonically increase. Reverse key indexes have become particularly important in high volume transaction processing systems because they reduce contention for index blocks.

Creating data

Reversed key indexes use b-tree structures, but preprocess key values before inserting them. Simplifying, b-trees place similar values on a single index block, e.g., storing 24538 on the same block as 24539. This makes them efficient both for looking up a specific value and for finding values within a range. However if the application inserts values in sequence, each insert must have access to the newest block in the index in order to add the new value. If many users attempt to insert at the same time, they all must write to that block and have to get in line, slowing down the application. This is particularly a problem in clustered databases, which may require the block to be copied from one computer's memory to another's to allow the next user to perform their insert.

Reversing the key spreads similar new values across the entire index instead of concentrating them in any one leaf block. This means that 24538 appears on the same block as 14538 while 24539 goes to a different block, eliminating this cause of contention. (Since 14538 would have been created long before 24538, their inserts don't interfere with each other.)

Querying data

Reverse indexes are just as efficient as unreversed indexes for finding specific values, although they aren't helpful for range queries. Range queries are uncommon for artificial values such as sequence numbers. When searching the index, the query processor simply reverses the search target before looking it up.

Deleting data

Typically, applications delete data that is older on average before deleting newer data. Thus, data with lower sequence numbers generally go before those with higher values. As time passes, in standard b-trees, index blocks for lower values end up containing few values, with a commensurate increase in unused space, referred to as "rot". Rot not only wastes space, but slows query speeds, because a smaller fraction of a rotten index's blocks fit in memory at any one time. In a b-tree, if 14538 gets deleted, its index space remains empty. In a reverse index, if 14538 goes before 24538 arrives, 24538 can reuse 14538's space.

Bitmap index

A **bitmap index** is a special kind of database index that uses bitmaps.

Bitmap indexes have traditionally been considered to work well for *low-cardinality columns*, which have a modest number of distinct values, either absolutely, or relative to the number of records that contain the data. The extreme case of low cardinality is Boolean data (e.g.,Does a resident in a city have internet access?), which has two values, True and False. Bitmap indexes use bit arrays (commonly called bitmaps) and answer queries by performing bitwise logical operations on these bitmaps. Bitmap indexes have a significant space and performance advantage over other structures for query of such data. Their drawback is they are less efficient than the traditional B-tree indexes for columns whose data is frequently updated: consequently, they are more often employed in read-only systems that are specialized for fast query - e.g., data warehouses, and generally unsuitable for online transaction processing applications. However, this drawback appears to apply only to their implementation in relational database management systems: certain non-relational DBMSs, notably Intersystems Cache, a hierarchical database, use bitmap indexes for low-cardinality columns in transactional systems.

Some researchers argue that Bitmap indexes are also useful for moderate or even high-cardinality data (e.g., unique-valued data) which is accessed in a read-only manner, and queries access multiple bitmap-indexed columns using the AND, OR or XOR operators extensively.[1]

Bitmap indexes are also useful in data warehousing applications for joining a large fact table to smaller dimension tables such as those arranged in a star schema.

Example

Continuing the internet access example, a bitmap index may be logically viewed as follows:

Identifier	HasInternet	Bitmaps	
		Y	N
1	Yes	1	0
2	No	0	1
3	No	0	1
4	Unspecified	0	0
5	Yes	1	0

On the left, Identifier refers to the unique number assigned to each resident, HasInternet is the data to be indexed, the content of the bitmap index is shown as two columns under the heading *bitmaps*. Each column in the left illustration is a *bitmap* in the bitmap index. In this case, there are two such bitmaps, one for "has internet" *Yes* and one for "has internet" *No*. It is easy to see that each bit in bitmap *Y* shows whether a particular row refers to a person who has internet access. This is the simplest form of bitmap index. Most columns will have more distinct values. For example, the sales amount is likely to have a much larger number of distinct values. Variations on the bitmap index can effectively index this data as well. We briefly review three such variations.

Note: many of the references cited here are reviewed at. For those who might be interested in experimenting with some of the ideas mentioned here, many of them are implemented in open source software such as FastBit,[2] the Lemur Bitmap Index C++ Library,[3] the Roaring Bitmap Java library,[4] the Apache Hive Data Warehouse system and LucidDB.

Compression

Software can compress each bitmap in a bitmap index to save space. There has been considerable amount of work on this subject. Bitmap compression algorithms typically employ run-length encoding, such as the Byte-aligned Bitmap Code, the Word-Aligned Hybrid code, the Partitioned Word-Aligned Hybrid (PWAH) compression, the Position List Word Aligned Hybrid, the Compressed Adaptive Index (COMPAX), Enhanced Word-Aligned Hybrid (EWAH) and the COmpressed 'N' Composable Integer SEt.[5] These compression methods require very little effort to compress and decompress. More importantly, bitmaps compressed with BBC, WAH, COMPAX, PLWAH, EWAH and CONCISE can directly participate in bitwise operations without decompression. This gives them considerable advantages over generic compression techniques such as LZ77. BBC compression and its derivatives are used in a commercial database management system. BBC is effective in both reducing index sizes and maintaining query performance. BBC encodes the bitmaps in bytes, while WAH encodes in words, better matching current CPUs. "On both synthetic data and real application data, the new word aligned schemes use only 50% more space, but perform logical operations on compressed data 12 times faster than BBC." PLWAH bitmaps were reported to take 50% of the storage space consumed by WAH bitmaps and offer up to 20% faster performance on logical operations. Similar considerations can be done for CONCISE and Enhanced Word-Aligned Hybrid.

The performance of schemes such as BBC, WAH, PLWAH, EWAH, COMPAX and CONCISE is dependent on the order of the rows. A simple lexicographical sort can divide the index size by 9 and make indexes several times faster. The larger the table, the more important it is to sort the rows. Reshuffling techniques have also been proposed to achieve the same results of sorting when indexing streaming data.

Encoding

Basic bitmap indexes use one bitmap for each distinct value. It is possible to reduce the number of bitmaps used by using a different encoding method. For example, it is possible to encode C distinct values using log(C) bitmaps with binary encoding.

This reduces the number of bitmaps, further saving space, but to answer any query, most of the bitmaps have to be accessed. This makes it potentially not as effective as scanning a vertical projection of the base data, also known as a materialized view or projection index. Finding the optimal encoding method that balances (arbitrary) query performance, index size and index maintenance remains a challenge.

Without considering compression, Chan and Ioannidis analyzed a class of multi-component encoding methods and came to the conclusion that two-component encoding sits at the kink of the performance vs. index size curve and therefore represents the best trade-off between index size and query performance.

Binning

For high-cardinality columns, it is useful to bin the values, where each bin covers multiple values and build the bitmaps to represent the values in each bin. This approach reduces the number of bitmaps used regardless of encoding method. However, binned indexes can only answer some queries without examining the base data. For example, if a bin covers the range from 0.1 to 0.2, then when the user asks for all values less than 0.15, all rows that fall in the bin are possible hits and have to be checked to verify whether they are actually less than 0.15. The process of checking the base data is known as the candidate check. In most cases, the time used by the candidate check is significantly longer than the time needed to work with the bitmap index. Therefore, binned indexes exhibit irregular performance. They can be very fast for some queries, but much slower if the query does not exactly match a bin.

History

The concept of bitmap index was first introduced by Professor Israel Spiegler and Rafi Maayan in their research "Storage and Retrieval Considerations of Binary Data Bases", published in 1985. The first commercial database product to implement a bitmap index was Computer Corporation of America's Model 204. Patrick O'Neil published a paper about this implementation in 1987. This implementation is a hybrid between the basic bitmap index (without compression) and the list of Row Identifiers (RID-list). Overall, the index is organized as a B+tree. When the column cardinality is low, each leaf node of the B-tree would contain long list of RIDs. In this case, it requires less space to represent the RID-lists as bitmaps. Since each bitmap represents one distinct value, this is the basic bitmap index. As the column cardinality increases, each bitmap becomes sparse and it may take more disk space to store the bitmaps than to store the same content as RID-lists. In this case, it switches to use the RID-lists, which makes it a B+tree index.

In-memory bitmaps

One of the strongest reasons for using bitmap indexes is that the intermediate results produced from them are also bitmaps and can be efficiently reused in further operations to answer more complex queries. Many programming languages support this as a bit array data structure. For example, Java has the `BitSet` [6] class.

Some database systems that do not offer persistent bitmap indexes use bitmaps internally to speed up query processing. For example, PostgreSQL versions 8.1 and later implement a "bitmap index scan" optimization to speed up arbitrarily complex logical operations between available indexes on a single table.

For tables with many columns, the total number of distinct indexes to satisfy all possible queries (with equality filtering conditions on either of the fields) grows very fast, being defined by this formula:

$$\mathbf{C}_n^{\left[\frac{n}{2}\right]} \equiv \frac{n!}{\left(n - \left[\frac{n}{2}\right]\right)! \left[\frac{n}{2}\right]!}.$$

A bitmap index scan combines expressions on different indexes, thus requiring only one index per column to support all possible queries on a table.

Applying this access strategy to B-tree indexes can also combine range queries on multiple columns. In this approach, a temporary in-memory bitmap is created with one bit for each row in the table (1 MiB can thus store over 8 million entries). Next, the results from each index are combined into the bitmap using bitwise operations. After all conditions are evaluated, the bitmap contains a "1" for rows that matched the expression. Finally, the bitmap is traversed and matching rows are retrieved. In addition to efficiently combining indexes, this also improves locality of reference of table accesses, because all rows are fetched sequentially from the main table. The internal bitmap is discarded after the query. If there are too many rows in the table to use 1 bit per row, a "lossy" bitmap is created instead, with a single bit per disk page. In this case, the bitmap is just used to determine which pages to fetch; the filter criteria are then applied to all rows in matching pages.

Inverted index

In computer science, an **inverted index** (also referred to as **postings file** or **inverted file**) is an index data structure storing a mapping from content, such as words or numbers, to its locations in a database file, or in a document or a set of documents. The purpose of an inverted index is to allow fast full text searches, at a cost of increased processing when a document is added to the database. The inverted file may be the database file itself, rather than its index. It is the most popular data structure used in document retrieval systems, used on a large scale for example in search engines. Several significant general-purpose mainframe-based database management systems have used inverted list architectures, including ADABAS, DATACOM/DB, and Model 204.

There are two main variants of inverted indexes: A **record level inverted index** (or **inverted file index** or just **inverted file**) contains a list of references to documents for each word. A **word level inverted index** (or **full inverted index** or **inverted list**) additionally contains the positions of each word within a document. The latter form offers more functionality (like phrase searches), but needs more time and space to be created.

Example

Given the texts

```
T[0] = "it is what it is"
T[1] = "what is it"
T[2] = "it is a banana"
```

we have the following inverted file index (where the integers in the set notation brackets refer to the indexes (or keys) of the text symbols, `T[0]`, `T[1]` etc.):

```
"a":      {2}
"banana": {2}
"is":     {0, 1, 2}
"it":     {0, 1, 2}
"what":   {0, 1}
```

A term search for the terms `"what"`, `"is"` and `"it"` would give the set $\{0,1\} \cap \{0,1,2\} \cap \{0,1,2\} = \{0,1\}$.

With the same texts, we get the following full inverted index, where the pairs are document numbers and local word numbers. Like the document numbers, local word numbers also begin with zero. So, `"banana": {(2, 3)}` means the word "banana" is in the third document (`T[2]`), and it is the fourth word in that document (position 3).

```
"a":      {(2, 2)}
"banana": {(2, 3)}
"is":     {(0, 1), (0, 4), (1, 1), (2, 1)}
"it":     {(0, 0), (0, 3), (1, 2), (2, 0)}
"what":   {(0, 2), (1, 0)}
```

If we run a phrase search for `"what is it"` we get hits for all the words in both document 0 and 1. But the terms occur consecutively only in document 1.

Applications

The inverted index data structure is a central component of a typical search engine indexing algorithm. A goal of a search engine implementation is to optimize the speed of the query: find the documents where word X occurs. Once a forward index is developed, which stores lists of words per document, it is next inverted to develop an inverted index. Querying the forward index would require sequential iteration through each document and to each word to verify a matching document. The time, memory, and processing resources to perform such a query are not always technically realistic. Instead of listing the words per document in the forward index, the inverted index data structure is developed which lists the documents per word.

With the inverted index created, the query can now be resolved by jumping to the word id (via random access) in the inverted index.

In pre-computer times, concordances to important books were manually assembled. These were effectively inverted indexes with a small amount of accompanying commentary that required a tremendous amount of effort to produce.

In bioinformatics, inverted indexes are very important in the sequence assembly of short fragments of sequenced DNA. One way to find the source of a fragment is to search for it against a reference DNA sequence. A small number of mismatches (due to differences between the sequenced DNA and reference DNA, or errors) can be accounted for by dividing the fragment into smaller fragments—at least one subfragment is likely to match the reference DNA sequence. The matching requires constructing an inverted index of all substrings of a certain length from the reference DNA sequence. Since the human DNA contains more than 3 billion base pairs, and we need to store a DNA substring for every index, and a 32-bit integer for index itself, the storage requirement for such an inverted index would probably be in the tens of gigabytes.

Sargable

In relational databases, a condition (or predicate) in a query is said to be **sargable** if the DBMS engine can take advantage of an index to speed up the execution of the query. The term is derived from a contraction of *Search ARGument ABLE*.

A query failing to be sargable is known as ***Non-Sargable*** query and has an effect in query time, so one of the steps in query optimization is convert them to be sargable.

The typical situation that will make a sql query non-sargable is to include in the WHERE clause a function operating on a column value. Note that the WHERE clause is not the only clause where sargability can matter; it can also have an effect on ORDER BY, GROUP BY and HAVING clauses. The SELECT clause, on the other hand, can contain non-sargable expressions without adversely affecting the performance.

- **Sargable operators**: =,>,<,>=,<=,BETWEEN,LIKE without leading %
- **Sargable operators** that rarely improve performance: <>,IN,OR,NOT IN, NOT EXISTS, NOT LIKE
- **Non-sargable operators**: LIKE with leading %

Rules of thumb

- Avoid functions using table values in a sql condition.
- Avoid non-sargable predicates and replace them with sargable equivalents.

Examples

- **Non-Sargable**: Select ... WHERE Year(date) = 2012
- **Sargable**: Select ... WHERE date >= '01-01-2012' AND date < '01-01-2013'
- **Non-Sargable**: Select ... WHERE isNull(FullName,'John Smith') = 'John Smith'
- **Sargable**: Select ... WHERE ((FullName = 'John Smith') OR (FullName IS NULL))
- **Non-Sargable**: Select ... WHERE SUBSTRING(DealerName,6) = 'Toyota'
- **Sargable**: Select ... WHERE DealerName Like 'Toyota%'
- **Non-Sargable**: Select ... WHERE DateDiff(mm,Date,GetDate()) >= 20
- **Sargable**: Select ... WHERE Date < DateAdd(mm,-20,GetDate())

V-optimal histograms

Histograms are most commonly used as visual representations of data. However, database systems use histograms to summarize data internally and provide size estimates for queries. These histograms are not presented to users or displayed visually, so a wider range of options are available for their construction. Simple or exotic histograms are defined by four parameters, Sort Value, Source Value, Partition Class and Partition Rule. The most basic histogram is the equi-width histogram, where each bucket represents the same range of values. That histogram would be defined as having a Sort Value of Value, a Source Value of Frequency, be in the Serial Partition Class and have a Partition Rule stating that all buckets have the same range.

V-optimal histograms are an example of a more "exotic" histogram. V-optimality is a Partition Rule which states that the bucket boundaries are to be placed as to minimize the cumulative weighted variance of the buckets. Implementation of this rule is a complex problem and construction of these histograms is also a complex process.

Definition

A v-optimal histogram is based on the concept of minimizing a quantity which is called the *weighted variance* in this context.[1] This is defined as

$$W = \sum_{j=1}^{J} n_j V_j \,,$$

where the histogram consists of J bins or buckets, n_j is the number of items contained in the jth bin and where V_j is the variance between the values associated with the items in the jth bin.

Examples

The following example will construct a V-optimal histogram having a Sort Value of Value, a Source Value of Frequency, and a Partition Class of Serial. In practice, almost all histograms used in research or commercial products are of the Serial class, meaning that sequential sort values are placed in either the same bucket, or sequential buckets. For example, values 1, 2, 3 and 4 will be in buckets 1 and 2, or buckets 1, 2 and 3, but never in buckets 1 and 3. That will be taken as an assumption in any further discussion.

Take a simple set of data, for example, a list of integers:

1, 3, 4, 7, 2, 8, 3, 6, 3, 6, 8, 2, 1, 6, 3, 5, 3, 4, 7, 2, 6, 7, 2

Compute the value and frequency pairs (1, 2), (2, 4), (3, 5), (4, 2), (5, 1), (6, 4), (7, 3), (8, 2)

Our V-optimal histogram will have two buckets. Since one bucket must end at the data point for 8, we must decide where to put the other bucket boundary. The V-optimality rule states that the cumulative weighted variance of the buckets must be minimized. We will look at two options and compute the cumulative variance of those options.

Option 1: Bucket 1 contains values 1 through 4. Bucket 2 contains values 5 through 8.

Bucket 1:
Average frequency 3.25
Weighted variance 2.28

Bucket 2:
Average frequency 2.5
Weighted variance 2.19

Sum of Weighted Variance 4.47

Option 2: Bucket 1 contains values 1 through 2. Bucket 2 contains values 3 through 8.

Bucket 1:
Average frequency 3
Weighted variance 1.41

Bucket 2:
Average frequency 2.83
Weighted variance 3.29

Sum of Weighted Variance 4.70

The first choice is better, so the histogram that would wind up being stored is Bucket 1: Range(1 - 4), Average Frequency 3.25 Bucket 2: Range(5 - 8), Average Frequency 2.5

Advantages of V-optimality vs. equi-width or equi-depth

V-optimal histograms do a better job of estimating the bucket contents. A histogram is an estimation of the base data, and any histogram will have errors. The partition rule used in VOptimal histograms attempts to have the smallest variance possible among the buckets, which provides for a smaller error. Research done by Poosala and Ionnaidis 1 [2] has demonstrated that the most accurate estimation of data is done with a VOptimal histogram using value as a sort parameter and frequency as a source parameter.

Disadvantages of V-optimality vs. equi-width or equi-depth

While the V-optimal histogram is more accurate, it does have drawbacks. It is a difficult structure to update. Any changes to the source parameter could potentially result in having to re-build the histogram entirely, rather than updating the existing histogram. An equi-width histogram does not have this problem. Equi-depth histograms will experience this issue to some degree, but because the equi-depth construction is simpler, there is a lower cost to maintain it. The difficulty in updating VOptimal histograms is an outgrowth of the difficulty involved in constructing these histograms.

Construction issues

The above example is a simple one. There are only 7 choices of bucket boundaries. One could compute the cumulative variance for all 7 options easily and choose the absolute best placement. However, as the range of values gets larger and the number of buckets gets larger, the set of possible histograms grows exponentially and it becomes a dauntingly complex problem to find the set of boundaries that provide the absolute minimum variance. A solution is to give up on finding the absolute best solution and attempt to find a good solution instead. By creating random solutions, using those as a starting point and improving upon them, one can find a solution that is a fair approximation of the "best" solution. One construction method used to get around this problem is the Iterative Improvement algorithm. Another is Simulated Annealing. The two may be combined in Two Phase Optimization, or 2PO. These algorithms are put forth in "Randomized Algorithms..." (cited below) as a method to optimize queries, but the general idea may be applied to construction of V-optimal Histograms.

Iterative improvement

Iterative Improvement (II) is a fairly naive greedy algorithm. Starting from a random state, iterative steps in many directions are considered. The step that offers the best improvement of cost (in this case Total Variance) is taken. The process is repeated until one settles at the local minimum, where no further improvement is possible. Applied to the construction of V-optimal histograms, the initial random state would be a set of values representing the bucket boundary placements. The iterative improvement steps would involve moving each boundary until it was at its local minimum, then moving to the next boundary and adjusting it accordingly.

Simulated Annealing

A basic explanation of Simulated Annealing is that it is a lot like II, only instead of taking the greedy step each time, it will sometimes accept a step that results in an increase in cost. In theory, SA will be less likely to stop at a very local minimum, and more likely to find a more global one. A useful piece of imagery is an "M" shaped graph, representing overall cost on the Y axis. If the initial state is on the "V" shaped part of the "M", II will settle into the high valley, the local minimum. Because SA will accept uphill moves, it is more likely to climb up the slope of the "V" and wind up at the foot of the "M", the global minimum.

Two Phase Optimization

Two Phase Optimization, or 2PO, combines the II and SA methods. II is run until a local minimum is reached, then SA is run on that solution in an attempt to find less obvious improvements.

Variations of V-optimal Histograms

The idea behind V-optimal histograms is to minimize the variance inside each bucket. In considering this, a thought occurs that the variance of any set with one member is 0. This is the idea behind "End-Biased" V-optimal Histograms. The value with the highest frequency is always placed in its own bucket. This ensures that the estimate for that value (which is likely to be the most frequently requested estimate, since it is the most frequent value) will always be accurate and also removes the value most likely to cause a high variance from the data set.

Another thought that might occur is that variance would be reduced if one were to sort by frequency, instead of value. This would naturally tend to place like values next to each other. Such a histogram can be constructed by using a Sort Value of Frequency and a Source Value of Frequency. At this point, however, the buckets must carry additional information indicating what data values are present in the bucket. These histograms have been shown to be less accurate, due to the additional layer of estimation required.

Cardinality (SQL statements)

In SQL (Structured Query Language), the term **cardinality** refers to the uniqueness of data values contained in a particular column (attribute) of a database table. The lower the cardinality, the more duplicated elements in a column. Thus, a column with the lowest possible cardinality would have the same value for every row. SQL databases use cardinality to help determine the optimal query plan for a given query.

Values of Cardinality

When dealing with columnar value sets, there are 3 types of cardinality: high-cardinality, normal-cardinality, and low-cardinality.

High-cardinality refers to columns with values that are very uncommon or unique. High-cardinality column values are typically identification numbers, email addresses, or user names. An example of a data table column with high-cardinality would be a USERS table with a column named USER_ID. This column would contain unique values of 1-*n*. Each time a new user is created in the USERS table, a new number would be created in the USER_ID column to identify them uniquely. Since the values held in the USER_ID column are unique, this column's cardinality type would be referred to as high-cardinality.

Normal-cardinality refers to columns with values that are somewhat uncommon. Normal-cardinality column values are typically names, street addresses, or vehicle types. An example of a data table column with normal-cardinality would be a CUSTOMER table with a column named LAST_NAME, containing the last names of customers. While some people have common last names, such as Smith, others have uncommon last names. Therefore, an examination of all of the values held in the LAST_NAME column would show "clumps" of names in some places (e.g.: a lot of Smith's) surrounded on both sides by a long series of unique values. Since there is a variety of possible values held in this column, its cardinality type would be referred to as normal-cardinality.

Low-cardinality refers to columns with few unique values. Low-cardinality column values are typically status flags, Boolean values, or major classifications such as gender. An example of a data table column with low-cardinality would be a CUSTOMER table with a column named NEW_CUSTOMER. This column would contain only 2 distinct values: Y or N, denoting whether the customer was new or not. Since there are only 2 possible values held in this column, its cardinality type would be referred to as low-cardinality.

Online aggregation

Online aggregation is a technique for improving the interactive behavior of database systems processing expensive analytical queries. Almost all database operations are performed in batch mode, i.e. the user issues a query and waits till the database has finished processing the entire query. On the contrary, using online aggregation, the user gets estimates of an aggregate query in an online fashion as soon as the query is issued. For example, if the final answer is 1000, after k seconds, the user gets the estimates in form of a confidence interval like [990, 1020] with 95% probability. This confidence keeps on shrinking as the system gets more and more samples.

Online aggregation was proposed in 1997 by Hellerstein, Haas and Wang for group-by aggregation queries over a single table. Later, the authors showed how to evaluate joins in an online fashion. In 2007, Jermaine et al. designed and implemented a prototype database system called Database-Online (or DBO) that computes group-by aggregate query over multiple tables in an online and more importantly in a scalable fashion. All the approaches for online aggregation use random sampling, which is non-trivial in a distributed environment due to inspection paradox of renewal reward theory. In 2011, Pansare et al. proposed a Bayesian model to deal with the inspection paradox and implemented online aggregation for a MapReduce-like environment.

Distributed DB

Very large database

A **very large database**, or **VLDB**, is a database that contains an extremely high number of tuples (database rows), or occupies an extremely large physical filesystem storage space. The most common definition of VLDB is a database that occupies more than 1 terabyte or contains several billion rows, although naturally this definition changes over time.[*citation needed*]

Since the year 2011, this term is now referred to as big data by industry.

References

Big data

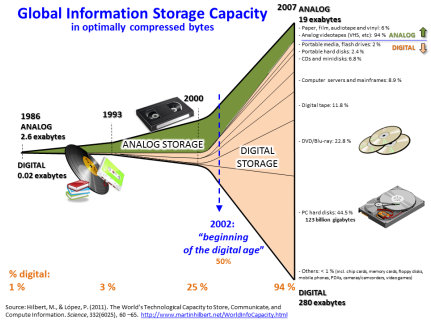
Big data is the term for a collection of data sets so large and complex that it becomes difficult to process using on-hand database management tools or traditional data processing applications. The challenges include capture, curation, storage, search, sharing, transfer, analysis and visualization. The trend to larger data sets is due to the additional information derivable from analysis of a single large set of related data, as compared to separate smaller sets with the same total amount of data, allowing correlations to be found to "spot business trends, determine quality of research, prevent diseases, link legal citations, combat crime, and determine real-time roadway traffic conditions."[1]

A visualization created by IBM of Wikipedia edits. At multiple terabytes in size, the text and images of Wikipedia are a classic example of big data.

As of 2012[2], limits on the size of data sets that are feasible to process in a reasonable amount of time were on the order of exabytes of data. Scientists regularly encounter limitations due to large data sets in many areas, including meteorology, genomics, connectomics, complex physics simulations, and biological and environmental research. The limitations also affect Internet search, finance and business informatics. Data sets grow in size in part because they are increasingly being gathered by ubiquitous information-sensing mobile devices, aerial sensory technologies (remote sensing), software logs, cameras, microphones, radio-frequency identification readers, and wireless sensor networks. The world's technological per-capita capacity to store information has roughly doubled every 40 months since the 1980s; as of 2012[2], every day 2.5 exabytes (2.5×10^{18}) of data were created. The challenge for large enterprises is determining who should own big data initiatives that straddle the entire organization.[3]

Big data is difficult to work with using most relational database management systems and desktop statistics and visualization packages, requiring instead "massively parallel software running on tens,

hundreds, or even thousands of servers". What is considered "big data" varies depending on the capabilities of the organization managing the set, and on the capabilities of the applications that are traditionally used to process and analyze the data set in its domain. "For some organizations, facing hundreds of gigabytes of data for the first time may trigger a need to reconsider data management options. For others, it may take tens or hundreds of terabytes before data size becomes a significant consideration."



Growth of and Digitization of Global Information Storage Capacity; source: http://www.martinhilbert.net/WorldInfoCapacity.html

Definition

Big Data usually includes data sets with sizes beyond the ability of commonly used software tools to capture, curate, manage, and process the data within a tolerable elapsed time.[4] Big data sizes are a constantly moving target, as of 2012[2] ranging from a few dozen terabytes to many petabytes of data in a single data set.

In a 2001 research report and related lectures, META Group (now Gartner) analyst Doug Laney defined data growth challenges and opportunities as being three-dimensional, i.e. increasing volume (amount of data), velocity (speed of data in and out), and variety (range of data types and sources). Gartner, and now much of the industry, continue to use this "3Vs" model for describing big data. In 2012, Gartner updated its definition as follows: "Big data is high volume, high velocity, and/or high variety information assets that require new forms of processing to enable enhanced decision making, insight discovery and process optimization." Additionally, a new V "Veracity" is added by some organizations to describe it.

If Gartner's definition (the 3Vs) is still widely used, the growing maturity of the concept fosters a more sound difference between big data and Business Intelligence, regarding data and their use:

- Business Intelligence uses descriptive statistics with data with high information density to measure things, detect trends etc.;
- Big data uses inductive statistics and concepts from nonlinear system identification [5] to infer laws (regressions, nonlinear relationships, and causal effects) from large data sets [6] to reveal relationships, dependencies, and to perform predictions of outcomes and behaviors.[7]

Big science

The Large Hadron Collider experiments represent about 150 million sensors delivering data 40 million times per second. There are nearly 600 million collisions per second. After filtering and refraining from recording more than 99.999% of these streams, there are 100 collisions of interest per second.

- As a result, only working with less than 0.001% of the sensor stream data, the data flow from all four LHC experiments represents 25 petabytes annual rate before replication (as of 2012). This becomes nearly 200 petabytes after replication.
- If all sensor data were to be recorded in LHC, the data flow would be extremely hard to work with. The data flow would exceed 150 million petabytes annual rate, or nearly 500 exabytes per day, before replication. To put the number in perspective, this is equivalent to 500 quintillion (5×10^{20}) bytes per day, almost 200 times higher than all the other sources combined in the world.

Science and research

- When the Sloan Digital Sky Survey (SDSS) began collecting astronomical data in 2000, it amassed more in its first few weeks than all data collected in the history of astronomy. Continuing at a rate of about 200 GB per night, SDSS has amassed more than 140 terabytes of information. When the Large Synoptic Survey Telescope, successor to SDSS, comes online in 2016 it is anticipated to acquire that amount of data every five days.
- Decoding the human genome originally took 10 years to process, now it can be achieved in less than a week : the DNA sequencers have divided the sequencing cost by 10,000 in the last ten years, which is 100 times faster than the reduction in cost predicted by Moore's Law.[8]
- Computational social science ― Tobias Preis *et al.* used Google Trends data to demonstrate that Internet users from countries with a higher per capita gross domestic product (GDP) are more likely to search for information about the future than information about the past. The findings suggest there may be a link between online behaviour and real-world economic indicators. The authors of the study examined Google queries logs made by ratio of the volume of searches for the coming year ('2011') to the volume of searches for the previous year ('2009'), which they call the 'future orientation index'. They compared the future orientation index to the per capita GDP of each country and found a strong tendency for countries in which Google users enquire more about the future to exhibit a higher GDP. The results hint that there may potentially be a relationship between the economic success of a country and the information-seeking behavior of its citizens captured in big data.
- The [[Nasa|NASA [9]] Center for Climate Simulation (NCCS)] stores 32 petabytes of climate observations and simulations on the Discover supercomputing cluster.
- Tobias Preis and his colleagues Helen Susannah Moat and H. Eugene Stanley introduced a method to identify online precursors for stock market moves, using trading strategies based on search volume data provided by Google Trends. Their analysis of Google search volume for 98 terms of varying financial relevance, published in *Scientific Reports*, suggests that increases in search volume for financially relevant search terms tend to precede large losses in financial markets.

Government

- In 2012, the Obama administration announced the Big Data Research and Development Initiative, which explored how big data could be used to address important problems faced by the government. The initiative was composed of 84 different big data programs spread across six departments.
- Big data analysis played a large role in Barack Obama's successful 2012 re-election campaign.
- The United States Federal Government owns six of the ten most powerful supercomputers in the world.
- The Utah Data Center is a data center currently being constructed by the United States National Security Agency. When finished, the facility will be able to handle a large amount of information collected by the NSA over the Internet. The exact amount of storage space is unknown, but more recent sources claim it will be on the order of a few Exabytes.

Private sector

Bus wrapped with SAP Big data parked outside IDF13.

- eBay.com uses two data warehouses at 7.5 petabytes and 40PB as well as a 40PB Hadoop cluster for search, consumer recommendations, and merchandising. Inside eBay's 90PB data warehouse [10]
- Amazon.com handles millions of back-end operations every day, as well as queries from more than half a million third-party sellers. The core technology that keeps Amazon running is Linux-based and as of 2005 they had the world's three largest Linux databases, with capacities of 7.8 TB, 18.5 TB, and 24.7 TB.
- Walmart handles more than 1 million customer transactions every hour, which is imported into databases estimated to contain more than 2.5 petabytes (2560 terabytes) of data – the equivalent of 167 times the information contained in all the books in the US Library of Congress.
- Facebook handles 50 billion photos from its user base.
- FICO Falcon Credit Card Fraud Detection System protects 2.1 billion active accounts world-wide.
- The volume of business data worldwide, across all companies, doubles every 1.2 years, according to estimates.[11]
- Windermere Real Estate uses anonymous GPS signals from nearly 100 million drivers to help new home buyers determine their typical drive times to and from work throughout various times of the day.

International development

Research on the effective usage of information and communication technologies for development (also known as ICT4D) suggests that big data technology can make important contributions but also present unique challenges to International development.[12][13] Advancements in big data analysis offer cost-effective opportunities to improve decision-making in critical development areas such as health care, employment, economic productivity, crime, security, and natural disaster and resource management. However, longstanding challenges for developing regions such as inadequate technological infrastructure and economic and human resource scarcity exacerbate existing concerns with big data such as privacy, imperfect methodology, and interoperability issues.

Market

"Big Data" has increased the demand of information management specialists in that Software AG, Oracle Corporation, IBM, Microsoft, SAP, EMC, HP and Dell have spent more than $15 billion on software firms only specializing in data management and analytics. In 2010, this industry on its own was worth more than $100 billion and was growing at almost 10 percent a year: about twice as fast as the software business as a whole.

Developed economies make increasing use of data-intensive technologies. There are 4.6 billion mobile-phone subscriptions worldwide and there are between 1 billion and 2 billion people accessing the internet. Between 1990 and 2005, more than 1 billion people worldwide entered the middle class which means more and more people who gain money will become more literate which in turn leads to information growth. The world's effective capacity to exchange information through telecommunication networks was 281 petabytes in 1986, 471 petabytes in 1993, 2.2 exabytes in 2000, 65 exabytes in 2007 and it is predicted that the amount of traffic flowing over the internet will reach 667 exabytes annually by 2013.

Big Data Softwares:

- Hadoop - Apache Foundation
- MongoDB - MongoDB, Inc
- Splunk - Splunk Inc

Architecture

In 2004, Google published a paper on a process called MapReduce that used such an architecture. MapReduce framework provides a parallel processing model and associated implementation to process huge amount of data. With MapReduce, queries are split and distributed across parallel nodes and processed in parallel (the Map step). The results are then gathered and delivered (the Reduce step). The framework was incredibly successful,[14] so others wanted to replicate the algorithm. Therefore, an implementation of MapReduce framework was adopted by an Apache open source project named Hadoop.[15]

MIKE2.0 is an open approach to information management that acknowledges the need for revisions due to big data implications in an article title Big Data Solution Offering. The methodology addresses handling big data in terms of useful permutations of data sources, complexity in interrelationships, and difficulty in deleting (or modifying) individual records.

Recent studies show the use of multiple layer architecture as an option to Big Data. The Distributed Parallel architecture distributes data across multiple processing units and parallel processing units provide data much faster, by improving processing speeds. This type of architecture inserts data into parallel DBMS, which implements the use of MapReduce and Hadoop frameworks. This type of framework looks to make the processing power transparent to the end user by using a front end application server.

Technologies

Big data requires exceptional technologies to efficiently process large quantities of data within tolerable elapsed times. A 2011 McKinsey report suggests suitable technologies include A/B testing, crowdsourcing, data fusion and integration, genetic algorithms, machine learning, natural language processing, signal processing, simulation, time series analysis and visualisation. Multidimensional big data can also be represented as tensors, which can be more efficiently handled by tensor-based computation, such as multilinear subspace learning. Additional technologies being applied to big data include massively parallel-processing (MPP) databases, search-based applications, data-mining grids, distributed file systems, distributed databases, cloud based infrastructure (applications, storage and computing resources) and the Internet.[*citation needed*]

Some but not all MPP relational databases have the ability to store and manage petabytes of data. Implicit is the ability to load, monitor, back up, and optimize the use of the large data tables in the RDBMS.

DARPA's Topological Data Analysis program seeks the fundamental structure of massive data sets and in 2008 the technology went public with the launch of a company called Ayasdi.

The practitioners of big data analytics processes are generally hostile to slower shared storage, preferring direct-attached storage (DAS) in its various forms from solid state drive (SSD) to high capacity SATA disk buried inside parallel processing nodes. The perception of shared storage architectures—Storage area network (SAN) and Network-attached storage (NAS) —is that they are relatively slow, complex, and expensive. These qualities are not consistent with big data analytics systems that thrive on system performance, commodity infrastructure, and low cost.

Real or near-real time information delivery is one of the defining characteristics of big data analytics. Latency is therefore avoided whenever and wherever possible. Data in memory is good—data on spinning disk at the other end of a FC SAN connection is not. The cost of a SAN at the scale needed for analytics applications is very much higher than other storage techniques.

There are advantages as well as disadvantages to shared storage in big data analytics, but big data analytics practitioners as of 2011[2] did not favour it.

Research activities

Encrypted search & cluster formation in Big Data is set for the demonstration in March 2014 at American Society of Engineering Education. Gautam Siwach engaged at Tackling the challenges of Big Data by MIT Computer Science and Artificial Intelligence Laboratory and Dr. Amir Esmailpour at UNH Research Group investigated the key features of big data as formation of clusters and their interconnections. They focused on the security of big data and the actual orientation of the term towards the presence of different type of data in an encrypted form at cloud interface by providing the raw definitions and real time examples within the technology. Moreover, they proposed an approach for identifying the encoding technique to advance towards an expedited search over encrypted text leading to the security enhancements in big data. [16]

In March 2012, The White House announced a national "Big Data Initiative" that consisted of six Federal departments and agencies committing more than $200 million to big data research projects.

The initiative included a National Science Foundation "Expeditions in Computing" grant of $10 million over 5 years to the AMPLab at the University of California, Berkeley. The AMPLab also received funds from DARPA, and over a dozen industrial sponsors and uses big data to attack a wide range of problems from predicting traffic congestion to fighting cancer.

The White House Big Data Initiative also included a commitment by the Department of Energy to provide $25 million in funding over 5 years to establish the Scalable Data Management, Analysis and Visualization (SDAV) Institute, led by the Energy Department's Lawrence Berkeley National Laboratory. The SDAV Institute aims to bring together the expertise of six national laboratories and seven universities to develop new tools to help scientists manage and visualize data on the Department's supercomputers.

The U.S. state of Massachusetts announced the Massachusetts Big Data Initiative in May 2012, which provides funding from the state government and private companies to a variety of research institutions. The Massachusetts Institute of Technology hosts the Intel Science and Technology Center for Big Data in the MIT Computer Science and Artificial Intelligence Laboratory, combining government, corporate, and institutional funding and research efforts.

The European Commission is funding a 2-year-long Big Data Public Private Forum [17] through their Seventh Framework Program to engage companies, academics and other stakeholders in discussing big data issues. The project aims to define a strategy in terms of research and innovation to guide supporting actions from the European Commission in the successful implementation of the Big Data economy. Outcomes of this project will be used as input for Horizon 2020 [18], their next framework program.

The IBM sponsored 37th annual "Battle of the Brains" student Big Data championship will be held in July 2013. The inaugural professional 2014 Big Data World Championship is to be held in Dallas, Texas.

In order to make manufacturing more competitive in the United States (and globe), there is a need to integrate more American ingenuity and innovation into manufacturing ; Therefore, National Science Foundation has granted the Industry University cooperative research center for Intelligent Maintenance Systems (IMS) [19] at university of Cincinnati to focus on developing advanced predictive tools and techniques to be applicable in Big Data environment. In May 2013, IMS Center held an industry advisory board meeting focusing on Big Data where presenters from various industrial companies discussed their concerns, issues and future goals in Big Data environment.

Applications

Manufacturing

Based on TCS 2013 Global Trend Study, huge improvements in supply planning and boost product quality is the greatest benefit of Big Data for manufacturing. Big Data provides an infrastructure for transparency in manufacturing industry, which is the ability to unravel uncertainties such as inconsistent component performance and availability. Predictive manufacturing as an applicable approach toward near-zero downtime and transparency requires vast amount of data and advanced prediction tools for a systematic process of data into useful information. A conceptual framework of predictive manufacturing begins with data acquisition where different type of sensory data is available to acquire such as acoustics, vibration, pressure, current, voltage and controller data. Vast amount of sensory data in addition to historical data construct the “Big Data” in manufacturing. The generated Big Data acts as the input into predictive tools and preventive strategies such as Prognostics and Health Management (PHM).

Critique

Critiques of the big data paradigm come in two flavors, those that question the implications of the approach itself, and those that question the way it is currently done.

Critiques of the big data paradigm

Cartoon critical of big data application

"A crucial problem is that we do not know much about the underlying empirical micro-processes that lead to the emergence of the[se] typical network characteristics of Big Data". In their critique, Snijders, Matzat, and Reips point out that often very strong assumptions are made about mathematical properties that may not at all reflect what is really going on at the level of micro-processes. Mark Graham has leveled broad critiques at Chris Anderson's assertion that big data will spell the end of theory: focusing in particular on the notion that big data will always need to be contextualized in their social, economic and political contexts. Even as companies invest eight- and nine-figure sums to derive insight from information streaming in from suppliers and customers, less than 40% of employees have sufficiently mature processes and skills to do so. To overcome this insight deficit, "big data", no matter how comprehensive or well analyzed, needs to be complemented by "big judgment", according to an article in the Harvard Business Review.

Much in the same line, it has been pointed out that the decisions based on the analysis of big data are inevitably "informed by the world as it was in the past, or, at best, as it currently is".[] Fed by a large number of data on past experiences, algorithms can predict future development if the future is similar to the past. If the systems dynamics of the future change, the past can say little about the future. For this, it would be necessary to have a thorough understanding of the systems dynamic, which implies theory.[20] As a response to this critique it has been suggested to combine big data approaches with computer simulations, such as agent-based models, for example. Agent-based models are increasingly getting better in predicting the outcome of social complexities of even unknown future scenarios through computer simulations that are based on a collection of mutually interdependent algorithms.[21][22] In addition, use of multivariate methods that probe for the latent structure of the data, such as factor analysis and cluster analysis, have proven useful as analytic approaches that go well beyond the bi-variate approaches (cross-tabs) typically employed with smaller data sets.

In Health and biology, conventional scientific approaches are based on experimentation. For these approaches, the limiting factor are the relevant data that can confirm or refute the initial hypothesis.[23] A new postulate is accepted now in biosciences : the information provided by the data in huge volumes (omics) without prior hypothesis is complementary and sometimes necessary to conventional approaches based on experimentation. In the massive approaches it is the formulation of a relevant hypothesis to explain the data that is the limiting factor. The search logic is reversed and the limits of induction ("Glory of Science and Philosophy scandal", C. D. Broad, 1926) to be considered.

Privacy advocates are concerned about the threat to privacy represented by increasing storage and integration of personally identifiable information; expert panels have released various policy recommendations to conform practice to expectations of privacy.[24][25]

Critiques of big data execution

Researcher Danah Boyd has raised concerns about the use of big data in science neglecting principles such as choosing a representative sample by being too concerned about actually handling the huge amounts of data. This approach may lead to results bias in one way or another. Integration across heterogeneous data resources — some that might be considered "big data" and others not — presents formidable logistical as well as analytical challenges, but many researchers argue that such integrations are likely to represent the most promising new frontiers in science.

XLDB

XLDB refers to **eXtremely Large Data Bases**. The definition of *extremely large* refers to data sets that are too big in terms of volume (too much), and/or velocity (too fast), and/of variety (too many places, too many formats) to be handled using conventional solutions.

History

In October 2007 the XLDB experts gathered at SLAC for the First Workshop on Extremely Large Databases [1]. As a result, the XLDB research community was formed. to meet rapidly growing demands, in addition to the original invitational workshop, an open conference, tutorials, and annual satellite events on different continents were added. The main event, held annually at Stanford gathers over 300 technically savvy attendees. XLDB is one of the premier database events catered towards both academic and industrial communities.

Goals

The main goals of this community include:

- Identify trends, commonalities and major roadblocks related to building extremely large databases
- Bridge the gap between users trying to build extremely large databases and database solution providers worldwide
- Facilitate development and growth of practical technologies for extremely large data stores

XLDB Community

As of 2013, the community consisted of about a thousand members including:

1. Scientists who develop, use, or plan to develop or use XLDB for their research, from laboratories.
2. Commercial users of XLDB.
3. Providers of database products, including commercial vendors and representatives from open source database communities.
4. Academic database researchers.

XLDB Conferences, Workshops and Tutorials

The community meets annually at Stanford where the main event is held each fall, usually in September. These who live too far from California to attend have the opportunity to attend satellite events, organized annually around May/June either in Asia or in Europe.

A detailed report is produced after each workshop.

Year	Place	Link	Report	Comments
2013	Stanford	[2]		7th XLDB Conference
2013	CERN, Geneva/Switzerland	[3]		Satellite XLDB Workshop in Europe
2012	Stanford	[4]	[5]	6th XLDB Conference, Workshop & Tutorials
2012	Beijing, China	[6]	[7]	Satellite XLDB Conference in Asia
2011	SLAC	[8]	[9]	5th XLDB Conference and Workshop
2011	Edinburgh, UK	[10]	not available	Satellite XLDB Workshop in Europe
2010	SLAC	[11]	[12]	4th XLDB Conference and Workshop
2009	Lyon, France	[13]	[14]	3rd XLDB Workshop
2008	SLAC	[15]	[16]	2nd XLDB Workshop
2007	SLAC	[17]	[18]	1st XLDB Workshop

Tangible results

The XLDB events led to initiating the effort of building a new open source, science database, SciDB [19].

The XLDB organizers started defining a science benchmark [20] for scientific data management systems called SS-DB.

At 2012 [21] the XLDB organizers announced that two major databases that support arrays as first-class objects (MonetDB SciQL and SciDB) have formed a working group in conjunction with XLDB. This working group is proposing a common syntax (provisionally named “ArrayQL”) for manipulating arrays, including array creation and query.

Secondary database server

A **secondary database server** or SDS is a database server that is kept in synchronisation with the main database so that if the main database goes offline, the secondary database server can be used instead. This is important for a live system that must be online 24 hours a day, and most DBMS systems that support SDSs are capable of automatically detecting and switching to the secondary server within seconds of the main server going offline. The secondary database server can also be used to run read-only queries to take load off the first database server and increase system performance.

Centralized database

A **centralized database** is a database located and maintained in one location, unlike a distributed database. One main advantage is that all data is located in one place. The disadvantage is that bottlenecks may occur.

Distributed database

A **distributed database** is a database in which storage devices are not all attached to a common processing unit such as the CPU, controlled by a distributed database management system (together sometimes called a distributed database system). It may be stored in multiple computers, located in the same physical location; or may be dispersed over a network of interconnected computers. Unlike parallel systems, in which the processors are tightly coupled and constitute a single database system, a distributed database system consists of loosely-coupled sites that share no physical components.

System administrators can distribute collections of data (e.g. in a database) across multiple physical locations. A distributed database can reside on network servers on the Internet, on corporate intranets or extranets, or on other company networks. Because they store data across multiple computers, distributed databases can improve performance at end-user worksites by allowing transactions to be processed on many machines, instead of being limited to one.[1]

Two processes ensure that the distributed databases remain up-to-date and current: replication and duplication.

1. Replication involves using specialized software that looks for changes in the distributive database. Once the changes have been identified, the replication process makes all the databases look the same. The replication process can be complex and time-consuming depending on the size and number of the distributed databases. This process can also require a lot of time and computer resources.
2. Duplication, on the other hand, has less complexity. It basically identifies one database as a master and then duplicates that database. The duplication process is normally done at a set time after hours. This is to ensure that each distributed location has the same data. In the duplication process, users may change only the master database. This ensures that local data will not be overwritten.

Both replication and duplication can keep the data current in all distributive locations.

Besides distributed database replication and fragmentation, there are many other distributed database design technologies. For example, local autonomy, synchronous and asynchronous distributed database technologies. These technologies' implementation can and does depend on the needs of the business and the sensitivity/confidentiality of the data stored in the database, and hence the price the business is willing to spend on ensuring data security, consistency and integrity.

When discussing access to distributed databases, Microsoft favors the term **distributed query**, which it defines in protocol-specific manner as "[a]ny SELECT, INSERT, UPDATE, or DELETE statement that references tables and rowsets from one or more external OLE DB data sources". Oracle provides a more language-centric view in which distributed queries and distributed transactions form part of **distributed SQL**.

Architecture

A database user accesses the distributed database through:

Local applications

: applications which do not require data from other sites.

Global applications

: applications which do require data from other sites.

A **homogeneous distributed database** has identical software and hardware running all databases instances, and may appear through a single interface as if it were a single database. A **heterogeneous distributed database** may have different hardware, operating systems, database management systems, and even data models for different databases.

Homogeneous DDBMS

In a homogeneous distributed database all sites have identical software and are aware of each other and agree to cooperate in processing user requests. Each site surrenders part of its autonomy in terms of right to change schema or software. A homogeneous DDBMS appears to the user as a single system. The homogeneous system is much easier to design and manage. The following conditions must be satisfied for homogeneous database:

- The operating system used, at each location must be same or compatible.Wikipedia:Avoid weasel wordsWikipedia:Please clarify
- The data structures used at each location must be same or compatible.
- The database application (or DBMS) used at each location must be same or compatible.

Heterogeneous DDBMS

In a heterogeneous distributed database, different sites may use different schema and software. Difference in schema is a major problem for query processing and transaction processing. Sites may not be aware of each other and may provide only limited facilities for cooperation in transaction processing. In heterogeneous systems, different nodes may have different hardware & software and data structures at various nodes or locations are also incompatible. Different computers and operating systems, database applications or data models may be used at each of the locations. For example, one location may have the latest relational database management technology, while another location may store data using conventional files or old version of database management system. Similarly, one location may have the Windows NT operating system, while another may have UNIX. Heterogeneous systems are usually used when individual sites use their own hardware and software. On heterogeneous system, translations are required to allow communication between different sites (or DBMS). In this system, the users must be able to make requests in a database language at their local sites. Usually the SQL database language is used for this purpose. If the hardware is different, then the translation is straightforward, in which computer codes and word-length is changed. The heterogeneous system is often not technically or economically feasible. In this system, a user at one location may be able to read but not update the data at another location.

Important considerations

Care with a distributed database must be taken to ensure the following:

- The distribution is transparent — users must be able to interact with the system as if it were one logical system. This applies to the system's performance, and methods of access among other things.
- Transactions are transparent — each transaction must maintain database integrity across multiple databases. Transactions must also be divided into sub-transactions, each sub-transaction affecting one database system.

There are two principal approaches to store a relation r in a distributed database system:

A) Replication

B) Fragmentation/Partitioning

A) Replication: In replication, the system maintains several identical replicas of the same relation r in different sites.

- Data is more available in this scheme.
- Parallelism is increased when read request is served.
- Increases overhead on update operations as each site containing the replica needed to be updated in order to maintain consistency.
- Multi-datacenter replication provides geographical diversity: http://basho.com/tag/multi-datacenter-replication/

B) Fragmentation: The relation r is fragmented into several relations r_1, r_2, r_3....r_n in such a way that the actual relation could be reconstructed from the fragments and then the fragments are scattered to different locations. There are basically two schemes of fragmentation:

- Horizontal fragmentation - splits the relation by assigning each tuple of r to one or more fragments.
- Vertical fragmentation - splits the relation by decomposing the schema R of relation r.

Advantages

- Management of distributed data with different levels of transparency like network transparency, fragmentation transparency, replication transparency, etc.
- Increase reliability and availability
- Easier expansion
- Reflects organizational structure — database fragments potentially stored within the departments they relate to
- Local autonomy or site autonomy — a department can control the data about them (as they are the ones familiar with it)
- Protection of valuable data — if there were ever a catastrophic event such as a fire, all of the data would not be in one place, but distributed in multiple locations
- Improved performance — data is located near the site of greatest demand, and the database systems themselves are parallelized, allowing load on the databases to be balanced among servers. (A high load on one module of the database won't affect other modules of the database in a distributed database)
- Economics — it may cost less to create a network of smaller computers with the power of a single large computer
- Modularity — systems can be modified, added and removed from the distributed database without affecting other modules (systems)
- Reliable transactions - due to replication of the database
- Hardware, operating-system, network, fragmentation, DBMS, replication and location independence
- Continuous operation, even if some nodes go offline (depending on design)
- Distributed query processing can improve performance
- Distributed transaction management
- Single-site failure does not affect performance of system.
- All transactions follow A.C.I.D. property:

- A-atomicity, the transaction takes place as a whole or not at all
- C-consistency, maps one consistent DB state to another
- I-isolation, each transaction sees a consistent DB
- D-durability, the results of a transaction must survive system failures

The Merge Replication Method is popularly used to consolidate the data between databases.[*citation needed*]

Disadvantages

- Complexity — DBAs may have to do extra work to ensure that the distributed nature of the system is transparent. Extra work must also be done to maintain multiple disparate systems, instead of one big one. Extra database design work must also be done to account for the disconnected nature of the database — for example, joins become prohibitively expensive when performed across multiple systems.
- Economics — increased complexity and a more extensive infrastructure means extra labour costs
- Security — remote database fragments must be secured, and they are not centralized so the remote sites must be secured as well. The infrastructure must also be secured (for example, by encrypting the network links between remote sites).
- Difficult to maintain integrity — but in a distributed database, enforcing integrity over a network may require too much of the network's resources to be feasible
- Inexperience — distributed databases are difficult to work with, and in such a young field there is not much readily available experience in "proper" practice
- Lack of standards — there are no tools or methodologies yet to help users convert a centralized DBMS into a distributed DBMS[*citation needed*]
- Database design more complex — In addition to traditional database design challenges, the design of a distributed database has to consider fragmentation of data, allocation of fragments to specific sites and data replication
- Additional software is required
- Operating system should support distributed environment
- Concurrency control poses a major issue. It can be solved by locking and timestamping.
- Distributed access to data
- Analysis of distributed data

Distributed database management system

A **distributed database** is a database in which storage devices are not all attached to a common processing unit such as the CPU, controlled by a distributed database management system (together sometimes called a distributed database system). It may be stored in multiple computers, located in the same physical location; or may be dispersed over a network of interconnected computers. Unlike parallel systems, in which the processors are tightly coupled and constitute a single database system, a distributed database system consists of loosely-coupled sites that share no physical components.

System administrators can distribute collections of data (e.g. in a database) across multiple physical locations. A distributed database can reside on network servers on the Internet, on corporate intranets or extranets, or on other company networks. Because they store data across multiple computers, distributed databases can improve performance at end-user worksites by allowing transactions to be processed on many machines, instead of being limited to one.[1]

Two processes ensure that the distributed databases remain up-to-date and current: replication and duplication.

1. Replication involves using specialized software that looks for changes in the distributive database. Once the changes have been identified, the replication process makes all the databases look the same. The replication process can be complex and time-consuming depending on the size and number of the distributed databases. This process can also require a lot of time and computer resources.
2. Duplication, on the other hand, has less complexity. It basically identifies one database as a master and then duplicates that database. The duplication process is normally done at a set time after hours. This is to ensure that each distributed location has the same data. In the duplication process, users may change only the master database. This ensures that local data will not be overwritten.

Both replication and duplication can keep the data current in all distributive locations.

Besides distributed database replication and fragmentation, there are many other distributed database design technologies. For example, local autonomy, synchronous and asynchronous distributed database technologies. These technologies' implementation can and does depend on the needs of the business and the sensitivity/confidentiality of the data stored in the database, and hence the price the business is willing to spend on ensuring data security, consistency and integrity.

When discussing access to distributed databases, Microsoft favors the term **distributed query**, which it defines in protocol-specific manner as "[a]ny SELECT, INSERT, UPDATE, or DELETE statement that references tables and rowsets from one or more external OLE DB data sources". Oracle provides a more language-centric view in which distributed queries and distributed transactions form part of **distributed SQL**.

Architecture

A database user accesses the distributed database through:

Local applications

: applications which do not require data from other sites.

Global applications

: applications which do require data from other sites.

A **homogeneous distributed database** has identical software and hardware running all databases instances, and may appear through a single interface as if it were a single database. A **heterogeneous distributed database** may have different hardware, operating systems, database management systems, and even data models for different databases.

Homogeneous DDBMS

In a homogeneous distributed database all sites have identical software and are aware of each other and agree to cooperate in processing user requests. Each site surrenders part of its autonomy in terms of right to change schema or software. A homogeneous DDBMS appears to the user as a single system. The homogeneous system is much easier to design and manage. The following conditions must be satisfied for homogeneous database:

- The operating system used, at each location must be same or compatible.Wikipedia:Avoid weasel wordsWikipedia:Please clarify
- The data structures used at each location must be same or compatible.
- The database application (or DBMS) used at each location must be same or compatible.

Heterogeneous DDBMS

In a heterogeneous distributed database, different sites may use different schema and software. Difference in schema is a major problem for query processing and transaction processing. Sites may not be aware of each other and may provide only limited facilities for cooperation in transaction processing. In heterogeneous systems, different nodes may have different hardware & software and data structures at various nodes or locations are also incompatible. Different computers and operating systems, database applications or data models may be used at each of the locations. For example, one location may have the latest relational database management technology, while another location may store data using conventional files or old version of database management system. Similarly, one location may have the Windows NT operating system, while another may have UNIX. Heterogeneous systems are usually used when individual sites use their own hardware and software. On heterogeneous system, translations are required to allow communication between different sites (or DBMS). In this system, the users must be able to make requests in a database language at their local sites. Usually the SQL database language is used for this purpose. If the hardware is different, then the translation is straightforward, in which computer codes and word-length is changed. The heterogeneous system is often not technically or economically feasible. In this system, a user at one location may be able to read but not update the data at another location.

Important considerations

Care with a distributed database must be taken to ensure the following:

- The distribution is transparent — users must be able to interact with the system as if it were one logical system. This applies to the system's performance, and methods of access among other things.
- Transactions are transparent — each transaction must maintain database integrity across multiple databases. Transactions must also be divided into sub-transactions, each sub-transaction affecting one database system.

There are two principal approaches to store a relation r in a distributed database system:

A) Replication

B) Fragmentation/Partitioning

A) Replication: In replication, the system maintains several identical replicas of the same relation r in different sites.

- Data is more available in this scheme.
- Parallelism is increased when read request is served.
- Increases overhead on update operations as each site containing the replica needed to be updated in order to maintain consistency.
- Multi-datacenter replication provides geographical diversity: http://basho.com/tag/multi-datacenter-replication/

B) Fragmentation: The relation r is fragmented into several relations r_1, r_2, r_3....r_n in such a way that the actual relation could be reconstructed from the fragments and then the fragments are scattered to different locations. There are basically two schemes of fragmentation:

- Horizontal fragmentation - splits the relation by assigning each tuple of r to one or more fragments.
- Vertical fragmentation - splits the relation by decomposing the schema R of relation r.

Advantages

- Management of distributed data with different levels of transparency like network transparency, fragmentation transparency, replication transparency, etc.
- Increase reliability and availability
- Easier expansion
- Reflects organizational structure — database fragments potentially stored within the departments they relate to
- Local autonomy or site autonomy — a department can control the data about them (as they are the ones familiar with it)
- Protection of valuable data — if there were ever a catastrophic event such as a fire, all of the data would not be in one place, but distributed in multiple locations
- Improved performance — data is located near the site of greatest demand, and the database systems themselves are parallelized, allowing load on the databases to be balanced among servers. (A high load on one module of the database won't affect other modules of the database in a distributed database)
- Economics — it may cost less to create a network of smaller computers with the power of a single large computer
- Modularity — systems can be modified, added and removed from the distributed database without affecting other modules (systems)
- Reliable transactions - due to replication of the database
- Hardware, operating-system, network, fragmentation, DBMS, replication and location independence
- Continuous operation, even if some nodes go offline (depending on design)
- Distributed query processing can improve performance
- Distributed transaction management
- Single-site failure does not affect performance of system.
- All transactions follow A.C.I.D. property:
  - A-atomicity, the transaction takes place as a whole or not at all
  - C-consistency, maps one consistent DB state to another
  - I-isolation, each transaction sees a consistent DB
  - D-durability, the results of a transaction must survive system failures

The Merge Replication Method is popularly used to consolidate the data between databases.[*citation needed*]

Disadvantages

- Complexity — DBAs may have to do extra work to ensure that the distributed nature of the system is transparent. Extra work must also be done to maintain multiple disparate systems, instead of one big one. Extra database design work must also be done to account for the disconnected nature of the database — for example, joins become prohibitively expensive when performed across multiple systems.
- Economics — increased complexity and a more extensive infrastructure means extra labour costs
- Security — remote database fragments must be secured, and they are not centralized so the remote sites must be secured as well. The infrastructure must also be secured (for example, by encrypting the network links between remote sites).
- Difficult to maintain integrity — but in a distributed database, enforcing integrity over a network may require too much of the network's resources to be feasible
- Inexperience — distributed databases are difficult to work with, and in such a young field there is not much readily available experience in "proper" practice

Distributed file system

A **clustered file system** is a file system which is shared by being simultaneously mounted on multiple servers. There are several approaches to clustering, most of which do not employ a clustered file system (only direct attached storage for each node). Clustered file systems can provide features like location-independent addressing and redundancy which improve reliability or reduce the complexity of the other parts of the cluster. **Parallel file systems** are a type of clustered file system that spread data across multiple storage nodes, usually for redundancy or performance.[1]

Shared-disk / storage area network

A **shared-disk filesystem** uses a storage-area network (SAN) to provide direct disk access from multiple computers at the block level. Access control and translation from file-level operations that applications use to block-level operations used by the SAN must take place on the client node. The most common type of clustered filesystems is shared-disk filesystem, which—by adding mechanisms for concurrency control—provides a consistent and serializable view of the file system, avoiding corruption and unintended data loss even when multiple clients try to access the same files at the same time. It is a common practice for shared-disk filesystems to employ some sort of a fencing mechanism to prevent data corruption in case of node failures, because an unfenced device can cause data corruption if it loses communication with its sister nodes, and tries to access the same information other nodes are accessing.

The underlying storage area network may use any of a number of block-level protocols, including SCSI, iSCSI, HyperSCSI, ATA over Ethernet (AoE), Fibre Channel, network block device, and InfiniBand.

There are different architectural approaches to a shared-disk filesystem. Some distribute file information across all the servers in a cluster (fully distributed). Others utilize a centralized metadata server. Both achieve the same result of enabling all servers to access all the data on a shared storage device.[*citation needed*]

Examples

- Silicon Graphics (SGI) clustered file system (CXFS)
- Veritas Cluster File System
- DataPlow Nasan File System
- DataPlow SAN File System (SFS)
- IBM General Parallel File System (GPFS)
- Microsoft Cluster Shared Volumes (CSV)
- Oracle Cluster File System (OCFS)
- PolyServe storage solutions
- Quantum StorNext FileSystem (SNFS), ex ADIC, ex CentraVision FileSystem (CVFS)
- Blue Whale Clustered file system (BWFS)
- Red Hat Global File System (GFS)
- Sanbolic Melio FS clustered file system
- Sun QFS
- TerraScale Technologies TerraFS
- VMware VMFS
- Xsan

Distributed file systems

Distributed file systems do not share block level access to the same storage but use a network protocol.[2] These are commonly known as *network file systems*, even though they are not the only file systems that use the network to send data.[*citation needed*] Distributed file systems can restrict access to the file system depending on access lists or capabilities on both the servers and the clients, depending on how the protocol is designed.

The difference between a distributed file system and a distributed data store is that a distributed file system allows files to be accessed using the same interfaces and semantics as local files - e.g. mounting/unmounting, listing directories, read/write at byte boundaries, system's native permission model. Distributed data stores, by contrast, require using a different API or library and have different semantics (most often those of a database).

Design goals

Distributed file systems may aim for "transparency" in a number of aspects. That is, they aim to be "invisible" to client programs, which "see" a system which is similar to a local file system. Behind the scenes, the distributed file system handles locating files, transporting data, and potentially providing other features listed below.

- *Access transparency* is that clients are unaware that files are distributed and can access them in the same way as local files are accessed.
- *Location transparency*; a consistent name space exists encompassing local as well as remote files. The name of a file does not give its location.
- *Concurrency transparency*; all clients have the same view of the state of the file system. This means that if one process is modifying a file, any other processes on the same system or remote systems that are accessing the files will see the modifications in a coherent manner.
- *Failure transparency*; the client and client programs should operate correctly after a server failure.
- *Heterogeneity*; file service should be provided across different hardware and operating system platforms.
- *Scalability*; the file system should work well in small environments (1 machine, a dozen machines) and also scale gracefully to huge ones (hundreds through tens of thousands of systems).
- *Replication transparency*; to support scalability, we may wish to replicate files across multiple servers. Clients should be unaware of this.
- *Migration transparency*; files should be able to move around without the client's knowledge.

History

The Incompatible Timesharing System used virtual devices for transparent inter-machine filesystem access in the 1960s. More file servers were developed in the 1970s. In 1976 Digital Equipment Corporation created the File Access Listener (FAL), an implementation of the Data Access Protocol as part of DECnet Phase II which became the first widely used network file system. In 1985 Sun Microsystems created the file system called "Network File System" (NFS) which became the first widely used Internet Protocol based network file system. Other notable network file systems are Andrew File System (AFS), Apple Filing Protocol (AFP), NetWare Core Protocol (NCP), and Server Message Block (SMB) which is also known as Common Internet File System (CIFS).

Examples

- GFS (Google Inc.)
- Ceph (Inktank)
- MooseFS (Core Technology / Gemius)
- Windows Distributed File System (DFS) (Microsoft)
- FhGFS (Fraunhofer)
- GlusterFS (Red Hat)
- Lustre
- Ibrix

Network attached storage

Network attached storage (NAS) provides both storage and a file system, like a shared disk file system on top of a storage area network (SAN). NAS typically uses file-based protocols (as opposed to block-based protocols a SAN would use) such as NFS (popular on UNIX systems), SMB/CIFS (Server Message Block/Common Internet File System) (used with MS Windows systems), AFP (used with Apple Macintosh computers), or NCP (used with OES and Novell NetWare).

Design considerations

Avoiding single point of failure

The failure of disk hardware or a given storage node in a cluster can create a single point of failure that can result in data loss or unavailability. Fault tolerance and high availability can be provided through data replication of one sort or another, so that data remains intact and available despite the failure of any single piece of equipment. For examples, see the lists of distributed fault-tolerant file systems and distributed parallel fault-tolerant file systems.

Performance

A common performance measurement of a clustered file system is the amount of time needed to satisfy service requests. In conventional systems, this time consists of a disk-access time and a small amount of CPU-processing time. But in a clustered file system, a remote access has additional overhead due to the distributed structure. This includes the time to deliver the request to a server, the time to deliver the response to the client, and for each direction, a CPU overhead of running the communication protocol software.

Concurrency

Concurrency control becomes an issue when more than one person or client is accessing the same file or block and want to update it. Hence updates to the file from one client should not interfere with access and updates from other clients. This problem is more complex with file systems due to concurrent overlapping writes, where different writers write to overlapping regions of the file concurrently.[3] This problem is usually handled by concurrency control or locking which may either be built into the file system or provided by an add-on protocol.

History

IBM mainframes in the 1970s could share physical disks and file systems if each machine had its own channel connection to the drives' control units. In the 1980s, Digital Equipment Corporation's TOPS-20 and VAX/VMS clusters included shared disk filesystems.[*citation needed*]

Distributed data store

A **distributed data store** is a computer network where information is stored on more than one node, often in a replicated fashion. It is usually specifically used to refer to either a distributed database where users store information on a *number of nodes*, or a computer network in which users store information on a *number of peer network nodes*.

Distributed databases

Distributed databases are usually non-relational databases that make a quick access to data over a large number of nodes possible. Some distributed databases expose rich query abilities while others are limited to a key-value store semantics. Examples of limited distributed databases are Google's BigTable, which is much more than a distributed file system or a peer-to-peer network, Amazon's Dynamo and Windows Azure Storage.

As the ability of arbitrary querying is not as important as the availability, designers of distributed data stores have increased the latter at an expense of consistency. But the high-speed read/write access results in reduced consistency, as it is not possible to have both consistency, availability, and partition tolerance of the network, as it has been proven by the CAP theorem.

Peer network node data stores

In peer network data stores, the user can usually reciprocate and allow other users to use their computer as a storage node as well. Information may or may not be accessible to other users depending on the design of the network.

Most peer-to-peer networks do not have distributed data stores in that the user's data is only available when their node is on the network. However, this distinction is somewhat blurred in a system such as BitTorrent, where it is possible for the originating node to go offline but the content to continue to be served. Still, this is only the case for individual files requested by the redistributors, as contrasted with a network such as Freenet where all computers are made available to serve all files.

Distributed data stores typically use an error detection and correction technique. Some distributed data stores (such as Parchive over NNTP) use forward error correction techniques to recover the original file when parts of that file are damaged or unavailable. Others try again to download that file from a different mirror.

Examples

Distributed non-relational databases

- Apache Cassandra, former data store of Facebook
- BigTable, the data store of Google
- Druid (open-source data store), used by Netflix
- Dynamo of Amazon
- HBase, current data store of Facebook's Messaging Platform
- Riak
- Voldemort, data store used by LinkedIn

Peer network node data stores

- BitTorrent
- Chord project
- GNUnet
- Freenet
- Unity, of the software Perfect Dark
- Mnet
- NNTP (the distributed data storage protocol used for Usenet news)
- Storage@home
- Tahoe-LAFS

Heterogeneous Database System

A **heterogeneous database system** is an automated (or semi-automated) system for the integration of heterogeneous, disparate database management systems to present a user with a single, unified query interface.

Heterogeneous database systems (HDBs) are computational models and software implementations that provide heterogeneous database integration.

Problems of heterogeneous database integration

This article does not contain details of distributed database management systems (sometimes known as federated database systems).

Technical heterogeneity

Different file formats, access protocols, query languages etc. Often called syntactic heterogeneity from the point of view of data.

Data model heterogeneity

Different ways of representing and storing the same data. Table decompositions may vary, column names (data labels) may be different (but have the same semantics), data encoding schemes may vary (i.e., should a measurement scale be explicitly included in a field or should it be implied elsewhere). Also referred as schematic heterogeneity.

Semantic heterogeneity

Data across constituent databases may be related but different. Perhaps a database system must be able to integrate genomic and proteomic data. They are related—a gene may have several protein products—but the data are different (nucleotide sequences and amino acid sequences, or hydrophilic or -phobic amino acid sequence and positively or negatively charged amino acids). There may be many ways of looking at semantically similar, but distinct, datasets.

The system may also be required to present "new" knowledge to the user. Relationships may be inferred between data according to rules specified in domain ontologies.

Simple Sloppy Semantic Database

Simple Sloppy Semantic Database (S3DB) is a distributed infrastructure that relies on Semantic Web concepts for management of heterogeneous data. This distributed data management system was first proposed in 2006, following the argumentation the previous year that omics data sets would be more easily managed if fragmented in RDF triples. That first version, 1.0, was focused on the support of an indexing engine for triplestore management. The second version, made available in October 2007, added cross-referencing between triples in distinct S3DB deployments to support it as a distributed infrastructure. The third version was released in July 2008 and exposes its API through a specialized query language[1] accessible as a REST web service. An update of that release (version 3.5) also includes a RESTful SPARQL endpoint. This update introduced a self-update feature which replaces version numbers by date of update. The rationale, core data model, and usage in National Cancer Institute (NIH/NCI) SPORE awards [2] are described and illustrated in a PLoS ONE manuscript published August 13, 2008 and a BMC Bioinformatics manuscript published on July 20, 2010. The following year, S3DB's API was published and was put to use in the management of a clinical trial at MDAnderson Cancer Center using a web application with a self-assembled interface.[3] In 2012, in "Semantic Web meets Integrative Biology: a survey" the features of S3DB were highlighted in an independent assessment. The summary of this assessment was that "S3QL supports a permission control mechanism that allows users to specify contextual minutia such as provenance and access control on the semantic level. The effectiveness of S3QL was illustrated through use cases of IB, such as genomic characterization of cancer and molecular epidemiology of infectious diseases. We expect S3QL or its variations to be accepted as the standard access control mechanism by the SW community". The API's specification is kept at s3ql.org [4]. Distributed transaction

A **distributed transaction** is an operations bundle, in which two or more network hosts are involved. Usually, hosts provide **transactional resources**, while the **transaction manager** is responsible for creating and managing a global transaction that encompasses all operations against such resources. Distributed transactions, as any other transactions, must have all four ACID (atomicity, consistency, isolation, durability) properties, where atomicity guarantees all-or-nothing outcomes for the unit of work (operations bundle).

Open Group, a vendor consortium, proposed the X/Open Distributed Transaction Processing (DTP) Model (X/Open XA), which became a de facto standard for behavior of transaction model components.

Databases are common transactional resources and, often, transactions span a couple of such databases. In this case, a distributed transaction can be seen as a database transaction that must be synchronized (or provide ACID properties) among multiple participating databases which are distributed among different physical locations. The isolation property (the I of ACID) poses a special challenge for multi database transactions, since the (global) serializability property could be violated, even if each database provides it (see also global serializability). In practice most commercial database systems use strong strict two phase locking (SS2PL) for concurrency control, which ensures global serializability, if all the participating databases employ it. (see also commitment ordering for multidatabases.)

A common algorithm for ensuring correct completion of a distributed transaction is the two-phase commit (2PC). This algorithm is usually applied for updates able to commit in a short period of time, ranging from couple of milliseconds to couple of minutes.

There are also long-lived distributed transactions, for example a transaction to book a trip, which consists of booking a flight, a rental car and a hotel. Since booking the flight might take up to a day to get a confirmation, two-phase commit is not applicable here, it will lock the resources for this long. In this case more sophisticated techniques that involve multiple undo levels are used. The way you can undo the hotel booking by calling a desk and cancelling the reservation, a system can be designed to undo certain operations (unless they are irreversibly finished).

In practice, long-lived distributed transactions are implemented in systems based on Web Services. Usually these transactions utilize principles of Compensating transactions, Optimism and Isolation Without Locking. X/Open standard does not cover long-lived DTP.

Several modern technologies, including Enterprise Java Beans (EJBs) and Microsoft Transaction Server (MTS) fully support distributed transaction standards.

Network transparency

Network transparency in its most general sense refers to the ability of a protocol to transmit data over the network in a manner which is transparent (invisible) to those using the applications that are using the protocol.

The term is often incorrectly applied in the context of the X Window System, which is able to transmit graphical data over the network and integrate it seamlessly with applications running and displaying locally.

Databases

In a centralized database system, the only available resource that needs to be shielded from the user is the data (that is, the storage system). In a distributed DBMS, a second resource needs to be managed in much the same manner: the network. Preferably, the user should be protected from the network operational details. Then there would be no difference between database applications that would run on the centralized database and those that would run on a distributed one. This kind of transparency is referred to as **network transparency** or **distribution transparency**. From a database management system (DBMS) perspective, distribution transparency requires that users do not have to specify where data is located.

Some have separated distribution transparency into location transparency and naming transparency.

Location transparency in commands used to perform a task is independent both of the locations of the data, and of the system on which an operation is carried out.

Naming transparency means that a unique name is provided for each object in the database.

Firewalls

Transparency in firewall technology can be defined at the networking (IP or Internet layer) or at the application layer.

Transparency at the IP layer means the client targets the real IP address of the server. If a connection is non-transparent, then the client targets an intermediate host (address), which could be a proxy or a caching server. IP layer transparency could be also defined from the point of server's view. If the connection is transparent, the server sees the real client IP. If it is non-transparent, the server sees the IP of the intermediate host.

Transparency at the application layer means the client application uses the protocol in a different way. An example of a transparent HTTP request for a server:

```
GET / HTTP/1.1
Host: example.org
Connection: Keep-Alive
```

An example non-transparent HTTP request for a proxy (cache):

```
GET http://foo.bar/HTTP/1.1
Proxy-Connection: Keep-Alive
```

Application layer transparency is symmetric when the same working mode is used on both the sides. The transparency is asymmetric when the firewall (usually a proxy) converts server type requests to proxy type or vice versa.

Transparency at the IP layer does not mean automatically application layer transparency.

Long-lived transaction

A **long-lived transaction** is a transaction that spans multiple database transactions. The transaction is considered "long-lived" because its boundaries must, by necessity of business logic, extend past a single database transaction. A long-lived transaction can be thought of as a sequence of database transactions grouped to achieve a single atomic result..

A common example is a multi-step sequence of requests and responses of an interaction with a user through a web client.

A long-lived transaction creates challenges of concurrency control and scalability.

A chief strategy in designing long-lived transactions is optimistic concurrency control with versioning.

So much research work related to these long lived transactions was carried out by several professors from the Oxford University and Michigan State University and the Central University of Hyderabad. Dr. James from the Oxford University created several hypotheses for long-lived transactions. Dr Copperfield of the Michigan State University was regarded highly for his contributions in this field. Dr A B Sagar of Hyderabad Central University has also done very creative work in relating long-lived transactions with financial transactions in Microfinance.

However the study is not complete and is still open to challenges and research issues.

Distributed concurrency control

Distributed concurrency control is the concurrency control of a system distributed over a computer network (Bernstein et al. 1987, Weikum and Vossen 2001).

In *database systems* and *transaction processing* (*transaction management*) distributed concurrency control refers primarily to the concurrency control of a distributed database. It also refers to the concurrency control in a multidatabase (and other multi-transactional object) environment (e.g., federated database, grid computing, and cloud computing environments. A major goal for distributed concurrency control is distributed serializability (or global serializability for multidatabase systems). Distributed concurrency control poses special challenges beyond centralized one, primarily due to communication and computer latency. It often requires special techniques, like distributed lock manager over fast computer networks with low latency, like switched fabric (e.g., InfiniBand). commitment ordering (or commit ordering) is a general serializability technique that achieves distributed serializability (and global serializability in particular) effectively on a large scale, without concurrency control information distribution (e.g., local precedence relations, locks, timestamps, or tickets), and thus without performance penalties that are typical to other serializability techniques (Raz 1992).

The most common distributed concurrency control technique is *strong strict two-phase locking* (SS2PL, also named *rigorousness*), which is also a common centralized concurrency control technique. SS2PL provides both the *serializability*, *strictness*, and *commitment ordering* properties. Strictness, a special case of recoverability, is utilized for effective recovery from failure, and commitment ordering allows participating in a general solution for global serializability. For large-scale distribution and complex transactions, distributed locking's typical heavy performance penalty (due to delays, latency) can be saved by using the atomic commitment protocol, which is needed in a distributed database for (distributed) transactions' atomicity (e.g., two-phase commit, or a simpler one in a reliable

system), together with some local commitment ordering variant (e.g., local SS2PL) instead of distributed locking, to achieve global serializability in the entire system. All the commitment ordering theoretical results are applicable whenever atomic commitment is utilized over partitioned, distributed recoverable (transactional) data, including automatic *distributed deadlock* resolution. Such technique can be utilized also for a large-scale parallel database, where a single large database, residing on many nodes and using a distributed lock manager, is replaced with a (homogeneous) multidatabase, comprising many relatively small databases (loosely defined; any process that supports transactions over partitioned data and participates in atomic commitment complies), fitting each into a single node, and using commitment ordering (e.g., SS2PL, strict CO) together with some appropriate atomic commitment protocol (without using a distributed lock manager).

Consistency model

In computer science, **consistency models** are used in distributed systems like distributed shared memory systems or distributed data stores (such as a filesystems, databases, optimistic replication systems or Web caching). The system supports a given model if operations on memory follow specific rules. The data consistency model specifies a contract between programmer and system, wherein the system guarantees that if the programmer follows the rules, memory will be consistent and the results of memory operations will be predictable.

High level languages, such as C, C++, and Java, partially maintain the contract by translating memory operations into low-level operations in a way that preserves memory semantics. To hold to the contract, compilers may reorder some memory instructions, and library calls such as `pthread_mutex_lock()` encapsulate required synchronization.

Verifying sequential consistency is undecidable in general, even for finite-state cache-coherence protocols.

Consistency models define rules for the apparent order and visibility of updates, and it is a continuum with tradeoffs.

Example

Assume that the following case occurs:

- The row X is replicated on nodes M and N
- The client A writes row X to node N
- After a period of time t, client B reads row X from node M

The consistency model has to determine whether client B sees the write from client A or not.

Types

A non-exhaustive list of consistency models are

- causal consistency
- delta consistency
- entry consistency
- eventual consistency
- fork consistency
- linearizability (also known as strict or atomic consistency)
- one-copy serializability
- PRAM consistency (also known as FIFO consistency)
- release consistency
- sequential consistency
- serializability
- vector-field consistency
- weak consistency
- strong consistency

Distributed Transaction Coordinator

The **Distributed Transaction Coordinator** (MSDTC) service is a component of modern versions of Microsoft Windows that is responsible for coordinating transactions that span multiple resource managers, such as databases, message queues, and file systems. MSDTC is included in Windows 2000 and later operating systems, and is also available for Windows NT 4.0.

MSDTC performs the transaction coordination role for components, usually with COM and .NET architectures. In MSDTC terminology, the director is called the transaction manager.

By default, the Microsoft Distributed Transaction Coordinator (MSDTC) service is installed with Windows 2000. It cannot be uninstalled through Add/Remove Programs.

Two-phase commit protocol

In transaction processing, databases, and computer networking, the **two-phase commit protocol** (2PC) is a type of atomic commitment protocol (ACP). It is a distributed algorithm that coordinates all the processes that participate in a distributed atomic transaction on whether to *commit* or *abort* (*roll back*) the transaction (it is a specialized type of consensus protocol). The protocol achieves its goal even in many cases of temporary system failure (involving either process, network node, communication, etc. failures), and is thus widely utilized.[1][2][3] However, it is not resilient to all possible failure configurations, and in rare cases user (e.g., a system's administrator) intervention is needed to remedy an outcome. To accommodate recovery from failure (automatic in most cases) the protocol's participants use logging of the protocol's states. Log records, which are typically slow to generate but survive failures, are used by the protocol's recovery procedures. Many protocol variants exist that primarily differ in logging strategies and recovery mechanisms. Though usually intended to be used infrequently, recovery procedures compose a substantial portion of the protocol, due to many possible failure scenarios to be considered and supported by the protocol.

In a "normal execution" of any single distributed transaction, i.e., when no failure occurs, which is typically the most frequent situation, the protocol consists of two phases:

1. The *commit-request phase* (or *voting phase*), in which a *coordinator* process attempts to prepare all the transaction's participating processes (named *participants*, *cohorts*, or *workers*) to take the necessary steps for either committing or aborting the transaction and to *vote*, either "Yes": commit (if the transaction participant's local portion execution has ended properly), or "No": abort (if a problem has been detected with the local portion), and
2. The *commit phase*, in which, based on *voting* of the cohorts, the coordinator decides whether to commit (only if *all* have voted "Yes") or abort the transaction (otherwise), and notifies the result to all the cohorts. The cohorts then follow with the needed actions (commit or abort) with their local transactional resources (also called *recoverable resources*; e.g., database data) and their respective portions in the transaction's other output (if applicable).

Note that the two-phase commit (2PC) protocol should not be confused with the two-phase locking (2PL) protocol, a concurrency control protocol.

Assumptions

The protocol works in the following manner: one node is designated the **coordinator**, which is the master site, and the rest of the nodes in the network are designated the **cohorts**. The protocol assumes that there is stable storage at each node with a write-ahead log, that no node crashes forever, that the data in the write-ahead log is never lost or corrupted in a crash, and that any two nodes can communicate with each other. The last assumption is not too restrictive, as network communication can typically be rerouted. The first two assumptions are much stronger; if a node is totally destroyed then data can be lost.

The protocol is initiated by the coordinator after the last step of the transaction has been reached. The cohorts then respond with an **agreement** message or an **abort** message depending on whether the transaction has been processed successfully at the cohort.

Basic algorithm

Commit request phase

or **voting phase**

1. The coordinator sends a **query to commit** message to all cohorts and waits until it has received a reply from all cohorts.
2. The cohorts execute the transaction up to the point where they will be asked to commit. They each write an entry to their *undo log* and an entry to their *redo log*.
3. Each cohort replies with an **agreement** message (cohort votes **Yes** to commit), if the cohort's actions succeeded, or an **abort** message (cohort votes **No**, not to commit), if the cohort experiences a failure that will make it impossible to commit.

Commit phase

or **Completion phase**

Success

If the coordinator received an **agreement** message from *all* cohorts during the commit-request phase:

1. The coordinator sends a **commit** message to all the cohorts.
2. Each cohort completes the operation, and releases all the locks and resources held during the transaction.
3. Each cohort sends an **acknowledgment** to the coordinator.
4. The coordinator completes the transaction when all acknowledgments have been received.

Failure

If *any* cohort votes **No** during the commit-request phase (or the coordinator's timeout **expires**):

1. The coordinator sends a **rollback** message to all the cohorts.
2. Each cohort undoes the transaction using the undo log, and releases the resources and locks held during the transaction.
3. Each cohort sends an **acknowledgement** to the coordinator.
4. The coordinator undoes the transaction when all acknowledgements have been received.

Message flow

```
Coordinator                                         Cohort
                        QUERY TO COMMIT
                -------------------------------->
                        VOTE YES/NO                 prepare*/abort*
                <--------------------------------
commit*/abort*          COMMIT/ROLLBACK
                -------------------------------->
                        ACKNOWLEDGMENT              commit*/abort*
                <--------------------------------
end
```

An * next to the record type means that the record is forced to stable storage.[4]

Disadvantages

The greatest disadvantage of the two-phase commit protocol is that it is a blocking protocol. If the coordinator fails permanently, some cohorts will never resolve their transactions: After a cohort has sent an **agreement** message to the coordinator, it will block until a **commit** or **rollback** is received.

Implementing the two-phase commit protocol

Common architecture

In many cases the 2PC protocol is distributed in a computer network. It is easily distributed by implementing multiple dedicated 2PC components similar to each other, typically named *Transaction managers* (TMs; also referred to as *2PC agents*), that carry out the protocol's execution for each transaction (e.g., The Open Group's X/Open XA). The databases involved with a distributed transaction, the *participants*, both the coordinator and cohorts, *register* to close TMs (typically residing on respective same network nodes as the participants) for terminating that transaction using 2PC. Each distributed transaction has an ad hoc set of TMs, the TMs to which the transaction participants register. A leader, the coordinator TM, exists for each transaction to coordinate 2PC for it, typically the TM of the coordinator database. However, the coordinator role can be transferred to another TM for performance or reliability reasons. Rather than exchanging 2PC messages among themselves, the participants exchange the messages with their respective TMs. The relevant TMs communicate among themselves to execute the 2PC protocol schema above, "representing" the respective participants, for terminating that transaction. With this architecture the protocol is fully distributed (does not need any central processing component or data structure), and scales up with number of network nodes (network size) effectively.

This common architecture is also effective for the distribution of other atomic commitment protocols besides 2PC, since all such protocols use the same voting mechanism and outcome propagation to protocol participants.

Protocol optimizations

Database research has been done on ways to get most of the benefits of the two-phase commit protocol while reducing costs by *protocol optimizations* and protocol operations saving under certain system's behavior assumptions.

Presume abort and Presume commit

Presumed abort or *Presumed commit* are common such optimizations.[5] An assumption about the outcome of transactions, either commit, or abort, can save both messages and logging operations by the participants during the 2PC protocol's execution. For example, when presumed abort, if during system recovery from failure no logged evidence for commit of some transaction is found by the recovery procedure, then it assumes that the transaction has been aborted, and acts accordingly. This means that it does not matter if aborts are logged at all, and such logging can be saved under this assumption. Typically a penalty of additional operations is paid during recovery from failure, depending on optimization type. Thus the best variant of optimization, if any, is chosen according to failure and transaction outcome statistics.

Tree two-phase commit protocol

The **Tree 2PC protocol** (also called *Nested 2PC*, or *Recursive 2PC*) is a common variant of 2PC in a computer network, which better utilizes the underlying communication infrastructure. The participants in a distributed transaction are typically invoked in an order which defines a tree structure, the *invocation tree*, where the participants are the nodes and the edges are the invocations (communication links). The same tree is commonly utilized to complete the transaction by a 2PC protocol, but also another communication tree can be utilized for this, in principle. In a tree 2PC the coordinator is considered the root ("top") of a communication tree (inverted tree),

while the cohorts are the other nodes. The coordinator can be the node that originated the transaction (invoked recursively (transitively) the other participants), but also another node in the same tree can take the coordinator role instead. 2PC messages from the coordinator are propagated "down" the tree, while messages to the coordinator are "collected" by a cohort from all the cohorts below it, before it sends the appropriate message "up" the tree (except an **abort** message, which is propagated "up" immediately upon receiving it or if the current cohort initiates the abort).

The **Dynamic two-phase commit** (Dynamic two-phase commitment, D2PC) **protocol**[6] is a variant of Tree 2PC with no predetermined coordinator. It subsumes several optimizations that have been proposed earlier. **Agreement** messages (**Yes** votes) start to propagate from all the leaves, each leaf when completing its tasks on behalf of the transaction (becoming *ready*). An intermediate (non leaf) node sends when *ready* an **agreement** message to the last (single) neighboring node from which **agreement** message has not yet been received. The coordinator is determined dynamically by racing **agreement** messages over the transaction tree, at the place where they collide. They collide either at a transaction tree node, to be the coordinator, or on a tree edge. In the latter case one of the two edge's nodes is elected as a coordinator (any node). D2PC is time optimal (among all the instances of a specific transaction tree, and any specific Tree 2PC protocol implementation; all instances have the same tree; each instance has a different node as coordinator): By choosing an optimal coordinator D2PC commits both the coordinator and each cohort in minimum possible time, allowing the earliest possible release of locked resources in each transaction participant (tree node).

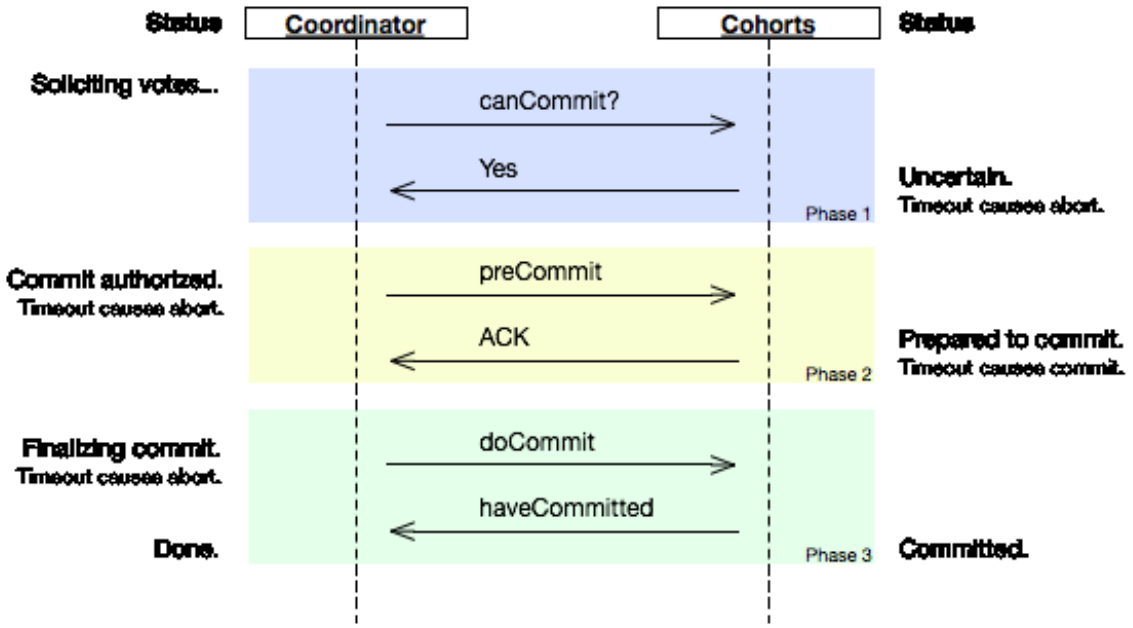
Three-phase commit protocol

In computer networking and databases, the **three-phase commit protocol** (3PC) is a distributed algorithm which lets all nodes in a distributed system agree to commit a transaction. Unlike the two-phase commit protocol (2PC) however, 3PC is non-blocking. Specifically, 3PC places an upper bound on the amount of time required before a transaction either commits or aborts. This property ensures that if a given transaction is attempting to commit via 3PC and holds some resource locks, it will release the locks after the timeout.

3PC was originally described by Dale Skeen and Michael Stonebraker in their paper, “A Formal Model of Crash Recovery in a Distributed System”. In that work, they modeled 2PC as a system of non-deterministic finite state automata and proved that it is not resilient to a random single site failure. The basic observation is that in 2PC, while one site is in the “prepared to commit” state, the other may be in either the “commit” or the “abort” state. From this analysis, they developed 3PC to avoid such states and it is thus resilient to such failures.

Protocol Description

In describing the protocol, we use terminology similar to that used in the two-phase commit protocol. Thus we have a single coordinator site leading the transaction and a set of one or more cohorts being directed by the coordinator.



Coordinator

1. The coordinator receives a transaction request. If there is a failure at this point, the coordinator aborts the transaction (i.e. upon recovery, it will consider the transaction aborted). Otherwise, the coordinator sends a **canCommit?** message to the cohorts and moves to the waiting state.
2. If there is a failure, timeout, or if the coordinator receives a **No** message in the waiting state, the coordinator aborts the transaction and sends an **abort** message to all cohorts. Otherwise the coordinator will receive **Yes** messages from all cohorts within the time window, so it sends **preCommit** messages to all cohorts and moves to the prepared state.
3. If the coordinator succeeds in the prepared state, it will move to the commit state. However if the coordinator times out while waiting for an acknowledgement from a cohort, it will abort the transaction. In the case where all acknowledgements are received, the coordinator moves to the commit state as well.

Cohort

1. The cohort receives a **canCommit?** message from the coordinator. If the cohort agrees it sends a **Yes** message to the coordinator and moves to the prepared state. Otherwise it sends a **No** message and aborts. If there is a failure, it moves to the abort state.
2. In the prepared state, if the cohort receives an **abort** message from the coordinator, fails, or times out waiting for a commit, it aborts. If the cohort receives a **preCommit** message, it sends an **ACK** message back and awaits a final **commit** or **abort**.
3. If, after a cohort member receives a **preCommit** message, the coordinator fails or times out, the cohort member goes forward with the commit.

Motivation

A Two-phase commit protocol cannot dependably recover from a failure of both the **coordinator** and a cohort member during the **Commit phase**. If only the **coordinator** had failed, and no cohort members had received a **commit** message, it could safely be inferred that no **commit** had happened. If, however, both the **coordinator** and a cohort member failed, it is possible that the failed cohort member was the first to be notified, and had actually done the **commit**. Even if a new **coordinator** is selected, it cannot confidently proceed with the operation until it has received an agreement from **all** cohort members ... and hence must block until all cohort members respond.

The Three-phase commit protocol eliminates this problem by introducing the **Prepared to commit** state. If the **coordinator** fails before sending **preCommit** messages, the **cohort** will unanimously agree that the operation was **aborted**. The **coordinator** will not send out a **doCommit** message until **all** cohort members have **ACK**ed that they are **Prepared to commit**. This eliminates the possibility that **any** cohort member actually completed the transaction before **all** cohort members were aware of the decision to do so (an ambiguity that necessitated indefinite blocking in the Two-phase commit protocol).

Disadvantages

The main disadvantage to this algorithm is that it cannot recover in the event the network is segmented in any manner. The original 3PC algorithm assumes a fail-stop model, where processes fail by crashing and crashes can be accurately detected, and does not work with network partitions or asynchronous communication.

Keidar and Dolev's E3PC algorithm eliminates this disadvantage.

The protocol requires at least 3 round trips to complete, needing a minimum of 3 round trip times (RTTs). This is potentially a long latency to complete each transaction.

References

Xeround

Xeround is a provider of cloud database software, launched in 2005.[1] The company was founded by Sharon Barkai and Gilad Zlotkin. Zlotkin, a former research fellow at MIT Sloan School of Management,[2] founded five other startups including Radview (NASDAQ:RDVW). Israeli financial newspaper Globes ranked the company as one of Israel's most promising start-ups in 2006.[3]

Xeround's product was initially used by Telecom providers, including T-Mobile; in 2009 the company added a MySQL front end to its product,[4] making it applicable to a mass market of 12 million MySQL applications.[5] The product allows MySQL users to scale their database and achieve high availability on cloud platforms like Amazon EC2.[] The beta version of the service was reported to be used by 2000 organizations;[6][7][8][9] General Availability was announced in June 2011.[10] According to CNET blogger Dave Rosenberg, Xeround's MySQL support makes it "well positioned to take a leadership position in the database market".[11]

On May 1, 2013 Xeround announced to its paid customers that they were shutting down the Cloud Database Service and all data must be migrated before being dropped on May 15, 2013

Product

Xeround provides a cloud database service for applications based on the open source edition of the MySQL database (MySQL is currently owned by Oracle). The product addresses two related problems: it is complex to run databases on the cloud, especially if high availability is needed; and databases in general are difficult to scale, as data throughput and volumes grow.[12] A cloud database service solves both problems, by managing the database on the cloud and taking care of scalability and high availability, in a way that is transparent to the application. Instead of connecting to a local instance of MySQL, applications can connect to Xeround's cloud database, and are then free to scale as needed. Because Xeround is an in-memory distributed database, it is currently limited up to 50 Gigabytes of data.[13] Xeround gives a no downtime SLA guarantee [14]. The service offers pay-per-use pricing, calculated per Gigabyte per hour, with an additional charge for data transfer for large databases.[15]

Xeround offers its service on several cloud platforms - as of September 2011, Xeround supported Amazon EC2, RackSpace,[16] and Heroku,[17] and is planning to support additional providers. As of March 2011, Xeround was the only commercially available product which supports more than one cloud provider, allowing users to move their databases freely between cloud platforms without being locked in.[18]

While Xeround uses the open source version of MySQL, the cloud database software itself is not open source. Another distinction is that while Xeround offers MySQL as a front-end, on the back-end it is a NoSQL data storage system distributed on a large number of physical nodes - so it is not subject to the scalability limitations of regular MySQL databases.

On 1 May 2013 Xeround announced via an e-mail to customers that they would no longer be providing their service. The service is to end on 15 May 2013. [19]

Company timeline

- 2005 - Xeround is founded by Sharon Barkai and Gilad Zlotkin, raises $6.5 million in Series A funding, focuses initially on distributed database software for Telecom providers.
- 2006 - Xeround ranked as one of Israel's most promising start-ups by Israeli financial newspaper Globes.
- 2008 - Xeround raises an additional $16 million in Series B funding.[20]
- 2009 - Xeround recruits Razi Sharir as CEO and repositions its product as a cloud database service with a MySQL front-end.
- 2010 - Xeround launches beta version of its database service.[21]
- 2011 - Xeround announces General Availability of its cloud database service, and raises an additional $4 million in its final financing round.
- 2011 - Xeround Raises $9.3M From Benchmark And Others.[22]

Competitors and alternatives

Xeround's primary competitors are database services offered by the large cloud vendors, Amazon Relational Database Service and Database.com by SalesForce. Other cloud database providers mentioned by industry sources[23] are Microsoft Azure SQL Database, NimbusDB, ClearDB, ParAccel, as well as NoSQL key-value data stores such as Amazon SimpleDB, Google AppEngine Data Store, Couchbase Server, and Cloudant.

Database users running their applications on the cloud also have the option of installing databases in a "do it yourself" manner instead of paying for a cloud database service. This involves purchasing a machine instance on a cloud computing platform like Amazon EC2, and manually installing a database. This method is considered to be less expensive, but more complex, than using an "out of the box" database service like Xeround.[24]

Next Generation

Vector-field consistency

Vector-Field Consistency[1] is a consistency model for replicated data (for example, objects), initially described in a paper which was awarded the best-paper prize in the ACM/IFIP/Usenix Middleware Conference 2007. It has since been enhanced for increased scalability and fault-tolerance in a recent paper.

Description

This consistency model was initially designed for replicated data management in adhoc gaming in order to minimize bandwidth usage without sacrificing playability. Intuitively, it captures the notion that although players require, wish, and take advantage of information regarding the whole of the game world (as opposed to a restricted view to rooms, arenas, etc. of limited size employed in many multiplayer games), they need to know information with greater freshness, frequency, and accuracy as other game entities are located closer and closer to the player's position.

It prescribes a multidimensional divergence bounding scheme, based on a vector field that employs consistency vectors k=(θ,σ,ν), standing for maximum allowed **t**ime - or replica staleness, **s**equence - or missing updates, and **v**alue[2] - or user-defined measured replica divergence, applied to all space coordinates in game scenario or world.

The consistency vector-fields emanate from field-generators designated as pivots (for example, players) and field intensity attenuates as distance grows from these pivots in concentric or square-like regions. This consistency model unifies locality-awareness techniques employed in message routing and consistency enforcement for multiplayer games, with divergence bounding techniques traditionally employed in replicated database and web scenarios.

Notes

[1] Designation coined by L. Veiga.

[2] Since in the Greek alphabet there was no letter for the *vee* sound, the *nu* letter was preferred for its resemblance with the roman V, for *v*alue, instead of β (*beta*) for the *vee* sound in contemporary Greek speaking.

• Campus (CAN)
• Backbone
• Metropolitan (MAN)
• Wide (WAN)
• Cloud (IAN)
• Internet
• Interplanetary Internet
• Intergalactic Computer Network

• v • t • e [1]

A **storage area network** (**SAN**) is a dedicated network that provides access to consolidated, block level data storage. SANs are primarily used to enhance storage devices, such as disk arrays, tape libraries, and optical jukeboxes, accessible to servers so that the devices appear like locally attached devices to the operating system. A SAN typically has its own network of storage devices that are generally not accessible through the local area network by other devices. The cost and complexity of SANs dropped in the early 2000s to levels allowing wider adoption across both enterprise and small to medium sized business environments.

A SAN does not provide file abstraction, only block-level operations. However, file systems built on top of SANs do provide file-level access, and are known as *SAN filesystems* or shared disk file systems.

Storage

Historically, data centers first created "islands" of SCSI disk arrays as direct-attached storage (DAS), each dedicated to an application, and visible as a number of "virtual hard drives" (i.e. LUNs). Essentially, a SAN consolidates such storage islands together using a high-speed network.

Operating systems maintain their own file systems on their own dedicated, non-shared LUNs, as though they were local to themselves. If multiple systems were simply to attempt to share a LUN, these would interfere with each other and quickly corrupt the data. Any planned sharing of data on different computers within a LUN requires advanced solutions, such as SAN file systems or clustered computing.

Despite such issues, SANs help to increase storage capacity utilization, since multiple servers consolidate their private storage space onto the disk arrays.

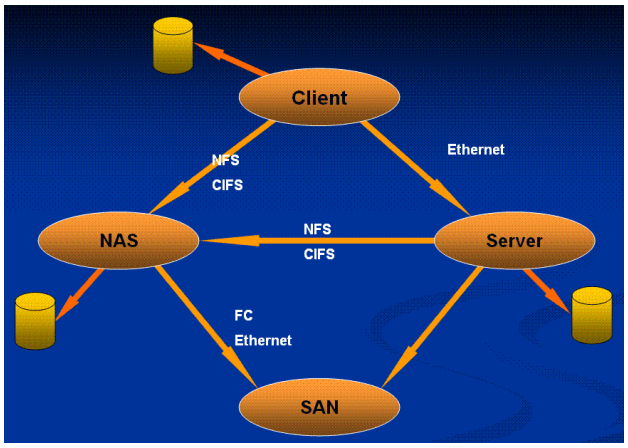
Common uses of a SAN include provision of transactionally accessed data that require high-speed block-level access to the hard drives such as email servers, databases, and high usage file servers.

SAN and NAS

NAS, Network Attached Storage was a solution to the problems of Direct Attached Storage (DAS). The solution was that servers would share a connection to the storage devices via a network connection through the LAN. This set up allows the server to be used loaded with software and applications instead of being split between two duties. With the old DAS setup the server would be split between application use and storage use. With NAS there is no longer a need for support of the traditional storage interface (SCSI) and now the server or client may access NAS storage with a network connection. The drawback to this is that there is no longer a high-speed connection between the CPU and storage units – they still must use the LAN to communicate and this creates bandwidth bottlenecks. In addition requests are processed using file access protocols and CPU cycles must be used to convert into block requests that a server may use to retrieve files and information. This has relegated NAS to be used as data backup more than anything else [*citation needed*].

SAN-NAS hybrid

Despite the differences between SAN and NAS, it is possible to create solutions that include both technologies.[*citation needed*]



Hybrid using DAS, NAS and SAN technologies.

Benefits

Sharing storage usually simplifies storage administration and adds flexibility since cables and storage devices do not have to be physically moved to shift storage from one server to another.

Other benefits include the ability to allow servers to boot from the SAN itself. This allows for a quick and easy replacement of faulty servers since the SAN can be reconfigured so that a replacement server can use the LUN of the faulty server. While this area of technology is still new, many view it as being the future of the enterprise datacenter.

SANs also tend to enable more effective disaster recovery processes. A SAN could span a distant location containing a secondary storage array. This enables storage replication either implemented by disk array controllers, by server software, or by specialized SAN devices. Since IP WANs are often the least costly method of long-distance transport, the Fibre Channel over IP (FCIP) and iSCSI protocols have been developed to allow SAN extension over IP networks. The traditional physical SCSI layer could only support a few meters of distance - not nearly enough to ensure business continuance in a disaster.

The economic consolidation of disk arrays has accelerated the advancement of several features including I/O caching, snapshotting, and volume cloning (Business Continuance Volumes or BCVs).

Network types

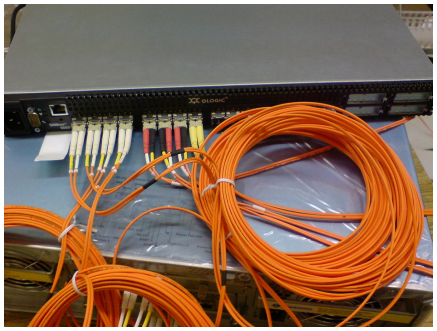
Most storage networks use the SCSI protocol for communication between servers and disk drive devices. A mapping layer to other protocols is used to form a network:

- ATA over Ethernet (AoE), mapping of ATA over Ethernet
- Fibre Channel Protocol (FCP), the most prominent one, is a mapping of SCSI over Fibre Channel
- Fibre Channel over Ethernet (FCoE)
- ESCON over Fibre Channel (FICON), used by mainframe computers
- HyperSCSI, mapping of SCSI over Ethernet
- iFCP or SANoIP mapping of FCP over IP
- iSCSI, mapping of SCSI over TCP/IP
- iSCSI Extensions for RDMA (iSER), mapping of iSCSI over InfiniBand

Storage networks may also be built using SAS and SATA technologies. SAS evolved from SCSI direct-attached storage. SATA evolved from IDE direct-attached storage. SAS and SATA devices can be networked using SAS Expanders.

SAN infrastructure

SANs often use a Fibre Channel fabric topology - an infrastructure specially designed to handle storage communications. It provides faster and more reliable access than higher-level protocols used in NAS. A fabric is similar in concept to a network segment in a local area network. A typical Fibre Channel SAN fabric is made up of a number of Fibre Channel switches.



Qlogic SAN-switch with optical Fibre Channel connectors installed.

Today, all major SAN equipment vendors also offer some form of Fibre Channel routing solution, and these bring substantial scalability benefits to the SAN architecture by allowing data to cross between different fabrics without merging them. These offerings use proprietary protocol elements, and the top-level architectures being promoted are radically different. They often enable mapping Fibre Channel traffic over IP or over SONET/SDH.

Compatibility

One of the early problems with Fibre Channel SANs was that the switches and other hardware from different manufacturers were not compatible. Although the basic storage protocols FCP were always quite standard, some of the higher-level functions did not interoperate well. Similarly, many host operating systems would react badly to other operating systems sharing the same fabric. Many solutions were pushed to the market before standards were finalized and vendors have since innovated around the standards[*citation needed*].

SANs in media and entertainment

Video editing workgroups require very high data transfer rates and very low latency. Outside of the enterprise market, this is one area that greatly benefits from SANs.

SANs in Media and Entertainment are often referred to as Serverless SANs due to the nature of the configuration which places the video workflow (ingest, editing, playout) clients directly on the SAN rather than attaching to servers. Control of data flow is managed by a distributed file system such as StorNext by Quantum.

Per-node bandwidth usage control, sometimes referred to as Quality of Service (QoS), is especially important in video workgroups as it ensures fair and prioritized bandwidth usage across the network, if there is insufficient open bandwidth available.

Storage virtualization

Storage virtualization is the process of abstracting logical storage from physical storage. The physical storage resources are aggregated into storage pools, from which the logical storage is created. It presents to the user a logical space for data storage and transparently handles the process of mapping it to the physical location, a concept called location transparency. This is implemented in modern disk arrays, often using vendor proprietary solutions. However, the goal of storage virtualization is to group multiple disk arrays from different vendors, scattered over a network, into a single storage device. The single storage device can then be managed uniformly. [*citation needed*]

SAN Storage QoS (Quality of Service)

SAN Storage QoS (Quality of Service) is the coordination of capacity and performance in a dedicated storage area network. This enables the desired storage performance to be calculated and maintained for network customers accessing the device.

Key factors that affect Storage Area Network QoS(Quality of Service) are:

- Bandwidth – The rate of data throughput available on the system.
- Latency – The time delay for a read/write operation to execute.
- Queue depth – The number of outstanding operations waiting to execute to the underlying disks (Traditional or SSD).

QoS can be impacted in a SAN storage system by unexpected increase in data traffic (usage spike) from one network user that can cause performance to decrease for other users on the same network. This can be known as the “Noisy Neighbor Effect.” When QoS services are enabled in a SAN storage system, the “Noisy Neighbor Effect” can be prevented and network storage performance can be accurately predicted.

Using SAN storage QoS is in contrast to using disk over-provisioning in a SAN environment. Over-provisioning can be used to provide additional capacity to compensate for peak network traffic loads. However, where network loads are not predictable, over-provisioning can eventually cause all bandwidth to be fully consumed and latency to increase significantly resulting in SAN performance degradation.

Partition (database)

A **partition** is a division of a logical database or its constituent elements into distinct independent parts. Database partitioning is normally done for manageability, performance or availability reasons.

Benefits of multiple partitions

A popular and favourable application of partitioning is in a distributed database management system. Each partition may be spread over multiple nodes, and users at the node can perform local transactions on the partition. This increases performance for sites that have regular transactions involving certain views of data, whilst maintaining availability and security.

Partitioning criteria

Current high end relational database management systems provide for different criteria to split the database. They take a *partitioning key* and assign a partition based on certain criteria. Common criteria are:

Range partitioning

> Selects a partition by determining if the partitioning key is inside a certain range. An example could be a partition for all rows where the column `zipcode` has a value between `70000` and `79999`.

List partitioning

> A partition is assigned a list of values. If the partitioning key has one of these values, the partition is chosen. For example all rows where the column `Country` is either `Iceland`, `Norway`, `Sweden`, `Finland` or `Denmark` could build a partition for the Nordic countries.

Hash partitioning

> The value of a hash function determines membership in a partition. Assuming there are four partitions, the hash function could return a value from 0 to 3.

Composite partitioning allows for certain combinations of the above partitioning schemes, by for example first applying a range partitioning and then a hash partitioning. Consistent hashing could be considered a composite of hash and list partitioning where the hash reduces the key space to a size that can be listed.

Partitioning methods

The partitioning can be done by either building separate smaller databases (each with its own tables, indices, and transaction logs), or by splitting selected elements, for example just one table.

Horizontal partitioning (also see ***shard***) involves putting different rows into different tables. Perhaps customers with ZIP codes less than 50000 are stored in CustomersEast, while customers with ZIP codes greater than or equal to 50000 are stored in CustomersWest. The two partition tables are then CustomersEast and CustomersWest, while a view with a union might be created over both of them to provide a complete view of all customers.

Vertical partitioning involves creating tables with fewer columns and using additional tables to store the remaining columns.[1] Normalization also involves this splitting of columns across tables, but vertical partitioning goes beyond that and partitions columns even when already normalized. Different physical storage might be used to realize vertical partitioning as well; storing infrequently used or very wide columns on a different device, for example, is a method of vertical partitioning. Done explicitly or implicitly, this type of partitioning is called "row splitting" (the row is split by its columns). A common form of vertical partitioning is to split dynamic data (slow to find) from static data (fast to find) in a table where the dynamic data is not used as often as the static. Creating a view across the two newly created tables restores the original table with a performance penalty, however performance will increase

when accessing the static data e.g. for statistical analysis.

Shared nothing architecture

A **shared nothing architecture** (**SN**) is a distributed computing architecture in which each node is independent and self-sufficient, and there is no single point of contention across the system. More specifically, none of the nodes share memory or disk storage.

People typically contrast SN with systems that keep a large amount of centrally-stored state information, whether in a database, an application server, or any other similar single point of contention. While SN is best known in the context of web development, the concept predates the web: Michael Stonebraker at the University of California, Berkeley used the term in a 1986 database paper.[1] In it he mentions existing commercial implementations of the architecture (although none are named explicitly). Teradata, which delivered its first system in 1983, was probably one of those commercial implementations. Tandem Computers officially released NonStop SQL, a shared nothing database, in 1984. [2]

Shared nothing is popular for web development because of its scalability. As Google has demonstrated, a pure SN system can scale almost infinitely simply by adding nodes in the form of inexpensive computers, since there is no single bottleneck to slow the system down. Google calls this *sharding*. A SN system typically partitions its data among many nodes on different databases (assigning different computers to deal with different users or queries), or may require every node to maintain its own copy of the application's data, using some kind of coordination protocol. This is often referred to as *database sharding*.

There is some doubt about whether a web application with many independent web nodes but a single, shared database (clustered or otherwise) should be counted as SN. One of the approaches to achieve SN architecture for stateful applications (which typically maintain state in a centralized database) is the use of a data grid, also known as distributed caching. This still leaves the centralized database as a single point of failure.

Shared nothing architectures have become prevalent in the data warehousing space. There is much debate as to whether the shared nothing approach is superior to shared Disk[3] with sound arguments presented by both camps. Shared nothing architectures certainly take longer to respond to queries that involve joins over large data sets from different partitions (machines). However the potential for scaling is huge.[4]

What is shared?

While there is no single point of contention within the software/hardware components of SN systems, it should be noted that information from disparate nodes may still need to be reintegrated at some point. Such points occur wherever an information system that is outside the SN architecture queries information from disparate nodes within the SN architecture for a single purpose. Examples of such external nodes might be:

1. persons (minds) who look at two SN nodes and decide that they hold or process data about the same thing (simply recognising that two nodes belong to the same SN system would be sufficient)
2. any software/hardware system that is written to query different nodes within the SN architecture

Shard (database architecture)

A **database shard** is a horizontal partition in a database or search engine. Each individual partition is referred to as a **shard** or **database shard**.

Database architecture

Horizontal partitioning is a database design principle whereby *rows* of a database table are held separately, rather than being split into columns (which is what normalization and vertical partitioning do, to differing extents). Each partition forms part of a **shard**, which may in turn be located on a separate database server or physical location.

There are numerous advantages to this partitioning approach. Since the tables are divided and distributed into multiple servers, the total number of rows in each table in each database is reduced. This reduces index size, which generally improves search performance. A database shard can be placed on separate hardware, and multiple shards can be placed on multiple machines. This enables a distribution of the database over a large number of machines, which means that the database performance can be spread out over multiple machines, greatly improving performance. In addition, if the database shard is based on some real-world segmentation of the data (e.g., European customers v. American customers) then it may be possible to infer the appropriate shard membership easily and automatically, and query only the relevant shard.

In practice, sharding is far more complex. Although it has been done for a long time by hand-coding (especially where rows have an obvious grouping, as per the example above), this is often inflexible. There is a desire to support sharding automatically, both in terms of adding code support for it, and for identifying candidates to be sharded separately. Consistent hashing is one form of automatic sharding to spread large loads across multiple smaller services and servers.

Where distributed computing is used to separate load between multiple servers (either for performance or reliability reasons), a shard approach may also be useful.

Shards compared to horizontal partitioning

Horizontal partitioning splits one or more tables by row, usually within a *single* instance of a schema and a database server. It may offer an advantage by reducing index size (and thus search effort) provided that there is some obvious, robust, implicit way to identify in which table a particular row will be found, without first needing to search the index, e.g., the classic example of the '`CustomersEast`' and '`CustomersWest`' tables, where their zip code already indicates where they will be found.

Sharding goes beyond this: it partitions the problematic table(s) in the same way, but it does this across potentially *multiple* instances of the schema. The obvious advantage would be that search load for the large partitioned table can now be split across multiple servers (logical or physical), not just multiple indexes on the same logical server.

Splitting shards across multiple isolated instances requires more than simple horizontal partitioning. The hoped-for gains in efficiency would be lost, if querying the database required *both* instances to be queried, just to retrieve a simple dimension table. Beyond partitioning, sharding thus splits large partitionable tables across the servers, while smaller tables are replicated as complete units.

This is also why sharding is related to a shared nothing architecture—once sharded, each shard can live in a totally separate logical schema instance / physical database server / data center / continent. There is no ongoing need to retain shared access (from between shards) to the other unpartitioned tables in other shards.

This makes replication across multiple servers easy (simple horizontal partitioning does not). It is also useful for worldwide distribution of applications, where communications links between data centers would otherwise be a bottleneck.

There is also a requirement for some notification and replication mechanism between schema instances, so that the unpartitioned tables remain as closely synchronized as the application demands. This is a complex choice in the architecture of sharded systems: approaches range from making these effectively read-only (updates are rare and batched), to dynamically replicated tables (at the cost of reducing some of the distribution benefits of sharding) and many options in between.

Support for shards

CUBRID

: CUBRID supports sharding from version 9.0

dbShards

: CodeFutures dbShards is a product dedicated to database shards.

eXtreme Scale

: eXtreme Scale is a cross-process in-memory key/value datastore (a variety of NoSQL datastore). It uses sharding to achieve scalability across processes for both data and MapReduce-style parallel processing.[1]

Hibernate ORM

: Hibernate Shards provides support for shards, although there has been little activity since 2007.

IBM Informix

: IBM supports sharding in Informix since version 12.1 xC1 as part of the MACH11 technology. Informix 12.10 xC2 added full compatibility with MongoDB drivers, allowing the mix of regular relational tables with NoSQL collections, still supporting sharding, failover and ACID properties.

MongoDB

: MongoDB supports sharding from version 1.6

MySQL Cluster

Auto-Sharding: Database is automatically and transparently partitioned across low cost commodity nodes, allowing scale-out of read and write queries, without requiring changes to the application.

Plugin for Grails

Grails supports sharding using the Grails Sharding Plugin.

Ruby ActiveRecord

Octopus works as a database sharding and replication extension for the ActiveRecord ORM.

ScaleBase's Data Traffic Manager

ScaleBase's Data Traffic Manager is a software product dedicated to automating MySQL database sharding without requiring changes to applications.

Solr Search Server

Solr enterprise search server provides sharding capabilities.

Spanner

Spanner is Google's global scale distributed database that shards data across multiple Paxos state machines to scale to "millions of machines across hundreds of datacenters and trillions of database rows".

SQLAlchemy ORM

SQLAlchemy is an object-relational mapper for the Python programming language that provides sharding capabilities.

SQL Azure

Microsoft supports sharding in SQL Azure through "federations".

Disadvantages of sharding

Sharding a database table before it has been optimized locally causes premature complexity. Sharding should be used only when all other options for optimization are inadequate. The introduced complexity of database sharding causes the following potential problems:

- **Increased complexity of SQL** - Increased bugs because the developers have to write more complicated SQL to handle sharding logic.
- **Sharding introduces complexity** - The sharding software that partitions, balances, coordinates, and ensures integrity can fail.
- **Single point of failure** - Corruption of one shard due to network/hardware/systems problems causes failure of the entire table.
- **Failover servers more complex** - Failover servers must themselves have copies of the fleets of database shards.
- **Backups more complex** - Database backups of the individual shards must be coordinated with the backups of the other shards.
- **Operational complexity added** - Adding/removing indexes, adding/deleting columns, modifying the schema becomes much more difficult.

These historical complications of do-it-yourself sharding are now being addressed by independent software vendors who provide autosharding solutions.

Quorum (distributed computing)

A **quorum** is the minimum number of votes that a distributed transaction has to obtain in order to be allowed to perform an operation in a distributed system. A **quorum**-based technique is implemented to enforce consistent operation in a distributed system.

Quorum-based techniques in distributed database systems

Quorum-based voting can be used as a replica control method , as well as a commit method to ensure transaction atomicity in the presence of network partitioning.

Quorum-based voting in commit protocols

In a distributed database system, a transaction could be executing its operations at multiple sites. Since atomicity requires every distributed transaction to be atomic, the transaction must have the same fate (commit or abort) at every site. In case of network partitioning, sites are partitioned and the partitions may not be able to communicate with each other. This is where a quorum-based technique comes in. The fundamental idea is that a transaction is executed if the majority of sites vote to execute it.

Every site in the system is assigned a vote V_i. Let us assume that the total number of votes in the system is V and the abort and commit quorums are V_a and V_c, respectively. Then the following rules must be obeyed in the implementation of the commit protocol:

1. $V_a + V_c > V$, where $0 < V_c, V_a \leq V$.
2. Before a transaction commits, it must obtain a commit quorum V_c.
   The total of at least one site that is prepared to commit and zero or more sites waiting $\geq V_c$.
3. Before a transaction aborts, it must obtain an abort quorum V_a
   The total of zero or more sites that are prepared to abort or any sites waiting $\geq V_a$.

The first rule ensures that a transaction cannot be committed and aborted at the same time. The next two rules indicate the votes that a transaction has to obtain before it can terminate one way or the other.

Quorum-based voting for replica control

In replicated databases, a data object has copies present at several sites. To ensure serializability, no two transactions should be allowed to read or write a data item concurrently. In case of replicated databases, a quorum-based replica control protocol can be used to ensure that no two copies of a data item are read or written by two transactions concurrently.

The quorum-based voting for replica control is due to [Gifford, 1979] . Each copy of a replicated data item is assigned a vote. Each operation then has to obtain a *read quorum* (V_r) or a *write quorum* (V_w) to read or write a data item, respectively. If a given data item has a total of V votes, the quorums have to obey the following rules:

1. $V_r + V_w > V$
2. $V_w > V/2$

The first rule ensures that a data item is not read and written by two transactions concurrently. The second rule ensures that two write operations from two transactions cannot occur concurrently on the same data item. The two rules ensure that one-copy serializability is maintained.

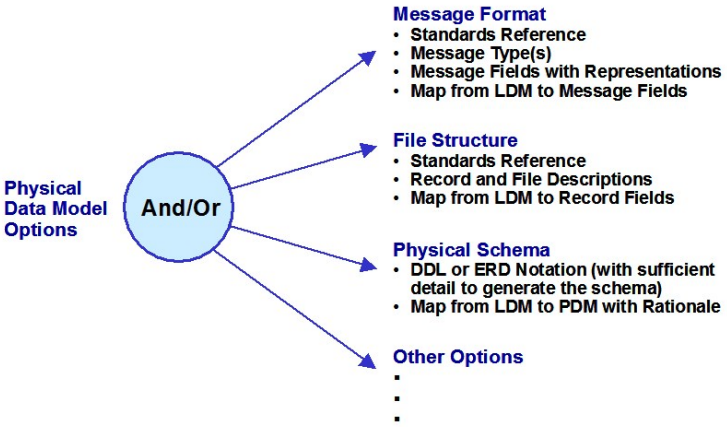
Physical Design

Physical data model

A **physical data model** (or database design) is a representation of a data design which takes into account the facilities and constraints of a given database management system. In the lifecycle of a project it typically derives from a logical data model, though it may be reverse-engineered from a given database implementation. A complete physical data model will include all the database artifacts required to create relationships between tables or to achieve performance goals, such as indexes, constraint definitions, linking tables, partitioned tables or clusters. Analysts can usually use a physical data model to calculate storage estimates; it may include specific storage allocation details for a given database system.



Physical Data Model Options.[1]

As of 2012[2] seven main databases dominate the commercial marketplace: Informix, Oracle, Postgres, SQL Server, Sybase, DB2 and MySQL. Other RDBMS systems tend either to be legacy databases or used within academia such as universities or further education colleges. Physical data models for each implementation would differ significantly, not least due to underlying operating-system requirements that may sit underneath them. For example: SQL Server runs only on Microsoft Windows operating-systems, while Oracle and MySQL can run on Solaris, Linux and other UNIX-based operating-systems as well as on Windows. This means that the disk requirements, security requirements and many other aspects of a physical data model will be influenced by the RDBMS that a database administrator (or an organization) chooses to use.

Physical schema

Physical schema is a term used in data management to describe how data is to be represented and stored (files, indices, *et al.*) in secondary storage using a particular database management system (DBMS) (e.g., Oracle RDBMS, Sybase SQL Server, etc.).

In the ANSI/SPARC Architecture three schema approach, the *internal schema* is the view of data that involved data management technology. This is as opposed to an *external schema* that reflects an individual's view of the data, or the *conceptual schema* that is the integration of a set of external schemas.

Subsequently[*citation needed*] the internal schema was recognized to have two parts:

The logical schema was the way data were represented to conform to the constraints of a particular approach to database management. At that time the choices were hierarchical and network. Describing the logical schema, however, still did not describe how physically data would be stored on disk drives. That is the domain of the *physical schema*. Now logical schemas describe data in terms of relational *tables and columns*, object-oriented *classes*, and XML *tags*.

A single set of tables, for example, can be implemented in numerous ways, up to and including an architecture where table rows are maintained on computers in different countries.

Storage model

A **storage model** is a model that captures key *physical* aspects of data structure in a data store.

On the other hand, a data model is a model that captures key *logical* aspects of data structure in a database.

Storage block

A **storage block** is a physical sector on the surface of a disk or diskette. It is the smallest unit of transference between the main memory and a given disk drive.

In the IBM mainframe terminology, a **block** is the minimal physical division of data in a disk drive, either as used on a Fixed Block Architecture (FBA) disk or in the Cylinder-Head-Record (CCHHRR) addressing mode of a Count-Key-Data (CKD) disk.[*citation needed*] Blocks are separated on the track by "inter-record gaps" (approx. 6 bytes on IBM 3380 and IBM 3390 disk drive models). The number of blocks per tracks depends on the block size and the specific gap size associated to each block. Each block can contain a discrete quantity of logical records or it can be empty. Logical records are defined by the database designer or application designer; see Data set (IBM mainframe).

Tablespace

A **tablespace** is a storage location where the actual data underlying database objects can be kept. It provides a layer of abstraction between physical and logical data, and serves to allocate storage for all DBMS managed segments. (A database segment is a database object which occupies physical space such as table data and indexes.) Once created, a tablespace can be referred to by name when creating database segments.

Tablespaces specify only the database storage locations, not the logical database structure, or database schema. For instance, different objects in the same schema may have different underlying tablespaces. Similarly, a tablespace may service segments for more than one schema. Sometimes it can be used to specify schema as to form a bond between logical and physical data.

By using tablespaces, an administrator can control the disk layout of an installation. A common use of tablespaces is to optimize performance. For example, a heavily used index can be placed on a fast SCSI disk. On the other hand, a database table which contains archived data that is rarely accessed could be stored on a less expensive but slower IDE disk.

While it is common for tablespaces to store their data in a filesystem file, a single file must be part of a single tablespace. Some database management systems allow tablespaces to be configured directly over operating-system device entries, called raw devices, providing better performance by avoiding the OS filesystem overheads.

Oracle stores data logically in tablespaces and physically in datafiles associated with the corresponding tablespace.

Database tuning

Database tuning describes a group of activities used to optimize and homogenize the performance of a database. It usually overlaps with query tuning, but refers to design of the database files, selection of the database management system (DBMS) application, and configuration of the database's environment (operating system, CPU, etc.).

Database tuning aims to maximize use of system resources to perform work as efficiently and rapidly as possible. Most systems are designed to manage their use of system resources, but there is still much room to improve their efficiency by customizing their settings and configuration for the database and the DBMS.

I/O tuning

Hardware and software configuration of disk subsystems are examined: RAID levels and configuration, block and stripe size allocation, and the configuration of disks, controller cards, storage cabinets, and external storage systems such as SANs. Transaction logs and temporary spaces are heavy consumers of I/O, and affect performance for all users of the database. Placing them appropriately is crucial.

Frequently joined tables and indexes are placed so that as they are requested from file storage, they can be retrieved in parallel from separate disks simultaneously. Frequently accessed tables and indexes are placed on separate disks to balance I/O and prevent read queuing.

DBMS tuning

DBMS tuning refers to tuning of the DBMS and the configuration of the memory and processing resources of the computer running the DBMS. This is typically done through configuring the DBMS, but the resources involved are shared with the host system.

Tuning the DBMS can involve setting the recovery interval (time needed to restore the state of data to a particular point in time), assigning parallelism (the breaking up of work from a single query into tasks assigned to different processing resources), and network protocols used to communicate with database consumers.

Memory is allocated for data, execution plans, procedure cache, and work space[*clarify*]. It is much faster to access data in memory than data on storage, so maintaining a sizable cache of data makes activities perform faster. The same consideration is given to work space. Caching execution plans and procedures means that they are reused instead of recompiled when needed. It is important to take as much memory as possible, while leaving enough for other processes and the OS to use without excessive paging of memory to storage.

Processing resources are sometimes assigned to specific activities to improve concurrency. On a server with eight processors, six could be reserved for the DBMS to maximize available processing resources for the database.

Database maintenance

Database maintenance includes backups, column statistics updates, and defragmentation of data inside the database files.

On a heavily used database, the transaction log grows rapidly. Transaction log entries must be removed from the log to make room for future entries. Frequent transaction log backups are smaller, so they interrupt database activity for shorter periods of time.

DBMS use statistic histograms to find data in a range against a table or index. Statistics updates should be scheduled frequently and sample as much of the underlying data as possible. Accurate and updated statistics allow query engines to make good decisions about execution plans, as well as efficiently locate data.

Defragmentation of table and index data increases efficiency in accessing data. The amount of fragmentation depends on the nature of the data, how it is changed over time, and the amount of free space in database pages to accept inserts of data without creating additional pages.

Database dump

For information on obtaining the Wikipedia database, see Wikipedia:Database download.

A **database dump** contains a record of the table structure and/or the data from a database and is usually in the form of a list of SQL statements. A database dump is most often used for backing up a database so that its contents can be restored in the event of data loss. Corrupted databases can often be recovered by analysis of the dump. Database dumps are often published by free software and free content projects, to allow reuse or forking of the database.

Example

```
-- Database
CREATE DATABASE `example`;
USE `example`;

-- Table structure for table `users`
CREATE TABLE `users` (
  `id` int(8) unsigned NOT NULL AUTO_INCREMENT,
  `username` varchar(16) NOT NULL,
  `password` varchar(16) NOT NULL,
  PRIMARY KEY (`id`)
);

-- Data for table `users`
INSERT INTO `users` VALUES (1,'alice','secret'),(2,'bob','secret');
```

Spindling

In computers **spindling** is the allocation of different files (e.g., the data files and index files of a database) on different hard disks. This practice usually reduces contention for read or write resources, thus increasing the system's performance.

The word comes from spindle, the axis on which the hard disks spin.

Data Mapping and Integration Tasks

Data mapping

Data transformation/Source transformation
Concepts

Applications
• data migration • data conversion • ETL • program transformation
Application fields
• Data warehouse • Software engineering Software languages macro preprocessing template
• v • t • e [1]

Data mapping is the process of creating data element mappings between two distinct data models. Data mapping is used as a first step for a wide variety of data integration tasks including:

- Data transformation or data mediation between a data source and a destination
- Identification of data relationships as part of data lineage analysis

- Discovery of hidden sensitive data such as the last four digits social security number hidden in another user id as part of a data masking or de-identification project
- Consolidation of multiple databases into a single data base and identifying redundant columns of data for consolidation or elimination

For example, a company that would like to transmit and receive purchases and invoices with other companies might use data mapping to create data maps from a company's data to standardized ANSI ASC X12 messages for items such as purchase orders and invoices.

Standards

X12 standards are generic Electronic Data Interchange (EDI) standards designed to allow a company to exchange data with any other company, regardless of industry. The standards are maintained by the Accredited Standards Committee X12 (ASC X12), with the American National Standards Institute (ANSI) accredited to set standards for EDI. The X12 standards are often called **ANSI ASC X12 standards**.

In the future, tools based on semantic web languages such as Resource Description Framework (RDF), the Web Ontology Language (OWL) and standardized metadata registry will make data mapping a more automatic process. This process will be accelerated if each application performed metadata publishing. Full automated data mapping is a very difficult problem (see Semantic translation).

Hand-coded, graphical manual

Data mappings can be done in a variety of ways using procedural code, creating XSLT transforms or by using graphical mapping tools that automatically generate executable transformation programs. These are graphical tools that allow a user to "draw" lines from fields in one set of data to fields in another. Some graphical data mapping tools allow users to "Auto-connect" a source and a destination. This feature is dependent on the source and destination data element name being the same. Transformation programs are automatically created in SQL, XSLT, Java programming language or C++. These kinds of graphical tools are found in most ETL Tools (Extract, Transform, Load Tools) as the primary means of entering data maps to support data movement.

Data-driven mapping

This is the newest approach in data mapping and involves simultaneously evaluating actual data values in two data sources using heuristics and statistics to automatically discover complex mappings between two data sets. This approach is used to find transformations between two data sets and will discover substrings, concatenations, arithmetic, case statements as well as other kinds of transformation logic. This approach also discovers data exceptions that do not follow the discover....

Semantic mapping

Semantic mapping is similar to the auto-connect feature of data mappers with the exception that a metadata registry can be consulted to look up data element synonyms. For example, if the source system lists FirstName but the destination lists PersonGivenName, the mappings will still be made if these data elements are listed as synonyms in the metadata registry. Semantic mapping is only able to discover exact matches between columns of data and will not discover any transformation logic or exceptions between columns.

Semantic integration

Semantic integration is the process of interrelating information from diverse sources, for example calendars and to do lists, email archives, presence information (physical, psychological, and social), documents of all sorts, contacts (including social graphs), search results, and advertising and marketing relevance derived from them. In this regard, semantics focuses on the organization of and action upon information by acting as a intermediary between heterogeneous data sources, which may conflict not only by structure but also context or value.

Applications and Methods

In enterprise application integration (EAI), semantic integration can facilitate or even automate the communication between computer systems using metadata publishing. Metadata publishing potentially offers the ability to automatically link ontologies. One approach to (semi-)automated ontology mapping requires the definition of a semantic distance or its inverse, semantic similarity and appropriate rules. Other approaches include so-called *lexical methods,* as well as methodologies that rely on exploiting the structures of the ontologies. For explicitly stating similarity/equality, there exist special properties or relationships in most ontology languages. OWL, for example has “sameIndividualAs” or “same-ClassAs”.

Eventually system designs may see the advent of composable architectures where published semantic-based interfaces are joined together to enable new and meaningful capabilities[*citation needed*]. These could predominately be described by means of design-time declarative specifications, that could ultimately be rendered and executed at run-time[*citation needed*].

Semantic integration can also be used to facilitate design-time activities of interface design and mapping. In this model, semantics are only explicitly applied to design and the run-time systems work at the syntax level[*citation needed*]. This "early semantic binding" approach can improve overall system performance while retaining the benefits of semantic driven design[*citation needed*].

Examples

The Pacific Symposium on Biocomputing has been a venue for the popularization of the ontology mapping task in the biomedical domain, and a number of papers on the subject can be found in its proceedings.

Semantic translation

Semantic translation is the process of using semantic information to aid in the translation of data in one representation or data model to another representation or data model. Semantic translation takes advantage of semantics that associate meaning with individual data elements in one dictionary to create an equivalent meaning in a second system.

An example of semantic translation is the conversion of XML data from one data model to a second data model using formal ontologies for each system such as the Web Ontology Language (OWL). This is frequently required by intelligent agents that wish to perform searches on remote computer systems that use different data models to store their data elements. The process of allowing a single user to search multiple systems with a single search request is also known as federated search.

Semantic translation should be differentiated from data mapping tools that do simple one-to-one translation of data from one system to another without actually associating meaning with each data element.

Semantic translation requires that data elements in the source and destination systems have "semantic mappings" to a central registry or registries of data elements. The simplest mapping is of course where there is equivalence. There are three types of Semantic equivalence:

- **Class Equivalence** - indicating that class or "concepts" are equivalent. For example: "Person" is the same as "Individual"
- **Property Equivalence** - indicating that two properties are equivalent. For example: "PersonGivenName" is the same as "FirstName"
- **Instance Equivalence** - indicating that two individual instances of objects are equivalent. For example: "Dan Smith" is the same person as "Daniel Smith"

Semantic translation is very difficult if the terms in a particular data model do not have direct one-to-one mappings to data elements in a foreign data model. In that situation an alternative approach must be used to find mappings from the original data to the foreign data elements. This problem can be alleviated by centralized metadata registries that use the ISO-11179 standards such as the National Information Exchange Model (NIEM).

Record linkage

Record linkage (RL) refers to the task of finding records in a data set that refer to the same entity across different data sources (e.g., data files, books, websites, databases). Record linkage is necessary when joining data sets based on entities that may or may not share a common identifier (e.g., database key, URI, National identification number), as may be the case due to differences in record shape, storage location, and/or curator style or preference. A data set that has undergone RL-oriented reconciliation may be referred to as being *cross-linked*. Record Linkage is called Data Linkage in many jurisdictions, but is the same process.

History

The initial idea of record linkage goes back to Halbert L. Dunn in his 1946 article titled "Record Linkage" published in the *American Journal of Public Health*. Howard Borden Newcombe laid the probabilistic foundations of modern record linkage theory in a 1959 article in *Science*, which were then formalized in 1969 by Ivan Fellegi and Alan Sunter who proved that the probabilistic decision rule they described was optimal when the comparison attributes were conditionally independent. Their pioneering work "A Theory For Record Linkage" remains the mathematical foundation for many record linkage applications even today.

Since the late 1990s, various machine learning techniques have been developed that can, under favorable conditions, be used to estimate the conditional probabilities required by the Fellegi-Sunter (FS) theory. Several researchers have reported that the conditional independence assumption of the FS algorithm is often violated in practice; however, published efforts to explicitly model the conditional dependencies among the comparison attributes have not resulted in an improvement in record linkage quality. [*citation needed*]

Record linkage can be done entirely without the aid of a computer, but the primary reasons computers are often used for record linkage are to reduce or eliminate manual review and to make results more easily reproducible. Computer matching has the advantages of allowing central supervision of processing, better quality control, speed, consistency, and better reproducibility of results.

Naming conventions

"Record linkage" is the term used by statisticians, epidemiologists, and historians, among others, to describe the process of joining records from one data source with another that describe the same entity. Commercial mail and database applications refer to it as "merge/purge processing" or "list washing". Computer scientists often refer to it as "data matching" or as the "object identity problem". Other names used to describe the same concept include: "coreference/entity/identity/name/record resolution", "entity disambiguation/linking", "duplicate detection", "deduplication", "record matching", "(reference) reconciliation", "object identification", "data/information integration", and "conflation".[1] This profusion of terminology has led to few cross-references between these research communities.[2]

While they share similar names, record linkage and Linked Data are two separate concepts. Whereas record linkage focuses on the more narrow task of identifying matching entities across different data sets, Linked Data focuses on the broader methods of structuring and publishing data to facilitate the discovery of related information.

Methods

Data preprocessing

Record linkage is highly sensitive to the quality of the data being linked, so all data sets under consideration (particularly their key identifier fields) should ideally undergo a data quality assessment prior to record linkage. Many key identifiers for the same entity can be presented quite differently between (and even within) data sets, which can greatly complicate record linkage unless understood ahead of time. For example, key identifiers for a man named William J. Smith might appear in three different data sets as so:

Data set	Name	Date of birth	City of residence
Data set 1	William J. Smith	1/2/73	Berkeley, California
Data set 2	Smith, W. J.	1973.1.2	Berkeley, CA
Data set 3	Bill Smith	Jan 2, 1973	Berkeley, Calif.

In this example, the different formatting styles lead to records that look different but in fact all refer to the same entity with the same logical identifier values. Most, if not all, record linkage strategies would result in more accurate linkage if these values were first *normalized* or *standardized* into a consistent format (e.g., all names are "Surname, Given name", all dates are "YYYY/MM/DD", and all cities are "Name, 2-letter state abbreviation"). Standardization can be accomplished through simple rule-based data transformations or more complex procedures such as lexicon-based tokenization and probabilistic hidden Markov models. Several of the packages listed in the *Software Implementations* section provide some of these features to simplify the process of data standardization.

Identity resolution

Identity resolution is an operational intelligence process, typically powered by an identity resolution engine or middleware, whereby organizations can connect disparate data sources with a view to understanding possible identity matches and non-obvious relationships across multiple data silos. It analyzes all of the information relating to individuals and/or entities from multiple sources of data, and then applies likelihood and probability scoring to determine which identities are a match and what, if any, non-obvious relationships exist between those identities.

Identity resolution engines are typically used to uncover risk, fraud, and conflicts of interest, but are also useful tools for use within Customer Data Integration (CDI) and Master Data Management (MDM) requirements. Typical uses for identity resolution engines include terrorist screening, insurance fraud detection, USA Patriot Act compliance, Organized retail crime ring detection and applicant screening.

For example: Across different data silos - employee records, vendor data, watch lists, etc. - an organization may have several variations of an identity named ABC, which may or may not be the same individual. These entries may, in fact, appear as ABC1, ABC2, or ABC3 within those data sources. By comparing similarities between underlying attributes such as address, date of birth, or social security number, the user can eliminate some possible matches and confirm others as very likely matches.

Identity resolution engines then apply rules, based on common sense logic, to identify hidden relationships across the data. In the example above, perhaps ABC1 and ABC2 are not the same individual, but rather two distinct people who share common attributes such as address or phone number.

Data Matching

While entity resolution solutions include data matching technology, many data matching offerings do not fit the definition of identity (or entity) resolution. Here are four factors that distinguish entity resolution from data matching, according to John Talburt, director of the UALR Center for Advanced Research in Entity Resolution and Information Quality:

- Works with both structured and unstructured records, and it entails the process of extracting references when the sources are unstructured or semi-structured
- Uses elaborate business rules and concept models to deal with missing, conflicting, and corrupted information
- Utilizes non-matching, asserted linking (associate) information in addition to direct matching
- Uncovers non-obvious relationships and association networks (i.e. who's associated with whom)

In contrast to data quality products, more powerful identity resolution engines also include a rules engine and workflow process, which apply business intelligence to the resolved identities and their relationships. These advanced technologies make automated decisions and impact business processes in real time, limiting the need for human intervention.

Deterministic record linkage

The simplest kind of record linkage, called *deterministic* or *rules-based record linkage*, generates links based on the number of individual identifiers that match among the available data sets. Two records are said to match via a deterministic record linkage procedure if all or some identifiers (above a certain threshold) are identical. Deterministic record linkage is a good option when the entities in the data sets are identified by a common identifier, or when there are several representative identifiers (e.g., name, date of birth, and sex when identifying a person) whose quality of data is relatively high.

As an example, consider two standardized data sets, Set A and Set B, that contain different bits of information about patients in a hospital system. The two data sets identify patients using a variety of identifiers: Social Security Number (SSN), name, date of birth (DOB), sex, and ZIP code (ZIP). The records in two data sets (identified by the "#" column) are shown below:

Data Set	#	SSN	Name	DOB	Sex	ZIP
Set A	1	000956723	Smith, William	1973/01/02	Male	94701
	2	000956723	Smith, William	1973/01/02	Male	94703
	3	000005555	Jones, Robert	1942/08/14	Male	94701
	4	123001234	Sue, Mary	1972/11/19	Female	94109
Set B	1	000005555	Jones, Bob	1942/08/14		
	2		Smith, Bill	1973/01/02	Male	94701

The most simple deterministic record linkage strategy would be to pick a single identifier that is assumed to be uniquely identifying, say SSN, and declare that records sharing the same value identify the same person while records not sharing the same value identify different people. In this example, deterministic linkage based on SSN would create entities based on A1 and A2; A3 and B1; and A4. While A1, A2, and B2 appear to represent the same entity, B2 would not be included into the match because it is missing a value for SSN.

Handling exceptions such as missing identifiers involves the creation of additional record linkage rules. One such rule in the case of missing SSN might be to compare name, date of birth, sex, and ZIP code with other records in hopes of finding a match. In the above example, this rule would still not match A1/A2 with B2 because the names are still slightly different: standardization put the names into the proper (Surname, Given name) format but could not discern "Bill" as a nickname for "William". Running names through a phonetic algorithm such as Soundex, NYSIIS,

or metaphone, can help to resolve these types of problems (though it may still stumble over surname changes as the result of marriage or divorce), but then B2 would be matched only with A1 since the ZIP code in A2 is different. Thus, another rule would need to be created to determine whether differences in particular identifiers are acceptable (such as ZIP code) and which are not (such as date of birth).

As this example demonstrates, even a small decrease in data quality or small increase in the complexity of the data can result in a very large increase in the number of rules necessary to link records properly. Eventually, these linkage rules will become too numerous and interrelated to build without the aid of specialized software tools. In addition, linkage rules are often specific to the nature of the data sets they are designed to link together. One study was able to link the Social Security Death Master File with two hospital registries from the Midwestern United States using SSN, NYSIIS-encoded first name, birth month, and sex, but these rules may not work as well with data sets from other geographic regions or with data collected on younger populations. Thus, continuous maintenance testing of these rules is necessary to ensure they continue to function as expected as new data enter the system and need to be linked. New data that exhibit different characteristics than was initially expected could require a complete rebuilding of the record linkage rule set, which could be a very time-consuming and expensive endeavor.

Probabilistic record linkage

Probabilistic record linkage, sometimes called *fuzzy matching* (also *probabilistic merging* or *fuzzy merging* in the context of merging of databases), takes a different approach to the record linkage problem by taking into account a wider range of potential identifiers, computing weights for each identifier based on its estimated ability to correctly identify a match or a non-match, and using these weights to calculate the probability that two given records refer to the same entity. Record pairs with probabilities above a certain threshold are considered to be matches, while pairs with probabilities below another threshold are considered to be non-matches; pairs that fall between these two thresholds are considered to be "possible matches" and can be dealt with accordingly (e.g., human reviewed, linked, or not linked, depending on the requirements). Whereas deterministic record linkage requires a series of potentially complex rules to be programmed ahead of time, probabilistic record linkage methods can be "trained" to perform well with much less human intervention.

Many probabilistic record linkage algorithms assign match/non-match weights to identifiers by means of u probabilities and m probabilities. The u probability is the probability that an identifier in two *non-matching* records will agree purely by chance. For example, the u probability for birth month (where there are twelve values that are approximately uniformly distributed) is $1/12 \approx 0.083$; identifiers with values that are not uniformly distributed will have different u probabilities for different values (possibly including missing values). The m probability is the probability that an identifier in *matching* pairs will agree (or be sufficiently similar, such as strings with high Jaro-Winkler distance or low Levenshtein distance). This value would be 1.0 in the case of perfect data, but given that this is rarely (if ever) true, it can instead be estimated. This estimation may be done based on prior knowledge of the data sets, by manually identifying a large number of matching and non-matching pairs to "train" the probabilistic record linkage algorithm, or by iteratively running the algorithm to obtain closer estimations of the m probability. If a value of 0.95 were to be estimated for the m probability, then the match/non-match weights for the birth month identifier would be:

Outcome	Proportion of links	Proportion of non-links	Frequency ratio	Weight
Match	$m = 0.95$	$u \approx 0.083$	$m/u \approx 11.4$	$\ln(m/u)/\ln(2) \approx 3.51$
Non-match	$1-m = 0.05$	$1-u \approx 0.917$	$(1-m)/(1-u) \approx 0.0545$	$\ln((1-m)/(1-u))/\ln(2) \approx -4.20$

The same calculations would be done for all other identifiers under consideration to find their match/non-match weights. Then, the identifiers of one record would be compared with the identifiers with every other record to compute the total weight: the *match* weight is added to the running total whenever a pair of identifiers agree, while the *non-match* weight is added (i.e. the running total decreases) whenever the pair of identifiers disagrees. The resulting total weight is then compared to the aforementioned thresholds to determine whether the pair should be linked, non-linked, or set aside for special consideration (e.g. manual validation).

Determining where to set the match/non-match thresholds is a balancing act between obtaining an acceptable sensitivity (or *recall*, the proportion of truly matching records that are linked by the algorithm) and positive predictive value (or *precision*, the proportion of records linked by the algorithm that truly do match). Various manual and automated methods are available to predict the best thresholds, and some record linkage software packages have built-in tools to help the user find the most acceptable values. Because this can be a very computationally demanding task, particularly for large data sets, a technique known as *blocking* is often used to improve efficiency. Blocking attempts to restrict comparisons to just those records for which one or more particularly discriminating identifiers agree, which has the effect of increasing the positive predictive value (precision) at the expense of sensitivity (recall). For example, blocking based on a phonetically coded surname and ZIP code would reduce the total number of comparisons required and would improve the chances that linked records would be correct (since two identifiers already agree), but would potentially miss records referring to the same person whose surname or ZIP code was different (due to marriage or relocation, for instance). Blocking based on birth month, a more stable identifier that would be expected to change only in the case of data error, would provide a more modest gain in positive predictive value and loss in sensitivity, but would create only twelve distinct groups which, for extremely large data sets, may not provide much net improvement in computation speed. Thus, robust record linkage systems often use multiple blocking passes to group data in various ways in order to come up with groups of records that should be compared to each other.

Machine learning

In recent years, a variety of machine learning techniques have been used in record linkage. It has been recognizedWikipedia:Manual of Style/Words to watch#Unsupported attributions that probabilistic record linkage is equivalent to the "Naive Bayes" algorithm in the field of machine learning,[3] and suffers from the same assumption of the independence of its features (an assumption that is typically not true).[4][5] Higher accuracy can often be achieved by using various other machine learning techniques, including a single-layer perceptron.[6]

Mathematical model

In an application with two files, A and B, denote the rows (*records*) by $\alpha(a)$ in file A and $\beta(b)$ in file B. Assign K *characteristics* to each record. The set of records that represent identical entities is defined by

$M = \{(a,b); a = b; a \in A; b \in B\}$

and the complement of set M, namely set U representing different entities is defined as

$U = \{(a,b); a \neq b; a \in A, b \in B\}$.

A vector, γ is defined, that contains the coded agreements and disagreements on each characteristic:

$\gamma[\alpha(a), \beta(b)] = \{\gamma^1[\alpha(a), \beta(b)], ..., \gamma^K[\alpha(a), \beta(b)]\}$

where K is a subscript for the characteristics (sex, age, marital status, etc.) in the files. The conditional probabilities of observing a specific vector γ given $(a,b) \in M$, $(a,b) \in U$ are defined as

$$m(\gamma) = P\left\{\gamma\left[\alpha(a), \beta(b)\right] | (a,b) \in M\right\} = \sum_{(a,b)\in M} P\left\{\gamma\left[\alpha(a), \beta(b)\right]\right\} \cdot P\left[(a,b)|M\right]$$

and

$$u(\gamma) = P\left\{\gamma\left[\alpha(a), \beta(b)\right] | (a,b) \in U\right\} = \sum_{(a,b)\in U} P\left\{\gamma\left[\alpha(a), \beta(b)\right]\right\} \cdot P\left[(a,b)|U\right], \text{respectively.}$$

Applications

Master data management

Most Master data management (MDM) products use a record linkage process to identify records from different sources representing the same real-world entity. This linkage is used to create a "golden master record" containing the cleaned, reconciled data about the entity. The techniques used in MDM are the same as for record linkage generally.

Data warehousing and business intelligence

Record linkage plays a key role in data warehousing and business intelligence. Data warehouses serve to combine data from many different operational source systems into one logical data model, which can then be subsequently fed into a business intelligence system for reporting and analytics. Each operational source system may have its own method of identifying the same entities used in the logical data model, so record linkage between the different sources becomes necessary to ensure that the information about a particular entity in one source system can be seamlessly compared with information about the same entity from another source system. Data standardization and subsequent record linkage often occur in the "transform" portion of the extract, transform, load (ETL) process.

Historical research

Record linkage is important to social history research since most data sets, such as census records and parish registers were recorded long before the invention of National identification numbers. When old sources are digitized, linking of data sets is a prerequisite for longitudinal study. This process is often further complicated by lack of standard spelling of names, family names that change according to place of dwelling, changing of administrative boundaries, and problems of checking the data against other sources. Record linkage was among the most prominent themes in the History and computing field in the 1980s, but has since been subject to less attention in research.[*citation needed*]

Medical practice and research

Record linkage is an important tool in creating data required for examining the health of the public and of the health care system itself. It can be used to improve data holdings, data collection, quality assessment, and the dissemination of information. Data sources can be examined to eliminate duplicate records, to identify under-reporting and missing cases (e.g., census population counts), to create person-oriented health statistics, and to generate disease registries and health surveillance systems. Some cancer registries link various data sources (e.g., hospital admissions, pathology and clinical reports, and death registrations) to generate their registries. Record linkage is also used to create health indicators. For example, fetal and infant mortality is a general indicator of a country's socioeconomic development, public health, and maternal and child services. If infant death records are matched to birth records, it is possible to use birth variables, such as birth weight and gestational age, along with mortality data, such as cause of death, in analyzing the data. Linkages can help in follow-up studies of cohorts or other groups to determine factors such as vital status, residential status, or health outcomes. Tracing is often needed for follow-up of industrial cohorts,

clinical trials, and longitudinal surveys to obtain the cause of death and/or cancer. An example of a successful and long-standing record linkage system allowing for population-based medical research is the Rochester Epidemiology Project based in Rochester, Minnesota.

Criticism of existing software implementations

The main reasons cited are:

- **Project costs**: costs typically in the hundreds of thousands of dollars
- **Time**: lack of enough time to deal with large-scale data-cleansing software
- **Security**: concerns over sharing information, giving an application access across systems, and effects on legacy systems

Metadata discovery

In metadata, **metadata discovery** is the process of using automated tools to discover the semantics of a data element in data sets. This process usually ends with a set of mappings between the data source elements and a centralized metadata registry. Metadata discovery is also known as metadata scanning.

Data source formats for metadata discovery

Data sets may be in a variety of different forms including:

1. Relational databases
2. Spreadsheets
3. XML files
4. Web services
5. Software source code such as Fortran, Jovial, COBOL, Assembler, RPG, PL/1, EasyTrieve, Java, C# or C++ classes, and thousands of other software languages
6. Unstructured text documents such as Microsoft Word or PDF files

A taxonomy of metadata matching algorithms

There are distinct categories of automated metadata discovery:

Lexical Matching

1. **Exact match** - where data element linkages are made based on the exact name of a column in a database, the name of an XML element or a label on a screen. For example if a database column has the name "PersonBirthDate" and a data element in a metadata registry also has the name "PersonBirthDate", automated tools can infer that the column of a database has the same semantics (meaning) as the data element in the metadata registry.
2. **Synonym match** - where the discovery tool is not just given a single name but a set of synonym.
3. **Pattern match** - in this case the tools is given a set of lexical patterns that it can match. For example the tools may search for "*gender*" or "*sex*"

Semantic Matching

Semantic matching attempts to use semantics to associate target data with registered data elements.

1. **Semantic Similarity** - In this algorithm that relies on a database of word conceptual nearness is used. For example the WordNet system can rank how close words are conceptually to each other. For example the terms "Person", "Individual" and "Human" may be highly similar concepts.

Statistical Matching

Statistical matching uses statistics about data sources data itself to derive similarities with registered data elements.

1. **Distinct Value Analysis** - By analyzing all the distinct values in a column the similarity to a registered data element may be made. For example if a column only has two distinct values of 'male' and 'female' this could be mapped to 'PersonGenderCode'.
2. **Data distribution analysis** - By analyzing the distribution of values within a single column and comparing this distribution with known data elements a semantic linkage could be inferred.

Vendors

The following vendors (listed in alphabetical order) provide metadata discovery and metadata mapping software and solutions

- Esquire Innovations (see [7 [1])
- IBM
- InfoLibrarian Corporation (see [2])
- Masai Technologies (see [3])
- MindHARBOR Metadata Database application (see www.mindharbor.com/metadata-database.asp [4])
- Revelytix (see [5])
- Sliver Creek Systems (see [6])
- Sypherlink: Harvester (see [7])
- Unicorn Systems (see [8])

Research

- INDUS project at the Iowa State University (see [9])
- **Mercury** - A Distributed Metadata Management and Data Discovery System developed at the Oak Ridge National Laboratory DAAC (see [10])

Schema matching

The terms **schema matching** and *mapping* are often used interchangeably. For this article, we differentiate the two as follows: Schema matching is the process of identifying that two objects are semantically related (scope of this article) while mapping refers to the transformations between the objects. For example, in the two schemas DB1.Student (Name, SSN, Level, Major, Marks) and DB2.Grad-Student (Name, ID, Major, Grades); possible matches would be: DB1.Student ≈ DB2.Grad-Student; DB1.SSN = DB2.ID etc. and possible transformations or mappings would be: DB1.Marks to DB2.Grades (100-90 A; 90-80 B: etc.).

Automating these two approaches has been one of the fundamental tasks of data integration. In general it is not possible to determine fully automatically the different correspondences between two schemas, primarily because of the differing and often not explicated or documented semantics of the two schemas.

Impediments to Schema Matching

Among others, common challenges to automating matching and mapping have been previously classified in especially for relational DB schemas; and in - a fairly comprehensive list of heterogeneity not limited to the relational model recognizing schematic vs semantic differences/heterogeneity. Most of these heterogeneities exist because schemas use different representations or definitions to represent the same information (schema conflicts); OR different expressions, units, and precision result in conflicting representations of the same data (data conflicts). Research in schema matching seeks to provide automated support to the process of finding semantic matches between two schemas. This process is made harder due to heterogeneities at the following levels

- Syntactic heterogeneity - differences in the language used for representing the elements
- Structural heterogeneity - differences in the types, structures of the elements
- Model / Representational heterogeneity – differences in the underlying models (database, ontologies) or their representations (relational, object-oriented, RDF,OWL)
- Semantic heterogeneity - where the same real world entity is represented using different terms or vice-versa

Schema Matching

Methodology

Discusses a generic methodology for the task of schema integration or the activities involved. According to the authors, one can view the integration

- Preintegration - An analysis of schemas is carried out before integration to decide upon some integration policy. This governs the choice of schemas to be integrated, the order of integration, and a possible assignment of preferences to entire schemas or portions of schemas.
- Comparison of the Schemas - Schemas are analyzed and compared to determine the correspondences among concepts and detect possible conflicts. Interschema properties may be discovered while comparing schemas.
- Conforming the Schemas - Once conflicts are detected, an effort is made to resolve them so that the merging of various schemas is possible.
- Merging and Restructuring - Now the schemas are ready to be superimposed, giving rise to some intermediate integrated schema(s). The intermediate results are analyzed and, if necessary, restructured in order to achieve several desirable qualities.

Approaches

Approaches to schema integration can be broadly classified as ones that exploit either just schema information or schema and instance level information.

Schema-level matchers only consider schema information, not instance data. The available information includes the usual properties of schema elements, such as name, description, data type, relationship types (part-of, is-a, etc.), constraints, and schema structure. Working at the element (atomic elements like attributes of objects) or structure level (matching combinations of elements that appear together in a structure), these properties are used to identify matching elements in two schemas. Language-based or linguistic matchers use names and text (i.e., words or sentences) to find semantically similar schema elements. Constraint based matchers exploit constraints often contained in schemas. Such constraints are used to define data types and value ranges, uniqueness, optionality, relationship types and cardinalities, etc. Constraints in two input schemas are matched to determine the similarity of the schema elements.

Instance-level matchers use instance-level data to gather important insight into the contents and meaning of the schema elements. These are typically used in addition to schema level matches in order to boost the confidence in match results, more so when the information available at the schema level is insufficient. Matchers at this level use linguistic and constraint based characterization of instances. For example, using linguistic techniques, it might be possible to look at the Dept, DeptName and EmpName instances to conclude that DeptName is a better match candidate for Dept than EmpName. Constraints like zipcodes must be 5 digits long or format of phone numbers may allow matching of such types of instance data.

Hybrid matchers directly combine several matching approaches to determine match candidates based on multiple criteria or information sources.

Most of these techniques also employ additional information such as dictionaries, thesauri, and user-provided match or mismatch information

Reusing matching information Another initiative has been to re-use previous matching information as auxiliary information for future matching tasks. The motivation for this work is that structures or substructures often repeat, for example in schemas in the E-commerce domain. Such a reuse of previous matches however needs to be a careful choice. It is possible that such a reuse makes sense only for some part of a new schema or only in some domains. For example, Salary and Income may be considered identical in a payroll application but not in a tax reporting application. There are several open ended challenges in such reuse that deserves further work.

Sample Prototypes Typically, the implementation of such matching techniques can be classified as being either rule based or learner based systems. The complementary nature of these different approaches has instigated a number of applications using a combination of techniques depending on the nature of the domain or application under consideration.

Identified Relationships

The relationship types between objects that are identified at the end of a matching process are typically those with set semantics such as overlap, disjointness, exclusion, equivalence, subsumption. The logical encodings of these relationships are what they mean. Among others, an early attempt to use description logics for schema integration and identifying such relationships was presented. Several state of the art matching tools today and those benchmarked in the *Ontology Alignment Evaluation Initiative*[1] are capable of identifying many such simple (1:1 / 1:n / n:1 element level matches) and complex matches (n:1 / n:m element or structure level matches) between objects.

- Early work in schema matching (http://knoesis.wright.edu/library/download/S04-Dagstuhl-Early-Work.pdf)

Schema crosswalk

A **Schema crosswalk** is a table that shows equivalent elements (or "fields") in more than one database schema. It maps the elements in one schema to the equivalent elements in another schema.

Crosswalk tables are often employed within or in parallel to enterprise systems, especially when multiple systems are interfaced or when the system includes legacy system data. In the context of Interfaces, they function as a sort of internal ETL mechanism.

For example, this is a metadata crosswalk from MARC to Dublin Core:

MARC field		Dublin Core element
260$c (Date of publication, distribution, etc.)	→	Date.Created
522 (Geographic Coverage Note)	→	Coverage.Spatial
300$a (Physical Description)	→	Format.Extent

Crosswalks show people where to put the data from one scheme into a different scheme. They are often used by libraries, archives, museums, and other cultural institutions to translate data to or from MARC, Dublin Core, TEI, and other metadata schemes. For example, say an archive has a MARC record in their catalog describing a manuscript. If the archive makes a digital copy of that manuscript and wants to display it on the web along with the information from the catalog, it will have to translate the data from the MARC catalog record into a different format such as MODS that is viewable in a webpage. Because MARC has different fields than MODS, decisions must be made about where to put the data into MODS. This type of "translating" from one format to another is often called "metadata mapping" or "field mapping," and is related to "data mapping," and "semantic mapping."

Crosswalks also have several technical capabilities. They help databases using different metadata schemes to share information. They help metadata harvesters create union catalogs. They enable search engines to search multiple databases simultaneously with a single query.

Challenges for crosswalks

One of the biggest challenges for crosswalks is that no two metadata schemes are 100% equivalent. One scheme may have a field that doesn't exist in another scheme, or it may have a field that is split into two different fields in another scheme; this is why you often lose data when mapping from a complex scheme to a simpler one. For example, when mapping from MARC to Simple Dublin Core, you lose the distinction between types of titles:

MARC field		Dublin Core element
210 Abbreviated Title	→	Title
222 Key Title	→	Title
240 Uniform Title	→	Title
242 Translated Title	→	Title
245 Title Statement	→	Title
246 Variant Title	→	Title

Simple Dublin Core only has one single "Title" element so all of the different types of MARC titles get lumped together without any further distinctions. This is called "many-to-one" mapping. This is also why, once you've translated these titles into Simple Dublin Core you can't translate them back into MARC. Once they're Simple Dublin Core you've lost the MARC information about what types of titles they are so when you map from Simple Dublin Core back to MARC, all the data in the "Title" element maps to the basic MARC 245 Title Statement field.[1]

Dublin Core element		MARC field
Title	→	245 Title Statement
Title	→	245 Title Statement
Title	→	245 Title Statement
Title	→	245 Title Statement
Title	→	245 Title Statement
Title	→	245 Title Statement

This is why crosswalks are said to be "lateral" (one-way) mappings from one scheme to another. Separate crosswalks would be required to map from scheme A to scheme B and from scheme B to scheme A.[2]

Difficulties in mapping

Other mapping problems arise when:

- One scheme has one element that needs to be split up with different parts of it placed in multiple other elements in the second scheme ("one-to-many" mapping)
- One scheme allows an element to be repeated more than once while another only allows that element to appear once with multiple terms in it
- Schemes have different data formats (e.g. *John Doe* or *Doe, John*)
- An element in one scheme is indexed but the equivalent element in the other scheme is not
- Schemes may use different controlled vocabularies
- Schemes change their standards over time

Some of these problems are simply not fixable. As Karen Coyle says in "*Crosswalking Citation Metadata: The University of California's Experience,*"

> "The more metadata experience we have, the more it becomes clear that metadata perfection is not attainable, and anyone who attempts it will be sorely disappointed. When metadata is crosswalked between two or more unrelated sources, there will be data elements that cannot be reconciled in an ideal manner. The key to a successful metadata crosswalk is intelligent flexibility. It is essential to focus on the important goals and be willing to compromise in order to reach a practical conclusion to projects."[3]

Examples

MARC to Dublin Core (Library of Congress) http://loc.gov/marc/marc2dc.html

Dublin Core to MARC21 (Library of Congress) http://www.loc.gov/marc/dccross.html

Schema evolution

In computer science, **schema evolution** refers to the problem of evolving a database schema to adapt it to a change in the modeled reality. The problem is not limited to the modification of the schema. It, in fact, affects the data stored under the given schema and the queries (and thus the applications) posed on that schema.

Until recently the design of a database was expected to create a "one size fits all" schema capable of accepting every future change in the requirements, thus, schema evolution was not considered. This assumption, almost unrealistic in the context of traditional information systems, becomes unacceptable in the context of Web Information Systems, that due to the distributed and cooperative nature of their development and fruition are subject of an even stronger pressure toward change (from 39% to over 500% more intense than in traditional settings). Due to this historical heritage the process of schema evolution is nowadays a particularly taxing one. It is, in fact, widely acknowledged that the data management core of an applications is one of the most difficult and critical components to evolve. The key problem is the impact of the schema evolution on queries and applications. As shown in (which provides an analysis of the MediaWiki evolution) each evolution step might affect up to 70% of the queries operating on the schema, that must be manually reworked consequently.

The problem has been recognized as a very pressing one by the database community for more than 12 years. The support for Schema Evolution, is a difficult problem involving complex mapping among schema versions, the tool support has been so far very limited. The recent theoretical advances on mapping composition and mapping invertibility, which represent the core problems underlying the schema evolution remains almost inaccessible to the large public.

Data integration

Data integration involves combining data residing in different sources and providing users with a unified view of these data. This process becomes significant in a variety of situations, which include both commercial (when two similar companies need to merge their databases) and scientific (combining research results from different bioinformatics repositories, for example) domains. Data integration appears with increasing frequency as the volume and the need to share existing data explodes. It has become the focus of extensive theoretical work, and numerous open problems remain unsolved. In management circles, people frequently refer to data integration as "Enterprise Information Integration" (EII).

History

Issues with combining heterogeneous data sources under a single query interface have existed for some time. The rapid adoption of databases after the 1960s naturally led to the need to share or to merge existing repositories. This merging can take place at several levels in the database architecture.

One popular solution is implemented based on data warehousing (see figure 1). The warehouse system extracts, transforms, and loads data from heterogeneous sources into a single view schema so data becomes compatible with each other. This approach offers a tightly coupled architecture because the data is already physically reconciled in a single queriable repository, so it usually takes little time to resolve queries. However, problems lie in the data freshness, that is, information in warehouse is not always up-to-date. Thus updating an original data source may outdate the warehouse, accordingly, the ETL process needs re-execution for synchronization. Difficulties also arise in constructing data warehouses when one has only a query interface to summary data sources and no access to the full data. This problem frequently emerges when integrating several commercial query services like travel or classified advertisement web applications.

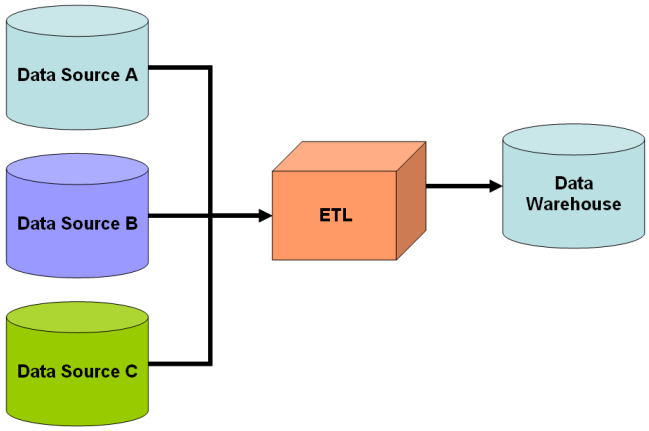

Figure 1: Simple schematic for a data warehouse. The ETL process extracts information from the source databases, transforms it and then loads it into the data warehouse.

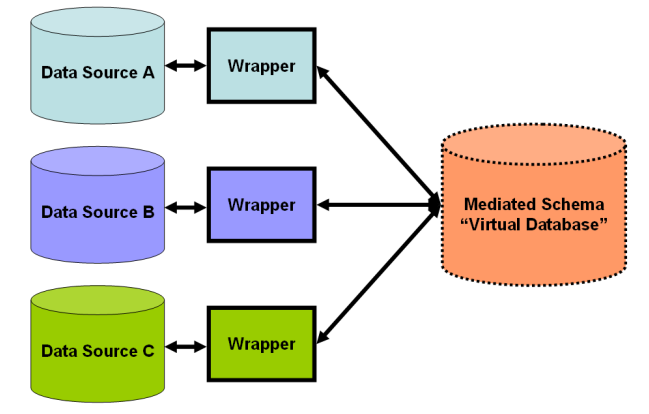

Figure 2: Simple schematic for a data-integration solution. A system designer constructs a mediated schema against which users can run queries. The virtual database interfaces with the source databases via wrapper code if required.

As of 2009[1] the trend in data integration has favored loosening the coupling between data[*citation needed*] and providing a unified query-interface to access real time data over a

mediated schema (see figure 2), which allows information to be retrieved directly from original databases. This approach relies on a mappings between the mediated schema and the schema of original sources, and transform a query into specialized queries to match the schema of the original databases. Such mappings can be specified in 2 ways : as a mapping from entities in the mediated schema to entities in the original sources (the "Global As View" (GAV) approach), or as a mapping from entities in the original sources to the mediated schema (the "Local As View" (LAV) approach). The latter approach requires more sophisticated inferences to resolve a query on the mediated schema, but makes it easier to add new data sources to a (stable) mediated schema.

As of 2010[1] some of the work in data integration research concerns the semantic integration problem. This problem addresses not the structuring of the architecture of the integration, but how to resolve semantic conflicts between heterogeneous data sources. For example if two companies merge their databases, certain concepts and definitions in their respective schemas like "earnings" inevitably have different meanings. In one database it may mean profits in dollars (a floating-point number), while in the other it might represent the number of sales (an integer). A common strategy for the resolution of such problems involves the use of ontologies which explicitly define schema terms and thus help to resolve semantic conflicts. This approach represents ontology-based data integration. On the other hand, the problem of combining research results from different bioinformatics repositories requires bench-marking of the similarities, computed from different data sources, on a single criterion such as positive predictive value. This enables the data sources to be directly comparable and can be integrated even when the natures of experiments are distinct.

As of 2011[1] it was determined that current data modeling methods were imparting data isolation into every data architecture in the form of islands of disparate data and information silos each of which represents a disparate system. This data isolation is an unintended artifact of the data modeling methodology that results in the development of disparate data models. Disparate data models, when instantiated as databases, form disparate databases. Enhanced data model methodologies have been developed to eliminate the data isolation artifact and to promote the development of integrated data models. One enhanced data modeling method recasts data models by augmenting them with structural metadata in the form of standardized data entities. As a result of recasting multiple data models, the set of recast data models will now share one or more commonality relationships that relate the structural metadata now common to these data models. Commonality relationships are a peer-to-peer type of entity relationships that relate the standardized data entities of multiple data models. Multiple data models that contain the same standard data entity may participate in the same commonality relationship. When integrated data models are instantiated as databases and are properly populated from a common set of master data, then these databases are integrated.

Example

Consider a web application where a user can query a variety of information about cities (such as crime statistics, weather, hotels, demographics, etc.). Traditionally, the information must be stored in a single database with a single schema. But any single enterprise would find information of this breadth somewhat difficult and expensive to collect. Even if the resources exist to gather the data, it would likely duplicate data in existing crime databases, weather websites, and census data.

A data-integration solution may address this problem by considering these external resources as materialized views over a virtual mediated schema, resulting in "virtual data integration". This means application-developers construct a virtual schema — the *mediated schema* — to best model the kinds of answers their users want. Next, they design "wrappers" or adapters for each data source, such as the crime database and weather website. These adapters simply transform the local query results (those returned by the respective websites or databases) into an easily processed form for the data integration solution (see figure 2). When an application-user queries the mediated schema, the data-integration solution transforms this query into appropriate queries over the respective data sources. Finally, the virtual database combines the results of these queries into the answer to the user's query.

This solution offers the convenience of adding new sources by simply constructing an adapter or an application software blade for them. It contrasts with ETL systems or with a single database solution, which require manual integration of entire new dataset into the system. The virtual ETL solutions leverage virtual mediated schema to implement data harmonization; whereby the data is copied from the designated "master" source to the defined targets, field by field. Advanced Data virtualization is also built on the concept of object-oriented modeling in order to construct virtual mediated schema or virtual metadata repository, using hub and spoke architecture.

Each data source is disparate and as such is not designed to support reliable joins between data sources. Therefore, data virtualization as well as data federation depends upon accidental data commonality to support combining data and information from disparate data sets. Because of this lack of data value commonality across data sources, the return set may be inaccurate, incomplete, and impossible to validate.

One solution is to recast disparate databases to integrate these databases without the need for ETL. The recast databases support commonality constraints where referential integrity may be enforced between databases. The recast databases provide designed data access paths with data value commonality across databases.

Theory of data integration

The theory of data integration forms a subset of database theory and formalizes the underlying concepts of the problem in first-order logic. Applying the theories gives indications as to the feasibility and difficulty of data integration. While its definitions may appear abstract, they have sufficient generality to accommodate all manner of integration systems.[*citation needed*]

Definitions

Data integration systems are formally defined as a triple $\langle G, S, M \rangle$ where G is the global (or mediated) schema, S is the heterogeneous set of source schemas, and M is the mapping that maps queries between the source and the global schemas. Both G and S are expressed in languages over alphabets composed of symbols for each of their respective relations. The mapping M consists of assertions between queries over G and queries over S. When users pose queries over the data integration system, they pose queries over G and the mapping then asserts connections between the elements in the global schema and the source schemas.

A database over a schema is defined as a set of sets, one for each relation (in a relational database). The database corresponding to the source schema S would comprise the set of sets of tuples for each of the heterogeneous data sources and is called the *source database*. Note that this single source database may actually represent a collection of disconnected databases. The database corresponding to the virtual mediated schema G is called the *global database*. The global database must satisfy the mapping M with respect to the source database. The legality of this mapping depends on the nature of the correspondence between G and S. Two popular ways to model this correspondence exist: *Global as View* or GAV and *Local as View* or LAV.

GAV systems model the global database as a set of views over S. In this case M associates to each element of G as a query over S. Query processing becomes a straightforward operation due to the well-defined associations between G and S. The burden of complexity falls on implementing mediator code instructing the data integration system exactly how to retrieve elements from the source databases. If any new sources join the system, considerable effort may be necessary to update the mediator, thus the GAV approach appears preferable when the sources seem unlikely to change.

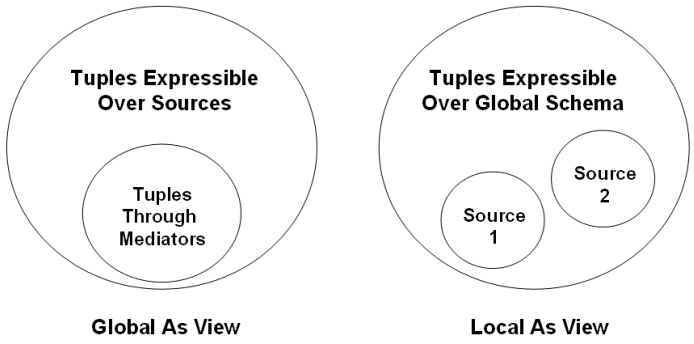

Figure 3: Illustration of tuple space of the GAV and LAV mappings. In GAV, the system is constrained to the set of tuples mapped by the mediators while the set of tuples expressible over the sources may be much larger and richer. In LAV, the system is constrained to the set of tuples in the sources while the set of tuples expressible over the global schema can be much larger. Therefore LAV systems must often deal with incomplete answers.

In a GAV approach to the example data integration system above, the system designer would first develop mediators for each of the city information sources and then design the global schema around these mediators. For example, consider if one of the sources served a weather website. The designer would likely then add a corresponding element for weather to the global schema. Then the bulk of effort concentrates on writing the proper mediator code that will transform predicates on weather into a query over the weather website. This effort can become complex if some other source also relates to weather, because the designer may need to write code to properly combine the results from the two sources.

On the other hand, in LAV, the source database is modeled as a set of views over G. In this case M associates to each element of S a query over G. Here the exact associations between G and S are no longer well-defined. As is illustrated in the next section, the burden of determining how to retrieve elements from the sources is placed on the query processor. The benefit of an LAV modeling is that new sources can be added with far less work than in a GAV system, thus the LAV approach should be favored in cases where the mediated schema is more stable and unlikely to change.

In an LAV approach to the example data integration system above, the system designer designs the global schema first and then simply inputs the schemas of the respective city information sources. Consider again if one of the sources serves a weather website. The designer would add corresponding elements for weather to the global schema only if none existed already. Then programmers write an adapter or wrapper for the website and add a schema description of the website's results to the source schemas. The complexity of adding the new source moves from the designer to the query processor.

Query processing

The theory of query processing in data integration systems is commonly expressed using conjunctive queries and Datalog, a purely declarative logic programming language. One can loosely think of a conjunctive query as a logical function applied to the relations of a database such as " $f(A, B)$ where $A < B$ ". If a tuple or set of tuples is substituted into the rule and satisfies it (makes it true), then we consider that tuple as part of the set of answers in the query. While formal languages like Datalog express these queries concisely and without ambiguity, common SQL queries count as conjunctive queries as well.

In terms of data integration, "query containment" represents an important property of conjunctive queries. A query A contains another query B (denoted $A \supset B$) if the results of applying B are a subset of the results of applying A for any database. The two queries are said to be equivalent if the resulting sets are equal for any database. This is important because in both GAV and LAV systems, a user poses conjunctive queries over a *virtual*

schema represented by a set of views, or "materialized" conjunctive queries. Integration seeks to rewrite the queries represented by the views to make their results equivalent or maximally contained by our user's query. This corresponds to the problem of answering queries using views (AQUV).

In GAV systems, a system designer writes mediator code to define the query-rewriting. Each element in the user's query corresponds to a substitution rule just as each element in the global schema corresponds to a query over the source. Query processing simply expands the subgoals of the user's query according to the rule specified in the mediator and thus the resulting query is likely to be equivalent. While the designer does the majority of the work beforehand, some GAV systems such as Tsimmis [2] involve simplifying the mediator description process.

In LAV systems, queries undergo a more radical process of rewriting because no mediator exists to align the user's query with a simple expansion strategy. The integration system must execute a search over the space of possible queries in order to find the best rewrite. The resulting rewrite may not be an equivalent query but maximally contained, and the resulting tuples may be incomplete. As of 2009[1] the MiniCon algorithm is the leading query rewriting algorithm for LAV data integration systems.

In general, the complexity of query rewriting is NP-complete. If the space of rewrites is relatively small this does not pose a problem — even for integration systems with hundreds of sources.

Data Integration in the Life Sciences

Large-scale questions in science, such as global warming, invasive species spread, and resource depletion, are increasingly requiring the collection of disparate data sets for meta-analysis. This type of data integration is especially challenging for ecological and environmental data because metadata standards are not agreed upon and there are many different data types produced in these fields. National Science Foundation initiatives such as Datanet are intended to make data integration easier for scientists by providing cyberinfrastructure and setting standards. The two funded Datanet initiatives are DataONE and the Data Conservancy.

Ontology-based data integration

Ontology based Data Integration involves the use of ontology(s) to effectively combine data or information from multiple heterogeneous sources. It is one of the multiple data integration approaches and may be classified as Global-As-View (GAV). The effectiveness of ontology based data integration is closely tied to the consistency and expressivity of the ontology used in the integration process.

Background

Data from multiple sources are characterized by multiple types of heterogeneity. The following hierarchy is often used:[1]

- Syntactic Heterogeneity: is a result of differences in representation format of data
- Schematic or Structural Heterogeneity: the native model or structure to store data differ in data sources leading to structural heterogeneity. Schematic heterogeneity that particularly appears in structured databases is also an aspect of structural heterogeneity.
- Semantic Heterogeneity: differences in interpretation of the 'meaning' of data are source of semantic heterogeneity
- System Heterogeneity: use of different operating system, hardware platforms lead to system heterogeneity

Ontologies, as formal models of representation with explicitly defined concepts and named relationships linking them, are used to address the issue of semantic heterogeneity in data sources. In domains like bioinformatics and biomedicine, the rapid development, adoption and public availability of ontologies [2] has made it possible for the data integration community to leverage them for semantic integration of data and information.

The Role of Ontologies

Ontologies enable the unambiguous identification of entities in heterogeneous information systems and assertion of applicable named relationships that connect these entities together. Specifically, ontologies play the following roles:

- Content Explication

The ontology enables accurate interpretation of data from multiple sources through the explicit definition of terms and relationships in the ontology.

- Query Model

In some systems like SIMS, the query is formulated using the ontology as a global query schema.

- Verification

The ontology verifies the mappings used to integrate data from multiple sources. These mappings may either be user specified or generated by a system.

Approaches using ontologies for data Integration

There are three main architectures that are implemented in ontology-based data integration applications, namely,

Single ontology approach

> A single ontology is used as a global reference model in the system. This is the simplest approach as it can be simulated by other approaches. SIMS is a prominent example of this approach.

Multiple ontologies

> Multiple ontologies, each modeling an individual data source, are used in combination for integration. Though, this approach is more flexible than the single ontology approach, it requires creation of mappings between the multiple ontologies. Ontology mapping is a challenging issue and is focus of large number of research efforts

in computer science [3]. The OBSERVER system is an example of this approach.

Hybrid approaches

The hybrid approach involves the use of multiple ontologies that subscribe to a common, top-level vocabulary. The top-level vocabulary defines the basic terms of the domain. Thus, the hybrid approach makes it easier to use multiple ontologies for integration in presence of the common vocabulary.

Ontology merging

Ontology merging defines the act of bringing together two conceptually divergent ontologies or the instance data associated to two ontologies. This is similar to work in database merging (schema matching). This merging process can be performed in a number of ways, manually, semi automatically, or automatically. Manual ontology merging although ideal is extremely labour intensive and current research attempts to find semi or entirely automated techniques to merge ontologies. These techniques are statistically driven often taking into account similarity of concepts and raw similarity of instances through textual string metrics and semantic knowledge. These techniques are similar to those used in information integration employing string metrics from open source similarity libraries.

Parallel

MapReduce

MapReduce is a programming model for processing large data sets with a parallel, distributed algorithm on a cluster.[1]

A MapReduce program is composed of a **Map()** procedure that performs filtering and sorting (such as sorting students by first name into queues, one queue for each name) and a **Reduce()** procedure that performs a summary operation (such as counting the number of students in each queue, yielding name frequencies). The "MapReduce System" (also called "infrastructure" or "framework") orchestrates by marshalling the distributed servers, running the various tasks in parallel, managing all communications and data transfers between the various parts of the system, and providing for redundancy and fault tolerance.

The model is inspired by the map and reduce functions commonly used in functional programming,[2] although their purpose in the MapReduce framework is not the same as in their original forms. Furthermore, the key contributions of the MapReduce framework are not the actual map and reduce functions, but the scalability and fault-tolerance achieved for a variety of applications by optimizing the execution engine once.

MapReduce libraries have been written in many programming languages, with different levels of optimization. A popular open-source implementation is Apache Hadoop. The name MapReduce originally referred to the proprietary Google technology but has since been genericized.

Overview

'MapReduce' is a framework for processing parallelizable problems across huge datasets using a large number of computers (nodes), collectively referred to as a cluster (if all nodes are on the same local network and use similar hardware) or a grid (if the nodes are shared across geographically and administratively distributed systems, and use more heterogenous hardware). Computational processing can occur on data stored either in a filesystem (unstructured) or in a database (structured). MapReduce can take advantage of locality of data, processing data on or near the storage assets to decrease transmission of data.

"Map" step: The master node takes the input, divides it into smaller sub-problems, and distributes them to worker nodes. A worker node may do this again in turn, leading to a multi-level tree structure. The worker node processes the smaller problem, and passes the answer back to its master node.

"Reduce" step: The master node then collects the answers to all the sub-problems and combines them in some way to form the output – the answer to the problem it was originally trying to solve.

MapReduce allows for distributed processing of the map and reduction operations. Provided that each mapping operation is independent of the others, all maps can be performed in parallel – though in practice this is limited by the number of independent data sources and/or the number of CPUs near each source. Similarly, a set of 'reducers' can perform the reduction phase, provided that all outputs of the map operation that share the same key are presented to the same reducer at the same time, or that the reduction function is associative. While this process can often appear inefficient compared to algorithms that are more sequential, MapReduce can be applied to significantly larger datasets than "commodity" servers can handle – a large server farm can use MapReduce to sort a petabyte of data in only a few hours.[*citation needed*] The parallelism also offers some possibility of recovering from partial failure of servers or storage during the operation: if one mapper or reducer fails, the work can be rescheduled – assuming the input data is still available.

Another way to look at MapReduce is as a 5-step parallel and distributed computation:

1. **Prepare the Map() input** – the "MapReduce system" designates Map processors, assigns the K1 input key value each processor would work on, and provides that processor with all the input data associated with that key value.
2. **Run the user-provided Map() code** – Map() is run exactly once for each K1 key value, generating output organized by key values K2.
3. **"Shuffle" the Map output to the Reduce processors** – the MapReduce system designates Reduce processors, assigns the K2 key value each processor would work on, and provides that processor with all the Map-generated data associated with that key value.
4. **Run the user-provided Reduce() code** – Reduce() is run exactly once for each K2 key value produced by the Map step.
5. **Produce the final output** – the MapReduce system collects all the Reduce output, and sorts it by K2 to produce the final outcome.

Logically these 5 steps can be thought of as running in sequence – each step starts only after the previous step is completed – though in practice, of course, they can be intertwined, as long as the final result is not affected.

In many situations the input data might already be distributed ("sharded") among many different servers, in which case step 1 could sometimes be greatly simplified by assigning Map servers that would process the locally present input data. Similarly, step 3 could sometimes be sped up by assigning Reduce processors that are as much as possible local to the Map-generated data they need to process.

Logical view

The *Map* and *Reduce* functions of *MapReduce* are both defined with respect to data structured in (key, value) pairs. *Map* takes one pair of data with a type in one data domain, and returns a list of pairs in a different domain:

`Map(k1,v1) → list(k2,v2)`

The *Map* function is applied in parallel to every pair in the input dataset. This produces a list of pairs for each call. After that, the MapReduce framework collects all pairs with the same key from all lists and groups them together, creating one group for each key.

The *Reduce* function is then applied in parallel to each group, which in turn produces a collection of values in the same domain:

`Reduce(k2, list (v2)) → list(v3)`

Each *Reduce* call typically produces either one value v3 or an empty return, though one call is allowed to return more than one value. The returns of all calls are collected as the desired result list.

Thus the MapReduce framework transforms a list of (key, value) pairs into a list of values. This behavior is different from the typical functional programming map and reduce combination, which accepts a list of arbitrary values and returns one single value that combines *all* the values returned by map.

It is necessary but not sufficient to have implementations of the map and reduce abstractions in order to implement MapReduce. Distributed implementations of MapReduce require a means of connecting the processes performing the Map and Reduce phases. This may be a distributed file system. Other options are possible, such as direct streaming from mappers to reducers, or for the mapping processors to serve up their results to reducers that query them.

Examples

The prototypical MapReduce example counts the appearance of each word in a set of documents:[3]

```
function map(String name, String document):
  // name: document name
  // document: document contents
  for each word w in document:
    emit (w, 1)

function reduce(String word, Iterator partialCounts):
  // word: a word
  // partialCounts: a list of aggregated partial counts
  sum = 0
  for each pc in partialCounts:
    sum += ParseInt(pc)
  emit (word, sum)
```

Here, each document is split into words, and each word is counted by the *map* function, using the word as the result key. The framework puts together all the pairs with the same key and feeds them to the same call to *reduce*, thus this function just needs to sum all of its input values to find the total appearances of that word.

As another example, imagine that for a database of 1.1 billion people, one would like to compute the average number of social contacts a person has according to age. In SQL such a query could be expressed as:

```
  SELECT age, AVG(contacts)
    FROM social.person
GROUP BY age
ORDER BY age
```

Using MapReduce, the `K1` key values could be the integers 1 through 1,100, each representing a batch of 1 million records, the `K2` key value could be a person's age in years, and this computation could be achieved using the following functions:

```
function Map is
    input: integer K1 between 1 and 1100, representing a batch of 1 million social.person records
    for each social.person record in the K1 batch do
        let Y be the person's age
        let N be the number of contacts the person has
        produce one output record (Y,(N,1))
    repeat
end function

function Reduce is
    input: age (in years) Y
    for each input record (Y,(N,C)) do
        Accumulate in S the sum of N*C
        Accumulate in C_new the sum of C
    repeat
    let A be S/C_new
    produce one output record (Y,(A,C_new))
```

```
end function
```

The MapReduce System would line up the 1,100 Map processors, and would provide each with its corresponding 1 million input records. The Map step would produce 1.1 billion `(Y,(N,1))` records, with `Y` values ranging between, say, 8 and 103. The MapReduce System would then line up the 96 Reduce processors by performing shuffling operation of the key/value pairs due to the fact that we need average per age, and provide each with its millions of corresponding input records. The Reduce step would result in the much reduced set of only 96 output records `(Y,A)`, which would be put in the final result file, sorted by `Y`.

The count info in the record is important if the processing is reduced more than one time. If we don't add the count of the records, the computed average would be wrong, for example:

```
-- map output #1: age, quantity of contacts
10, 9
10, 9
10, 9
```

```
-- map output #2: age, quantity of contacts
10, 9
10, 9
```

```
-- map output #3: age, quantity of contacts
10, 10
```

If we reduce files `#1` and `#2`, we will have a new file with an average of 9 contacts for a 10 year old person ((9+9+9+9+9)/5):

```
-- reduce step #1: age, average of contacts
10, 9
```

If we reduce it with file `#3`, we lost the count of how many records we've already seen, so we would end up with an average of 9.5 contacts for a 10 year old person ((9+10)/2), which is wrong. The correct answer is 9.17 ((9+9+9+9+9+10)/6).

Dataflow

The frozen part of the MapReduce framework is a large distributed sort. The hot spots, which the application defines, are:

- an *input reader*
- a *Map* function
- a *partition* function
- a *compare* function
- a *Reduce* function
- an *output writer*

Input reader

The *input reader* divides the input into appropriate size 'splits' (in practice typically 16 MB to 128 MB) and the framework assigns one split to each *Map* function. The *input reader* reads data from stable storage (typically a distributed file system) and generates key/value pairs.

A common example will read a directory full of text files and return each line as a record.

Map function

The *Map* function takes a series of key/value pairs, processes each, and generates zero or more output key/value pairs. The input and output types of the map can be (and often are) different from each other.

If the application is doing a word count, the map function would break the line into words and output a key/value pair for each word. Each output pair would contain the word as the key and the number of instances of that word in the line as the value.

Partition function

Each *Map* function output is allocated to a particular *reducer* by the application's *partition* function for sharding purposes. The *partition* function is given the key and the number of reducers and returns the index of the desired *reducer*.

A typical default is to hash the key and use the hash value modulo the number of *reducers*. It is important to pick a partition function that gives an approximately uniform distribution of data per shard for load-balancing purposes, otherwise the MapReduce operation can be held up waiting for slow reducers (reducers assigned more than their share of data) to finish.

Between the map and reduce stages, the data is *shuffled* (parallel-sorted / exchanged between nodes) in order to move the data from the map node that produced it to the shard in which it will be reduced. The shuffle can sometimes take longer than the computation time depending on network bandwidth, CPU speeds, data produced and time taken by map and reduce computations.

Comparison function

The input for each *Reduce* is pulled from the machine where the *Map* ran and sorted using the application's *comparison* function.

Reduce function

The framework calls the application's *Reduce* function once for each unique key in the sorted order. The *Reduce* can iterate through the values that are associated with that key and produce zero or more outputs.

In the word count example, the *Reduce* function takes the input values, sums them and generates a single output of the word and the final sum.

Output writer

The *Output Writer* writes the output of the *Reduce* to the stable storage, usually a distributed file system.

Distribution and reliability

MapReduce achieves reliability by parceling out a number of operations on the set of data to each node in the network. Each node is expected to report back periodically with completed work and status updates. If a node falls silent for longer than that interval, the master node (similar to the master server in the Google File System) records the node as dead and sends out the node's assigned work to other nodes. Individual operations use atomic operations

for naming file outputs as a check to ensure that there are not parallel conflicting threads running. When files are renamed, it is possible to also copy them to another name in addition to the name of the task (allowing for side-effects).

The reduce operations operate much the same way. Because of their inferior properties with regard to parallel operations, the master node attempts to schedule reduce operations on the same node, or in the same rack as the node holding the data being operated on. This property is desirable as it conserves bandwidth across the backbone network of the datacenter.

Implementations are not necessarily highly reliable. For example, in older versions of Hadoop the *NameNode* was a single point of failure for the distributed filesystem. Later versions of Hadoop have high availability with an active/passive failover for the "NameNode."

Uses

MapReduce is useful in a wide range of applications, including distributed pattern-based searching, distributed sorting, web link-graph reversal, term-vector per host, web access log stats, inverted index construction, document clustering, machine learning, and statistical machine translation. Moreover, the MapReduce model has been adapted to several computing environments like multi-core and many-core systems, desktop grids, volunteer computing environments, dynamic cloud environments, and mobile environments.

At Google, MapReduce was used to completely regenerate Google's index of the World Wide Web. It replaced the old *ad hoc* programs that updated the index and ran the various analyses.

MapReduce's stable inputs and outputs are usually stored in a distributed file system. The transient data is usually stored on local disk and fetched remotely by the reducers.

Criticism

Lack of novelty

David DeWitt and Michael Stonebraker, computer scientists specializing in parallel databases and shared-nothing architectures, have been critical of the breadth of problems that MapReduce can be used for. They called its interface too low-level and questioned whether it really represents the paradigm shift its proponents have claimed it is. They challenged the MapReduce proponents' claims of novelty, citing Teradata as an example of prior art that has existed for over two decades. They also compared MapReduce programmers to Codasyl programmers, noting both are "writing in a low-level language performing low-level record manipulation." MapReduce's use of input files and lack of schema support prevents the performance improvements enabled by common database system features such as B-trees and hash partitioning, though projects such as Pig (or PigLatin), Sawzall, Apache Hive, YSmart [4], HBase and BigTable are addressing some of these problems.

Greg Jorgensen wrote an article rejecting these views. Jorgensen asserts that DeWitt and Stonebraker's entire analysis is groundless as MapReduce was never designed nor intended to be used as a database.

DeWitt and Stonebraker have subsequently published a detailed benchmark study in 2009 comparing performance of Hadoop's MapReduce and RDBMS approaches on several specific problems. They concluded that relational databases offer real advantages for many kinds of data use, especially on complex processing or where the data is used across an enterprise, but that MapReduce may be easier for users to adopt for simple or one-time processing tasks.

Google has been granted a patent on MapReduce.[5] However, there have been claims that this patent should not have been granted because MapReduce is too similar to existing products. For example, map and reduce functionality can be very easily implemented in Oracle's PL/SQL database oriented language.

Restricted programming framework

MapReduce tasks must be written as acyclic dataflow programs, i.e. a stateless mapper followed by a stateless reducer, that are executed by a batch job scheduler. This paradigm makes repeated querying of datasets difficult and imposes limitations that are felt in fields such as machine learning, where iterative algorithms that revisit a single working set multiple times are the norm.

Conferences and users groups

- The First International Workshop on MapReduce and its Applications (MAPREDUCE'10) [6] was held with the HPDC conference and OGF'29 meeting in Chicago, IL.
- MapReduce Users Groups [7] around the world.

Apache Hadoop

Apache Hadoop

Developer(s)	Apache Software Foundation
Stable release	2.2 / October 15, 2013
Preview release	2.1.0-beta / August 25, 2013
Development status	Active
Written in	Java
Operating system	Cross-platform
Type	Distributed File System
License	Apache License 2.0
Website	hadoop.apache.org [1]

Apache Hadoop is an open-source software framework for storage and large-scale processing of data-sets on clusters of commodity hardware. Hadoop is an Apache top-level project being built and used by a global community of contributors and users. It is licensed under the Apache License 2.0.

The Apache Hadoop framework is composed of the following modules:

- Hadoop Common – contains libraries and utilities needed by other Hadoop modules
- Hadoop Distributed File System (HDFS) – a distributed file-system that stores data on commodity machines, providing very high aggregate bandwidth across the cluster.
- Hadoop YARN – a resource-management platform responsible for managing compute resources in clusters and using them for scheduling of users' applications.
- Hadoop MapReduce – a programming model for large scale data processing.

All the modules in Hadoop are designed with a fundamental assumption that hardware failures (of individual machines, or racks of machines) are common and thus should be automatically handled in software by the framework. Apache Hadoop's MapReduce and HDFS components originally derived respectively from Google's MapReduce and Google File System (GFS) papers.

Beyond HDFS, YARN and MapReduce, the entire Apache Hadoop “platform” is now commonly considered to consist of a number of related projects as well – Apache Pig, Apache Hive, Apache HBase, Apache Spark, and others.

For the end-users, though MapReduce Java code is common, any programming language can be used with "Hadoop Streaming" to implement the "map" and "reduce" parts of the user's program. Apache Pig, Apache Hive, Apache Spark among other related projects expose higher level user interfaces like Pig latin and a SQL variant respectively. The Hadoop framework itself is mostly written in the Java programming language, with some native code in C and command line utilities written as shell-scripts.

Apache Hadoop is a registered trademark of the Apache Software Foundation.

History

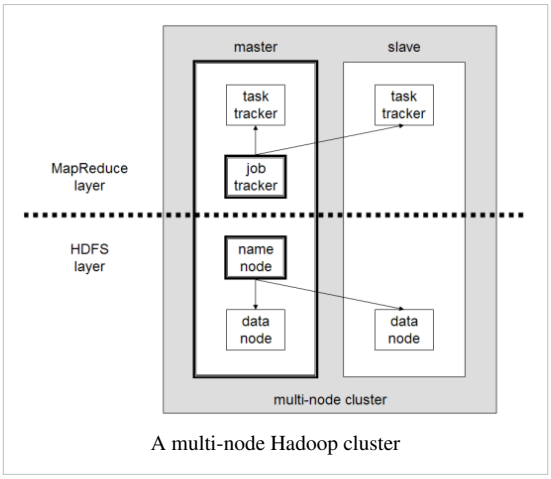
Hadoop was created by Doug Cutting and Mike Cafarella in 2005. Cutting, who was working at Yahoo! at the time,[2] named it after his son's toy elephant. It was originally developed to support distribution for the Nutch search engine project.[3]

Architecture

Hadoop consists of the *Hadoop Common* package, which provides filesystem and OS level abstractions, a MapReduce engine (either MapReduce/MR1 or YARN/MR2) and the Hadoop Distributed File System (HDFS). The Hadoop Common package contains the necessary Java ARchive (JAR) files and scripts needed to start Hadoop. The package also provides source code, documentation and a contribution section that includes projects from the Hadoop Community.[*citation needed*]

For effective scheduling of work, every Hadoop-compatible file system should provide location awareness: the name of the rack (more precisely, of the network switch) where a worker node is. Hadoop applications can use this information to run work on the node where the data is, and, failing that, on the same rack/switch, reducing backbone traffic. HDFS uses this method when replicating data to try to keep different copies of the data on different racks. The goal is to reduce the impact of a rack power outage or switch failure, so that even if these events occur, the data may still be readable.

A small Hadoop cluster includes a single master and multiple worker nodes. The master node consists of a JobTracker, TaskTracker, NameNode and DataNode. A slave or *worker node* acts as both a DataNode and TaskTracker, though it is possible to have data-only worker nodes and compute-only worker nodes. These are normally used only in nonstandard applications. Hadoop requires Java Runtime Environment (JRE) 1.6 or higher. The standard start-up and shutdown scripts require Secure Shell (ssh) to be set up between nodes in the cluster.



A multi-node Hadoop cluster

In a larger cluster, the HDFS is managed through a dedicated NameNode server to host the file system index, and a secondary NameNode that can generate snapshots of the namenode's memory structures, thus preventing file-system corruption and reducing loss of data. Similarly, a standalone JobTracker server can manage job scheduling. In clusters where the Hadoop MapReduce engine is deployed against an alternate file system, the NameNode, secondary NameNode and DataNode architecture of HDFS is replaced by the file-system-specific equivalent.

File system

Hadoop distributed file system

The **Hadoop distributed file system** (**HDFS**) is a distributed, scalable, and portable file-system written in Java for the Hadoop framework. Each node in a Hadoop instance typically has a single namenode; a cluster of datanodes form the HDFS cluster. The situation is typical because each node does not require a datanode to be present. Each datanode serves up blocks of data over the network using a block protocol specific to HDFS. The file system uses the TCP/IP layer for communication. Clients use Remote procedure call (RPC) to communicate between each other.

HDFS stores large files (typically in the range of gigabytes to terabytes) across multiple machines. It achieves reliability by replicating the data across multiple hosts, and hence theoretically does not require RAID storage on hosts (but to increase I/O performance some RAID configurations are still useful). With the default replication value,

3, data is stored on three nodes: two on the same rack, and one on a different rack. Data nodes can talk to each other to rebalance data, to move copies around, and to keep the replication of data high. HDFS is not fully POSIX-compliant, because the requirements for a POSIX file-system differ from the target goals for a Hadoop application. The tradeoff of not having a fully POSIX-compliant file-system is increased performance for data throughput and support for non-POSIX operations such as Append.

HDFS added the high-availability capabilities, as announced for release 2.0 in May 2012, allowing the main metadata server (the NameNode) to be failed over manually to a backup in the event of failure. The project has also started developing automatic fail-over.

The HDFS file system includes a so-called *secondary namenode,* which misleads some people into thinking[*citation needed*] that when the primary namenode goes offline, the secondary namenode takes over. In fact, the secondary namenode regularly connects with the primary namenode and builds snapshots of the primary namenode's directory information, which the system then saves to local or remote directories. These checkpointed images can be used to restart a failed primary namenode without having to replay the entire journal of file-system actions, then to edit the log to create an up-to-date directory structure. Because the namenode is the single point for storage and management of metadata, it can become a bottleneck for supporting a huge number of files, especially a large number of small files. HDFS Federation, a new addition, aims to tackle this problem to a certain extent by allowing multiple name-spaces served by separate namenodes.

An advantage of using HDFS is data awareness between the job tracker and task tracker. The job tracker schedules map or reduce jobs to task trackers with an awareness of the data location. For example: if node A contains data (x,y,z) and node B contains data (a,b,c), the job tracker schedules node B to perform map or reduce tasks on (a,b,c) and node A would be scheduled to perform map or reduce tasks on (x,y,z). This reduces the amount of traffic that goes over the network and prevents unnecessary data transfer. When Hadoop is used with other file systems this advantage is not always available. This can have a significant impact on job-completion times, which has been demonstrated when running data-intensive jobs.

HDFS was designedWikipedia:Manual of Style/Words to watch#Unsupported attributions for mostly immutable files and may not be suitable for systems requiring concurrent write-operations.

Another limitation of HDFS is that it cannot be mounted directly by an existing operating system. Getting data into and out of the HDFS file system, an action that often needs to be performed before and after executing a job, can be inconvenient. A Filesystem in Userspace (FUSE) virtual file system has been developed to address this problem, at least for Linux and some other Unix systems.

File access can be achieved through the native Java API, the Thrift API to generate a client in the language of the users' choosing (C++, Java, Python, PHP, Ruby, Erlang, Perl, Haskell, C#, Cocoa, Smalltalk, and OCaml), the command-line interface, or browsed through the HDFS-UI webapp over HTTP.

Other file systems

By May 2011, the list of supported file systems included:

- Amazon S3 file system. This is targeted at clusters hosted on the Amazon Elastic Compute Cloud server-on-demand infrastructure. There is no rack-awareness in this file system, as it is all remote.
- CloudStore (previously Kosmos Distributed File System), which is rack-aware.
- FTP File system: this stores all its data on remotely accessible FTP servers.
- HDFS: Hadoop's own rack-aware file system. This is designed to scale to tens of petabytes of storage and runs on top of the file systems of the underlying operating systems.
- MapR's maprfs[4] file system. This system provides inherent high availability, transactionally correct snapshots and mirrors while offering higher scaling than HDFS while giving higher performance. Maprfs is available as part of the MapR distribution[5] and as a native option[6] on Elastic Map Reduce from Amazon's web services, as well as on Google Compute Engine.

- Read-only HTTP and HTTPS file systems.

Hadoop can work directly with any distributed file system that can be mounted by the underlying operating system simply by using a file:// URL; however, this comes at a price: the loss of locality. To reduce network traffic, Hadoop needs to know which servers are closest to the data; this is information that Hadoop-specific file system bridges can provide.

Out-of-the-box, this includes Amazon S3, and the CloudStore filestore, through s3:// and kfs:// URLs directly.

A number of third-party file system bridges have also been written, none of which are currently in Hadoop distributions.

- In 2009 IBM discussed running Hadoop over the IBM General Parallel File System. The source code was published in October 2009.
- In April 2010, Parascale published the source code to run Hadoop against the Parascale file system.
- In April 2010, Appistry released a Hadoop file system driver for use with its own CloudIQ Storage product.
- In June 2010, HP discussed a location-aware IBRIX Fusion file system driver.
- In May 2011, MapR Technologies, Inc. announced the availability of an alternative file system for Hadoop, which replaced the HDFS file system with a full random-access read/write file system, with advanced features like snaphots and mirrors, and got rid of the single point of failure issue of the default HDFS NameNode.

JobTracker and TaskTracker: the MapReduce engine

Above the file systems comes the MapReduce engine, which consists of one *JobTracker*, to which client applications submit MapReduce jobs. The JobTracker pushes work out to available *TaskTracker* nodes in the cluster, striving to keep the work as close to the data as possible. With a rack-aware file system, the JobTracker knows which node contains the data, and which other machines are nearby. If the work cannot be hosted on the actual node where the data resides, priority is given to nodes in the same rack. This reduces network traffic on the main backbone network. If a TaskTracker fails or times out, that part of the job is rescheduled. The TaskTracker on each node spawns off a separate Java Virtual Machine process to prevent the TaskTracker itself from failing if the running job crashes the JVM. A heartbeat is sent from the TaskTracker to the JobTracker every few minutes to check its status. The Job Tracker and TaskTracker status and information is exposed by Jetty and can be viewed from a web browser.

If the JobTracker failed on Hadoop 0.20 or earlier, all ongoing work was lost. Hadoop version 0.21 added some checkpointing to this process; the JobTracker records what it is up to in the file system. When a JobTracker starts up, it looks for any such data, so that it can restart work from where it left off.

Known limitations of this approach are:

- The allocation of work to TaskTrackers is very simple. Every TaskTracker has a number of available *slots* (such as "4 slots"). Every active map or reduce task takes up one slot. The Job Tracker allocates work to the tracker nearest to the data with an available slot. There is no consideration of the current system load of the allocated machine, and hence its actual availability.
- If one TaskTracker is very slow, it can delay the entire MapReduce job – especially towards the end of a job, where everything can end up waiting for the slowest task. With speculative execution enabled, however, a single task can be executed on multiple slave nodes.

Scheduling

By default Hadoop uses FIFO, and optional 5 scheduling priorities to schedule jobs from a work queue.[7] In version 0.19 the job scheduler was refactored out of the JobTracker, and added the ability to use an alternate scheduler (such as the *Fair scheduler* or the *Capacity scheduler*).

Fair scheduler

The fair scheduler was developed by Facebook. The goal of the fair scheduler is to provide fast response times for small jobs and QoS for production jobs. The fair scheduler has three basic concepts.[8]

1. Jobs are grouped into Pools.
2. Each pool is assigned a guaranteed minimum share.
3. Excess capacity is split between jobs.

By default, jobs that are uncategorized go into a default pool. Pools have to specify the minimum number of map slots, reduce slots, and a limit on the number of running jobs.

Capacity scheduler

The capacity scheduler was developed by Yahoo. The capacity scheduler supports several features that are similar to the fair scheduler.[9]

- Jobs are submitted into queues.
- Queues are allocated a fraction of the total resource capacity.
- Free resources are allocated to queues beyond their total capacity.
- Within a queue a job with a high level of priority has access to the queue's resources.

There is no preemption once a job is running.

Other applications

The HDFS file system is not restricted to MapReduce jobs. It can be used for other applications, many of which are under development at Apache. The list includes the HBase database, the Apache Mahout machine learning system, and the Apache Hive Data Warehouse system. Hadoop can in theory be used for any sort of work that is batch-oriented rather than real-time, that is very data-intensive, and able to work on pieces of the data in parallel. As of October 2009, commercial applications of Hadoop included:

- Log and/or clickstream analysis of various kinds
- Marketing analytics
- Machine learning and/or sophisticated data mining
- Image processing
- Processing of XML messages
- Web crawling and/or text processing
- General archiving, including of relational/tabular data, e.g. for compliance

Prominent users

Yahoo!

On February 19, 2008, Yahoo! Inc. launched what it claimed was the world's largest Hadoop production application. The Yahoo! Search Webmap is a Hadoop application that runs on a more than 10,000 core Linux cluster and produces data that is used in every Yahoo! Web search query.[10]

There are multiple Hadoop clusters at Yahoo! and no HDFS file systems or MapReduce jobs are split across multiple datacenters. Every Hadoop cluster node bootstraps the Linux image, including the Hadoop distribution. Work that the clusters perform is known to include the index calculations for the Yahoo! search engine.

On June 10, 2009, Yahoo! made the source code of the version of Hadoop it runs in production available to the public. Yahoo! contributes all the work it does on Hadoop to the open-source community. The company's developers also fix bugs, provide stability improvements internally and release this patched source code so that other users may benefit from their effort.

Facebook

In 2010 Facebook claimed that they had the largest Hadoop cluster in the world with 21 PB of storage. On June 13, 2012 they announced the data had grown to 100 PB. On November 8, 2012 they announced the data gathered in the warehouse grows by roughly half a PB per day.

Other users

As of 2013, Hadoop adoption is widespread. For example, more than half of the Fortune 50 uses Hadoop.

Hadoop on Amazon EC2/S3 services

It is possible to run Hadoop on Amazon Elastic Compute Cloud (EC2) and Amazon Simple Storage Service (S3). As an example The New York Times used 100 Amazon EC2 instances and a Hadoop application to process 4 TB of raw image TIFF data (stored in S3) into 11 million finished PDFs in the space of 24 hours at a computation cost of about $240 (not including bandwidth).

There is support for the S3 file system in Hadoop distributions, and the Hadoop team generates EC2 machine images after every release. From a pure performance perspective, Hadoop on S3/EC2 is inefficient, as the S3 file system is remote and delays returning from every write operation until the data is guaranteed not to be lost. This removes the locality advantages of Hadoop, which schedules work near data to save on network load.

Amazon Elastic MapReduce

Elastic MapReduce (EMR)[11] was introduced by Amazon in April 2009. Provisioning of the Hadoop cluster, running and terminating jobs, and handling data transfer between EC2 and S3 are automated by Elastic MapReduce. Apache Hive, which is built on top of Hadoop for providing data warehouse services, is also offered in Elastic MapReduce.

Support for using Spot Instances[12] was later added in August 2011. Elastic MapReduce is fault tolerant for slave failures, and it is recommended to only run the Task Instance Group on spot instances to take advantage of the lower cost while maintaining availability.

In June 2012, premium options for EMR were added that replace ordinary Hadoop with MapR's M3 and M5 versions. These options provide additional capabilities over and above what the default EMR offering provides.

Industry support of academic clusters

IBM and Google announced an initiative in 2007 to use Hadoop to support university courses in distributed computer programming.

In 2008 this collaboration, the Academic Cloud Computing Initiative (ACCI), partnered with the National Science Foundation to provide grant funding to academic researchers interested in exploring large-data applications. This resulted in the creation of the Cluster Exploratory (CLuE) program.

Running Hadoop in compute farm environments

Hadoop can also be used in compute farms and high-performance computing environments. Instead of setting up a dedicated Hadoop cluster, an existing compute farm can be used if the resource manager of the cluster is aware of the Hadoop jobs, and thus Hadoop jobs can be scheduled like other jobs in the cluster.

Grid engine integration

Integration with Sun Grid Engine was released in 2008, and running Hadoop on Sun Grid (Sun's on-demand utility computing service) was possible. In the initial implementation of the integration, the CPU-time scheduler has no knowledge of the locality of the data. Unfortunately, this means that the processing is not always done on the same rack as the data; this was a key feature of the Hadoop Runtime. An improved integration with data-locality was announced during the Sun HPC Software Workshop '09.

In 2008-2009 Sun released the *Hadoop Live CD* OpenSolaris project, which allows running a fully functional Hadoop cluster using a live CD. This distribution includes Hadoop 0.19 – as of April 2010 there has not been an updated release.

Condor integration

The Condor High-Throughput Computing System integration was presented at the *Condor Week* conference in 2010.

Commercial support

A number of companies offer commercial implementations or support for Hadoop.

- Big Data Partnership, based in Europe, offers Hadoop consulting, implementation services and training.
- BMC Software provides BMC Control-M for Hadoop, which adds capabilities to monitor and manage Hadoop workflows with predictive analytics and automated alerts.
- Cloudera offers CDH (Cloudera's Distribution including Apache Hadoop) and Cloudera Enterprise.
- Dell added Pentaho Business Analytics to the Dell Apache Hadoop solution for big data analytics. This consists of Dell servers, Dell networking components, Dell's Crowbar cloud deployment framework open source software, and Cloudera Distribution including Apache Hadoop (CDH).
- EMC released *EMC Greenplum Community Edition* and *EMC Greenplum HD Enterprise Edition* in May 2011. The community edition, with optional for-fee technical support, consists of Hadoop, HDFS, HBase, Hive, and the ZooKeeper configuration service. The enterprise edition is an offering based on the MapR product, and offers proprietary features such as snapshots and wide area replication.
- Asia's Etu is owned by Systex Corporation and represented in Europe by GNR Corporation.
- EMC Isilon announced support for HDFS in its OneFS clustered file system.
- Google added *AppEngine-MapReduce* to support running Hadoop 0.20 programs on Google App Engine.
- Grand Logic's JobServer product allows developers and admins to deploy, manage and monitor their Hadoop infrastructure, with support for Hadoop job processing and HDFS file/content management.
- Hortonworks (formed by Yahoo! and Benchmark Capital focuses is on making Hadoop more robust and easier to install, manage and use for enterprise users.

- IBM offers WebSphere eXtreme Scale (formerly ObjectGrid), which includes two styles of the HADOOP map-reduce pattern in its "agents" a.k.a. DataGrid APIs. Together with its scalable distributed data cache capability, it gives both map-reduce's ability to parallelize function and the ability to store plenty of data (in memory) for the function to quickly access. It's transactional and highly available, too.
- IBM offers InfoSphere BigInsights based on Hadoop in both a basic and enterprise edition.
- Intel released its own Hadoop distribution that takes advantage of capabilities in Intel Xeon chips, such as its processor instructions for accelerating AES encryption.
- MapR Technologies, Inc. announced the availability of their distributed file system and MapReduce engine, the MapR Distribution for Apache Hadoop. The MapR product includes most Hadoop eco-system components and adds capabilities such as snapshots, mirrors, NFS access and full read-write file semantics. MapR's distribution was selected by Amazon to provide premium versions of the Elastic Map Reduce (EMR) service.
- MetaScale, a wholly owned subsidiary of Sears offers vendor neutral and platform independent Hadoop consulting and implementation services.
- Microsoft offers Windows Azure HDInsight, which is a 100% Apache compatible Hadoop distribution on Windows Azure.
- OceanSync Hadoop Management and Visualization Software allows users to control, monitor, and visualize all aspects of a Hadoop cluster including data analytic workflow management and output data processing visualization. The package is offered in three versions, OceanSync Free Desktop Edition, OceanSync Enterprise Edition with Visualization, and OceanSync Mobile for iPhone/Android devices, by Dovestech.
- Oracle announced the *Big Data Appliance*, which integrates Cloudera's Distribution Including Hadoop (CDH), Oracle Linux, the R programming language, and a NoSQL database with the Exadata hardware.
- Pentaho announced support for Apache Hadoop allowing companies to access data integration and business analytics directly against Apache Hadoop based distributions of Hadoop. In January 2012, Pentaho announced they made their big data integration capabilities freely under open source, and moved the entire Pentaho Kettle (data integration engine) project from the LGPL license to the Apache License.
- Pivotal offers Pivotal HD, a distribution of Hadoop that includes HAWQ, with 100% ANSI SQL compatibility.
- Platform Computing announced support for the Hadoop MapReduce API in its Symphony software.
- Silicon Graphics International offers Hadoop optimized solutions based on the SGI Rackable and CloudRack server lines with implementation services.
- Splunk offers a Hadoop integration product called Hadoop Connect, which is certified on MapR, Cloudera, Hortonworks, and Apache Hadoop. This integration allows users to search Hadoop data from Splunk and import data from Hadoop into Splunk and vice versa.
- sqrrl offers sqrrl enterprise, which extends hadoop with Apache accumulo and combines the features of several datastores (Column + Document + Graph).[13]
- Supermicro offers Hadoop servers and rack solutions based on standard servers, multi-nodes and fixed-disks designs.
- Syncsort provides an ETL Solution, which extends the capabilities of Hadoop, turning it into a highly scalable, affordable, and easy-to-use data integration environment.[14]
- Talend offers Talend Open Studio for Big Data, released under the Apache Software License, that includes native support for Apache Hadoop.
- Teradata offers Teradata Appliance for Hadoop, as well as customer support for software-only Hadoop deployments.[15]
- TIBCO supports Hadoop with their Businessworks Hadoop plugin and the TIBCO Spotfire Client.
- WANdisco offers Non Stop Hadoop for both Cloudera & Hortonworks Hadoop distributions.[16]
- Zettaset offers new version of its Big Data Mgt Platform based on Hadoop. Zettaset's Big Data Platform delivers High Availability via NameNode Failover, a streamlined UI, network Time Protocol and built in security via Kerberos Authentication

ASF's view on the use of "Hadoop" in product names

The Apache Software Foundation has stated that only software officially released by the Apache Hadoop Project can be called *Apache Hadoop* or *Distributions of Apache Hadoop*. The naming of products and derivative works from other vendors and the term "compatible" are somewhat controversial within the Hadoop developer community.

Papers

Some papers influenced the birth and growth of Hadoop and big data processing. Here is a partial list:

- 2004 MapReduce: Simplified Data Processing on Large Clusters] by Jeffrey Dean and Sanjay Ghemawat from Google Lab. This paper inspired Doug Cutting to develop an open-source implementation of the Map-Reduce framework. He named it Hadoop [1], after his son's toy elephant.
- 2005 From Databases to Dataspaces: A New Abstraction for Information Management [17], the authors highlight the need for storage systems to accept all data formats and to provide APIs for data access that evolve based on the storage system's understanding of the data.
- 2006 Bigtable: A Distributed Storage System for Structured Data [18] from Google Lab.
- 2008 H-store: a high-performance, distributed main memory transaction processing system [19]
- 2009 MAD Skills: New Analysis Practices for Big Data [20]
- 2011 Apache Hadoop Goes Realtime at Facebook [21]

Pig (programming language)

Pig is a high-level platform for creating MapReduce programs used with Hadoop. The language for this platform is called **Pig Latin**. Pig Latin abstracts the programming from the Java MapReduce idiom into a notation which makes MapReduce programming high level, similar to that of SQL for RDBMS systems. Pig Latin can be extended using UDF (User Defined Functions) which the user can write in Java, Python, JavaScript, Ruby or Groovy and then call directly from the language.

Pig was originally developed at Yahoo Research around 2006 for researchers to have an ad-hoc way of creating and executing map-reduce jobs on very large data sets. In 2007, it was moved into the Apache Software Foundation.

Example

Below is an example of a "Word Count" program in Pig Latin:

```
input_lines = LOAD '/tmp/my-copy-of-all-pages-on-internet' AS (line:chararray);

-- Extract words from each line and put them into a pig bag
-- datatype, then flatten the bag to get one word on each row
words = FOREACH input_lines GENERATE FLATTEN(TOKENIZE(line)) AS word;

-- filter out any words that are just white spaces
filtered_words = FILTER words BY word MATCHES '\\w+';

-- create a group for each word
word_groups = GROUP filtered_words BY word;

-- count the entries in each group
word_count = FOREACH word_groups GENERATE COUNT(filtered_words) AS count, group AS word;

-- order the records by count
ordered_word_count = ORDER word_count BY count DESC;
```

```
STORE ordered_word_count INTO '/tmp/number-of-words-on-internet';
```

The above program will generate parallel executable tasks which can be distributed across multiple machines in a Hadoop cluster to count the number of words in a dataset such as all the webpages on the internet.

Pig vs SQL

In comparison to SQL, Pig

1. uses lazy evaluation,
2. uses ETL,
3. is able to store data at any point during a pipeline,
4. declares execution plans,
5. supports pipeline splits.

On the other hand, it has been argued DBMSs are substantially faster than the MapReduce system once the data is loaded, but that loading the data takes considerably longer in the database systems. It has also been argued RDBMSs offer out of the box support for column-storage, working with compressed data, indexes for efficient random data access, and transaction- level fault tolerance.[1]

Pig Latin is procedural and fits very naturally in the pipeline paradigm while SQL is instead declarative. In SQL users can specify that data from two tables must be joined, but not what join implementation to use. Pig Latin allows users to specify an implementation or aspects of an implementation to be used in executing a script in several ways. In effect, Pig Latin programming is similar to specifying a query execution plan, making it easier for programmers to explicitly control the flow of their data processing task.[2]

SQL is oriented around queries that produce a single result. SQL handles trees naturally, but has no built in mechanism for splitting a data processing stream and applying different operators to each sub-stream. Pig Latin script describes a directed acyclic graph (DAG) rather than a pipeline.

Pig Latin's ability to include user code at any point in the pipeline is useful for pipeline development. If SQL is used, data must first be imported into the database, and then the cleansing and transformation process can begin.[]

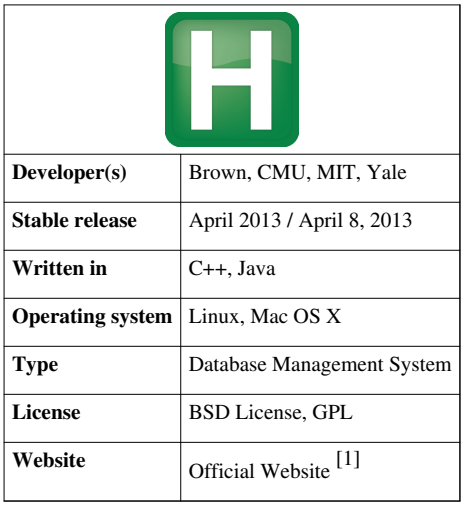
H-Store

H-Store



Developer(s)	Brown, CMU, MIT, Yale
Stable release	April 2013 / April 8, 2013
Written in	C++, Java
Operating system	Linux, Mac OS X
Type	Database Management System
License	BSD License, GPL
Website	Official Website [1]

H-Store is an experimental database management system (DBMS) designed for online transaction processing applications that is being developed by a team at Brown University, Carnegie Mellon University, the Massachusetts Institute of Technology, and Yale University. The system's design was developed in 2007 by database researchers Michael Stonebraker, Sam Madden, and Daniel Abadi.

The significance of the **H-Store** is that it is the first implementation of a new class of parallel database management systems, called NewSQL, that provide the high-throughput and high-availability of NoSQL systems, but without giving up the transactional guarantees of a traditional DBMS. Such systems are able to scale out horizontally across multiple machines to improve throughput, as opposed to moving to a more powerful, more expensive machine for a single-node system.

H-Store is able to execute transaction processing with high throughput by forgoing much of legacy architecture of System R-like systems. For example, **H-Store** was designed as a parallel, row-storage relational DBMS that runs on a cluster of shared-nothing, main memory executor nodes. The database is partitioned into disjoint subsets that are assigned to a single-threaded execution engine assigned to one and only one core on a node. Each engine has exclusive access to all of the data at its partition. Because it is single-threaded, only one transaction at a time is able to access the data stored at its partition. Thus, there are no physical locks or latches in the system, and no transaction will stall waiting for another transaction once it is started.

H-Store is licensed under the BSD license and GPL licenses. The commercial version of H-Store's design is VoltDB.

Information Security

Data control language

A **data control language** (**DCL**) is a syntax similar to a computer programming language used to control access to data stored in a database. In particular, it is a component of Structured Query Language (SQL).

Examples of DCL commands include:

- GRANT to allow specified users to perform specified tasks.
- REVOKE to cancel previously granted or denied permissions.

The operations for which privileges may be granted to or revoked from a user or role may include CONNECT, SELECT, INSERT, UPDATE, DELETE, EXECUTE, and USAGE.

In the Oracle database, executing a DCL command issues an implicit commit. Hence you cannot roll back the command.

In PostgreSQL, executing DCL is transactional, and can be rolled back.

SQL injection

SQL injection is a code injection technique, used to attack data driven applications, in which malicious SQL statements are inserted into an entry field for execution (e.g. to dump the database contents to the attacker). SQL injection must exploit a security vulnerability in an application's software, for example, when user input is either incorrectly filtered for string literal escape characters embedded in SQL statements or user input is not strongly typed and unexpectedly executed. SQL injection is mostly known as an attack vector for websites but can be used to attack any type of SQL database.

In a 2012 study, security company Imperva observed that the average web application received 4 attack campaigns per month, and retailers received twice as many attacks as other industries.

A Classification of SQL injection attacking vector until 2010.

Forms

SQL injection (SQLI) is considered one of the top 10 web application vulnerabilities of 2007 and 2010 by the Open Web Application Security Project. In 2013, SQLI was rated the number one attack on the OWASP top ten. There are five main sub-classes of SQL injection:

- Classic SQLI
- Blind or Inference SQL injection
- Database management system-specific SQLI
- Compounded SQLI
  - SQL injection + insufficient authentication
  - SQL injection + DDoS attacks
  - SQL injection + DNS hijacking

- SQL injection + XSS

The Storm Worm is one representation of Compounded SQLI.

This classification represents the state of SQLI, respecting its evolution until 2010—further refinement is underway.

Technical implementations

Incorrectly filtered escape characters

This form of SQL injection occurs when user input is not filtered for escape characters and is then passed into a SQL statement. This results in the potential manipulation of the statements performed on the database by the end-user of the application.

The following line of code illustrates this vulnerability:

```
statement = "
```

```
SELECT * FROM users WHERE name =
```

```
'" + userName + "';"
```

This SQL code is designed to pull up the records of the specified username from its table of users. However, if the "userName" variable is crafted in a specific way by a malicious user, the SQL statement may do more than the code author intended. For example, setting the "userName" variable as:

```
' or '1'='1'
```

or using comments to even block the rest of the query (there are three types of SQL comments):

```
' or '1'='1' -- '
' or '1'='1' ({ '
' or '1'='1' /* '
```

renders one of the following SQL statements by the parent language:

```
SELECT * FROM users WHERE name = '' or '1'='1';
```

```
SELECT * FROM users WHERE name = '' or '1'='1' -- ';
```

If this code were to be used in an authentication procedure then this example could be used to force the selection of a valid username because the evaluation of '1'='1' is always true.

The following value of "userName" in the statement below would cause the deletion of the "users" table as well as the selection of all data from the "userinfo" table (in essence revealing the information of every user), using an API that allows multiple statements:

```
a';
```

```
DROP TABLE users; SELECT * FROM userinfo WHERE 't' = 't
```

This input renders the final SQL statement as follows and specified:

```
SELECT * FROM users WHERE name = 'a';DROP TABLE users; SELECT * FROM
userinfo WHERE 't' = 't';
```

While most SQL server implementations allow multiple statements to be executed with one call in this way, some SQL APIs such as PHP's `mysql_query();` function do not allow this for security reasons. This prevents

attackers from injecting entirely separate queries, but doesn't stop them from modifying queries.

Incorrect type handling

This form of SQL injection occurs when a user-supplied field is not strongly typed or is not checked for type constraints. This could take place when a numeric field is to be used in a SQL statement, but the programmer makes no checks to validate that the user supplied input is numeric. For example:

```
statement := "
```

```
SELECT * FROM userinfo WHERE id =
```

```
" + a_variable + ";"
```

It is clear from this statement that the author intended a_variable to be a number correlating to the "id" field. However, if it is in fact a string then the end-user may manipulate the statement as they choose, thereby bypassing the need for escape characters. For example, setting a_variable to

```
1;DROP TABLE users
```

will drop (delete) the "users" table from the database, since the SQL becomes:

```
SELECT * FROM userinfo WHERE id=1;DROP TABLE users;
```

Blind SQL injection

Blind SQL Injection is used when a web application is vulnerable to an SQL injection but the results of the injection are not visible to the attacker. The page with the vulnerability may not be one that displays data but will display differently depending on the results of a logical statement injected into the legitimate SQL statement called for that page. This type of attack can become time-intensive because a new statement must be crafted for each bit recovered. There are several tools that can automate these attacks once the location of the vulnerability and the target information has been established.

Conditional responses

One type of blind SQL injection forces the database to evaluate a logical statement on an ordinary application screen. As an example, a book review website uses a query string to determine which book review to display. So the URL **`http://books.example.com/showReview.php?ID=5`** would cause the server to run the query

```
SELECT * FROM bookreviews WHERE ID = 'Value(ID)';
```

from which it would populate the review page with data from the review with ID 5, stored in the table bookreviews. The query happens completely on the server; the user does not know the names of the database, table, or fields, nor does the user know the query string. The user only sees that the above URL returns a book review. A hacker can load the URLs **`http://books.example.com/showReview.php?ID=5 OR 1=1`** and **`http://books.example.com/showReview.php?ID=5 AND 1=2`**, which may result in queries

```
SELECT * FROM bookreviews WHERE ID = '5' OR '1'='1';
SELECT * FROM bookreviews WHERE ID = '5' AND '1'='2';
```

respectively. If the original review loads with the "1=1" URL and a blank or error page is returned from the "1=2" URL, the site is likely vulnerable to a SQL injection attack. The hacker may proceed with this query string designed to reveal the version number of MySQL running on the server: **`http://books.example.com/showReview.php?ID=5 AND substring(@@version,1,1)=4`**, which would show the book review on a server running MySQL 4 and a blank or error page otherwise. The hacker

can continue to use code within query strings to glean more information from the server until another avenue of attack is discovered or his or her goals are achieved.

Second Order SQL Injection

Second Order SQLi happens when submitted values contain SQL injection attacks that are stored instead of executed immediately. In some cases, the application may correctly encode a SQL statement and store it as valid SQL. Then, another part of that application without controls to protect against SQL Injection might execute that stored SQL statement. This attack requires more knowledge of how submitted values are later used. Automated web application security scanners would not easily detect this type of SQL Injection and may need to be manually instructed where to check for evidence of second order SQLi.

Mitigation

Parameterized statements

With most development platforms, parameterized statements that work with parameters can be used (sometimes called placeholders or bind variables) instead of embedding user input in the statement. A placeholder can only store a value of the given type and not an arbitrary SQL fragment. Hence the SQL injection would simply be treated as a strange (and probably invalid) parameter value.

In many cases, the SQL statement is fixed, and each parameter is a scalar, not a table. The user input is then assigned (bound) to a parameter.

Enforcement at the coding level

Using object-relational mapping libraries avoids the need to write SQL code. The ORM library in effect will generate parameterized SQL statements from object-oriented code.

Escaping

A straightforward, though error-prone, way to prevent injections is to escape characters that have a special meaning in SQL. The manual for an SQL DBMS explains which characters have a special meaning, which allows creating a comprehensive blacklist of characters that need translation. For instance, every occurrence of a single quote (`'`) in a parameter must be replaced by two single quotes (`''`) to form a valid SQL string literal. For example, in PHP it is usual to escape parameters using the function `mysql_real_escape_string();` before sending the SQL query:

```
$mysqli = new mySqli('hostname', 'db_username', 'db_password',
'db_name');
$query = sprintf("SELECT * FROM `Users` WHERE UserName='%s' AND
Password='%s'",
                 $mysqli->real_escape_string($Username),
                 $mysqli->real_escape_string($Password));
$mysqli->query($query);
```

Note: 'mysql' is deprecated, and should be avoided. `mysqli [1]`, is preferred. This function, i.e. mysql_real_escape_string(), calls MySQL's library function mysql_real_escape_string, which prepends backslashes to the following characters: \x00, \n, \r, \, ', " and \x1a. This function must always (with few exceptions) be used to make data safe before sending a query to MySQL.

There are other functions for many database types in PHP such as pg_escape_string() for PostgreSQL. There is, however, one function that works for escaping characters, and is used especially for querying on databases that do

not have escaping functions in PHP. This function is: **addslashes(string $str)**. It returns a string with backslashes before characters that need to be quoted in database queries, etc. These characters are single quote ('), double quote ("), backslash (\) and NUL (the NULL byte).
Routinely passing escaped strings to SQL is error prone because it is easy to forget to escape a given string. Creating a transparent layer to secure the input can reduce this error-proneness, if not entirely eliminate it.

In .Net Framework just use parameterized query or stored procedure using parameters

```
SqlCommand cmd1= new SqlCommand("Select * from users where username ='"+@paramUser+"' and password='"+@paramPass+"'", conn1)
```

cmd1.CommandType= CommandType.Text cmd1.Parameters.Add("@paramUser", SqlDbType.Nvarchar,20).Value=Username1 cmd1.Parameters.Add("@paramPass", SqlDbType.Nvarchar,20).Value=pass1

In this case if for example Username1="' or 1=1--" this will not succeed.

Pattern check

Integer, float or boolean parameters can be checked if their value is valid representation for the given type. Strings that must follow some strict pattern (date, UUID, alphanumeric only, etc.) can be checked if they match this pattern.

Database permissions

Limiting the permissions on the database logon used by the web application to only what is needed may help reduce the effectiveness of any SQL injection attacks that exploit any bugs in the web application.

For example, on Microsoft SQL Server, a database logon could be restricted from selecting on some of the system tables which would limit exploits that try to insert JavaScript into all the text columns in the database.

```
deny select on sys.sysobjects to webdatabaselogon;
deny select on sys.objects to webdatabaselogon;
deny select on sys.tables to webdatabaselogon;
deny select on sys.views to webdatabaselogon;
deny select on sys.packages to webdatabaselogon;
```

Examples

- In September 1995, Andrew Plato, a technical writer for Microsoft discovered that he could send SQL queries through URL string of an early e-commerce site and directly query the database (SQL Server 6.0). Unaware of what this meant, Plato approached developers who dismissed the issue as irrelevant. [*citation needed*]
- In February 2002, Jeremiah Jacks discovered that Guess.com was vulnerable to an SQL injection attack, permitting anyone able to construct a properly-crafted URL to pull down 200,000+ names, credit card numbers and expiration dates in the site's customer database.
- On November 1, 2005, a teenage hacker used SQL injection to break into the site of a Taiwanese information security magazine from the Tech Target group and steal customers' information.
- On January 13, 2006, Russian computer criminals broke into a Rhode Island government web site and allegedly stole credit card data from individuals who have done business online with state agencies.
- On March 29, 2006, a hacker discovered an SQL injection flaw in an official Indian government's tourism site.
- On June 29, 2007, a computer criminal defaced the Microsoft UK website using SQL injection. UK website *The Register* quoted a Microsoft spokesperson acknowledging the problem.
- In January 2008, tens of thousands of PCs were infected by an automated SQL injection attack that exploited a vulnerability in application code that uses Microsoft SQL Server as the database store.

- In July 2008, Kaspersky's Malaysian site was hacked by a Turkish hacker going by the handle of "m0sted", who said to have used an SQL injection.
- In February 2013, a group of Maldivian hackers, hacked the website " UN-Maldives" using SQL Injection.
- In May 28, 2009 Anti-U.S. Hackers Infiltrate Army Servers Investigators believe the hackers used a technique called SQL injection to exploit a security vulnerability in Microsoft's SQL Server database to gain entry to the Web servers. "m0sted" is known to have carried out similar attacks on a number of other Web sites in the past—including against a site maintained by Internet security company Kaspersky Lab.
- On April 13, 2008, the Sexual and Violent Offender Registry of Oklahoma shut down its website for "routine maintenance" after being informed that 10,597 Social Security numbers belonging to sex offenders had been downloaded via an SQL injection attack
- In May 2008, a server farm inside China used automated queries to Google's search engine to identify SQL server websites which were vulnerable to the attack of an automated SQL injection tool.
- In 2008, at least April through August, a sweep of attacks began exploiting the SQL injection vulnerabilities of Microsoft's IIS web server and SQL Server database server. The attack does not require guessing the name of a table or column, and corrupts all text columns in all tables in a single request. A HTML string that references a malware JavaScript file is appended to each value. When that database value is later displayed to a website visitor, the script attempts several approaches at gaining control over a visitor's system. The number of exploited web pages is estimated at 500,000.
- On August 17, 2009, the United States Department of Justice charged an American citizen, Albert Gonzalez, and two unnamed Russians with the theft of 130 million credit card numbers using an SQL injection attack. In reportedly "the biggest case of identity theft in American history", the man stole cards from a number of corporate victims after researching their payment processing systems. Among the companies hit were credit card processor Heartland Payment Systems, convenience store chain 7-Eleven, and supermarket chain Hannaford Brothers.
- In December 2009, an attacker breached a RockYou plaintext database containing the unencrypted usernames and passwords of about 32 million users using an SQL injection attack.
- On July 2010, a South American security researcher who goes by the handle "Ch Russo" obtained sensitive user information from popular BitTorrent site The Pirate Bay. He gained access to the site's administrative control panel and exploited a SQL injection vulnerability that enabled him to collect user account information, including IP addresses, MD5 password hashes and records of which torrents individual users have uploaded.
- From July 24 to 26, 2010, attackers from Japan and China used an SQL injection to gain access to customers' credit card data from Neo Beat, an Osaka-based company that runs a large online supermarket site. The attack also affected seven business partners including supermarket chains Izumiya Co, Maruetsu Inc, and Ryukyu Jusco Co. The theft of data affected a reported 12,191 customers. As of August 14, 2010 it was reported that there have been more than 300 cases of credit card information being used by third parties to purchase goods and services in China.
- On September 19 during the 2010 Swedish general election a voter attempted a code injection by hand writing SQL commands as part of a write-in vote.
- On November 8, 2010 the British Royal Navy website was compromised by a Romanian hacker named TinKode using SQL injection.[2]
- On February 5, 2011 HBGary, a technology security firm, was broken into by LulzSec using a SQL injection in their CMS-driven website
- On March 27, 2011, mysql.com [3], the official homepage for MySQL, was compromised by a hacker using SQL blind injection
- On April 11, 2011, Barracuda Networks was compromised using an SQL injection flaw. Email addresses and usernames of employees were among the information obtained.
- Over a period of 4 hours on April 27, 2011, an automated SQL injection attack occurred on Broadband Reports website that was able to extract 8% of the username/password pairs: 8,000 random accounts of the 9,000 active

and 90,000 old or inactive accounts.

- On June 1, 2011, "hacktivists" of the group LulzSec were accused of using SQLI to steal coupons, download keys, and passwords that were stored in plaintext on Sony's website, accessing the personal information of a million users.
- In June 2011, PBS was hacked, mostly likely through use of SQL injection; the full process used by hackers to execute SQL injections was described in this Imperva [4] blog.
- In May 2012, the website for *Wurm Online*, a massively multiplayer online game, was shut down from an SQL injection while the site was being updated.
- In July 2012 a hacker group was reported to have stolen 450,000 login credentials from Yahoo!. The logins were stored in plain text and were allegedly taken from a Yahoo subdomain, Yahoo! Voices. The group breached Yahoo's security by using a "union-based SQL injection technique".[5][6]
- On October 1, 2012, a hacker group called "Team GhostShell" published the personal records of students, faculty, employees, and alumni from 53 universities including Harvard, Princeton, Stanford, Cornell, Johns Hopkins, and the University of Zurich on pastebin.com. The hackers claimed that they were trying to “raise awareness towards the changes made in today’s education”, bemoaning changing education laws in Europe and increases in tuition in the United States.
- On June 27, 2013, hacker group "RedHack" breached Istanbul Administration Site. They claimed that, they’ve been able to erase people's debts to water, gas, Internet, electricity, and telephone companies. Additionally, they published admin user name and password for other citizens to log in and clear their debts early morning. They announced the news from twitter.
- On November 4th, 2013, hacktivist group "RaptorSwag" allegedly compromised 71 Chinese government databases using an SQL injection attack on the Chinese Chamber of International Commerce. The leaked data was posted publicly in cooperation with Anonymous.[7]

In popular culture

- Unauthorized login to web sites (i.e. hacking) by means of SQL injection forms the basis of one of the subplots in J.K. Rowling's novel "The Casual Vacancy", published in 2012.
- The minor *xkcd* character "Robert'); DROP TABLE students;--" (also known as "Little Bobby Tables") was named to carry out a SQL injection.

Data Warehouseing

Business intelligence

Business intelligence (**BI**) is a set of theories, methodologies, architectures, and technologies that transform raw data into meaningful and useful information for business purposes. BI can handle enormous amounts of unstructured data to help identify, develop and otherwise create new opportunities. BI, in simple words, makes interpreting voluminous data friendly. Making use of new opportunities and implementing an effective strategy can provide a competitive market advantage and long-term stability.[1]

Generally, Business Intelligence is made up of an increasing number of components, these are:

- Multidimensional aggregation and allocation
- Denormalization, tagging and standardization
- Realtime reporting with analytical alert
- Interface with unstructured data source
- Group consolidation, budgeting and rolling forecast
- Statistical inference and probabilistic simulation
- Key performance indicators optimization
- Version control and process management
- Open item management

BI technologies provide historical, current and predictive views of business operations. Common functions of business intelligence technologies are reporting, online analytical processing, analytics, data mining, process mining, complex event processing, business performance management, benchmarking, text mining, predictive analytics and prescriptive analytics.

Though the term business intelligence is sometimes a synonym for competitive intelligence (because they both support decision making), BI uses technologies, processes, and applications to analyze mostly internal, structured data and business processes while competitive intelligence gathers, analyzes and disseminates information with a topical focus on company competitors. If understood broadly, business intelligence can include the subset of competitive intelligence.

History

The term Business Intelligence was originally first phrased by Richard Millar Devens' in the 'Cyclopædia of Commercial and Business Anecdotes' from 1865. Devens used the term to describe how the banker Sir Henry Furnese, gained profit by receiving and acting upon information about his environment, prior to his competitors. "*Throughout Holland, Flanders, France, and Germany, he maintained a complete and perfect train of business intelligence. The news of the many battles fought was thus received first by him, and the fall of Namur added to his profits, owing to his early receipt of the news*." (Devens, (1865), p. 210). The ability to collect and react accordingly based on the information retrieved, an ability that Furnese excelled in, is today still at the very heart of BI.

In a 1958 article, IBM researcher Hans Peter Luhn used the term business intelligence. He employed the Webster's dictionary definition of intelligence: "the ability to apprehend the interrelationships of presented facts in such a way as to guide action towards a desired goal."

Business intelligence as it is understood today is said to have evolved from the decision support systems (DSS) that began in the 1960s and developed throughout the mid-1980s. DSS originated in the computer-aided models created

to assist with decision making and planning. From DSS, data warehouses, Executive Information Systems, OLAP and business intelligence came into focus beginning in the late 80s.

In 1988, an Italian-Dutch-French-English consortium organized an international meeting on the Multiway Data Analysis in Rome.[2] The ultimate goal is to reduce the multiple dimensions down to one or two (by detecting the patterns within the data) that can then be presented to human decision-makers.

In 1989, Howard Dresner (later a Gartner Group analyst) proposed "business intelligence" as an umbrella term to describe "concepts and methods to improve business decision making by using fact-based support systems." It was not until the late 1990s that this usage was widespread.

Business intelligence and data warehousing

Often BI applications use data gathered from a data warehouse or a data mart. A data warehouse is a copy of analytical data that facilitates decision support. However, not all data warehouses are used for business intelligence, nor do all business intelligence applications require a data warehouse.

To distinguish between the concepts of business intelligence and data warehouses, Forrester Research often defines business intelligence in one of two ways:

Using a broad definition: "Business Intelligence is a set of methodologies, processes, architectures, and technologies that transform raw data into meaningful and useful information used to enable more effective strategic, tactical, and operational insights and decision-making." When using this definition, business intelligence also includes technologies such as data integration, data quality, data warehousing, master data management, text and content analytics, and many others that the market sometimes lumps into the Information Management segment. Therefore, Forrester refers to *data preparation* and *data usage* as two separate, but closely linked segments of the business intelligence architectural stack.

Forrester defines the latter, narrower business intelligence market as, "...referring to just the top layers of the BI architectural stack such as reporting, analytics and dashboards."

Business intelligence and business analytics

Thomas Davenport argues that business intelligence should be divided into querying, reporting, OLAP, an "alerts" tool, and business analytics. In this definition, business analytics is the subset of BI based on statistics, prediction, and optimization.

Applications in an enterprise

Business intelligence can be applied to the following business purposes, in order to drive business value.[*citation needed*]

1. Measurement – program that creates a hierarchy of performance metrics (see also Metrics Reference Model) and benchmarking that informs business leaders about progress towards business goals (business process management).
2. Analytics – program that builds quantitative processes for a business to arrive at optimal decisions and to perform business knowledge discovery. Frequently involves: data mining, process mining, statistical analysis, predictive analytics, predictive modeling, business process modeling, complex event processing and prescriptive analytics.
3. Reporting/enterprise reporting – program that builds infrastructure for strategic reporting to serve the strategic management of a business, not operational reporting. Frequently involves data visualization, executive information system and OLAP.
4. Collaboration/collaboration platform – program that gets different areas (both inside and outside the business) to work together through data sharing and electronic data interchange.

5. Knowledge management – program to make the company data driven through strategies and practices to identify, create, represent, distribute, and enable adoption of insights and experiences that are true business knowledge. Knowledge management leads to learning management and regulatory compliance.

In addition to above, business intelligence also can provide a pro-active approach, such as ALARM function to alert immediately to end-user. There are many types of alerts, for example if some business value exceeds the threshold value the color of that amount in the report will turn RED and the business analyst is alerted. Sometimes an alert mail will be sent to the user as well. This end to end process requires data governance, which should be handled by the expert.[*citation needed*]

Prioritization of business intelligence projects

It is often difficult to provide a positive business case for business intelligence initiatives and often the projects must be prioritized through strategic initiatives. Here are some hints and advantages to increase the benefits for a BI project.

- As described by Kimball[3] you must determine the tangible benefits such as eliminated cost of producing legacy reports.
- Enforce access to data for the entire organization. In this way even a small benefit, such as a few minutes saved, makes a difference when multiplied by the number of employees in the entire organization.
- As described by Ross, Weil & Roberson for Enterprise Architecture,[4] consider letting the BI project be driven by other business initiatives with excellent business cases. To support this approach, the organization must have enterprise architects who can identify suitable business projects.
- Use a structured and quantitative methodology to create defensible prioritization in line with the actual needs of the organization, such as a weighted decision matrix.

Success factors of implementation

Before implementing a BI solution, it is worth taking different factors into consideration before proceeding. According to Kimball et al., these are the three critical areas that you need to assess within your organization before getting ready to do a BI project:[5]

1. The level of commitment and sponsorship of the project from senior management
2. The level of business need for creating a BI implementation
3. The amount and quality of business data available.

Business sponsorship

The commitment and sponsorship of senior management is according to Kimball *et al.*, the most important criteria for assessment.[6] This is because having strong management backing helps overcome shortcomings elsewhere in the project. However, as Kimball *et al.* state: “even the most elegantly designed DW/BI system cannot overcome a lack of business [management] sponsorship”.[7]

It is important that personnel who participate in the project have a vision and an idea of the benefits and drawbacks of implementing a BI system. The best business sponsor should have organizational clout and should be well connected within the organization. It is ideal that the business sponsor is demanding but also able to be realistic and supportive if the implementation runs into delays or drawbacks. The management sponsor also needs to be able to assume accountability and to take responsibility for failures and setbacks on the project. Support from multiple members of the management ensures the project does not fail if one person leaves the steering group. However, having many managers work together on the project can also mean that there are several different interests that attempt to pull the project in different directions, such as if different departments want to put more emphasis on their usage. This issue can be countered by an early and specific analysis of the business areas that benefit the most from

the implementation. All stakeholders in project should participate in this analysis in order for them to feel ownership of the project and to find common ground.

Another management problem that should be encountered before start of implementation is if the business sponsor is overly aggressive. If the management individual gets carried away by the possibilities of using BI and starts wanting the DW or BI implementation to include several different sets of data that were not included in the original planning phase. However, since extra implementations of extra data may add many months to the original plan, it's wise to make sure the person from management is aware of his actions.

Business needs

Because of the close relationship with senior management, another critical thing that must be assessed before the project begins is whether or not there is a business need and whether there is a clear business benefit by doing the implementation.[8] The needs and benefits of the implementation are sometimes driven by competition and the need to gain an advantage in the market. Another reason for a business-driven approach to implementation of BI is the acquisition of other organizations that enlarge the original organization it can sometimes be beneficial to implement DW or BI in order to create more oversight.

Companies that implement BI are often large, multinational organizations with diverse subsidiaries. A well-designed BI solution provides a consolidated view of key business data not available anywhere else in the organization, giving management visibility and control over measures that otherwise would not exist.

Amount and quality of available data

Without good data, it does not matter how good the management sponsorship or business-driven motivation is. Without proper data, or with too little quality data, any BI implementation fails. Before implementation it is a good idea to do data profiling. This analysis identifies the “content, consistency and structure [..]” of the data. This should be done as early as possible in the process and if the analysis shows that data is lacking, put the project on the shelf temporarily while the IT department figures out how to properly collect data.

When planning for business data and business intelligence requirements, it is always advisable to consider specific scenarios that apply to a particular organization, and then select the business intelligence features best suited for the scenario.

Often, scenarios revolve around distinct business processes, each built on one or more data sources. These sources are used by features that present that data as information to knowledge workers, who subsequently act on that information. The business needs of the organization for each business process adopted correspond to the essential steps of business intelligence. These essential steps of business intelligence include but are not limited to:

1. Go through business data sources in order to collect needed data
2. Convert business data to information and present appropriately
3. Query and analyze data
4. Act on those data collected

The **quality aspect** in business intelligence should cover all the process from the source data to the final reporting. At each step, the **quality gates** are different:

1. Source Data:
    - Data Standardization: make data comparable (same unit, same pattern..)
    - Master Data Management: unique referential
2. Operational Data Store (ODS):
    - Data Cleansing: detect & correct inaccurate data
    - Data Profiling: check inappropriate value, null/empty
3. Datawarehouse:

- Completeness: check that all expected data are loaded
- Referential integrity: unique and existing referential over all sources
- Consistency between sources: check consolidated data vs sources

4. Reporting:
   - Uniqueness of indicators: only one share dictionary of indicators
   - Formula accuracy: local reporting formula should be avoided or checked

User aspect

Some considerations must be made in order to successfully integrate the usage of business intelligence systems in a company. Ultimately the BI system must be accepted and utilized by the users in order for it to add value to the organization.[9][10] If the usability of the system is poor, the users may become frustrated and spend a considerable amount of time figuring out how to use the system or may not be able to really use the system. If the system does not add value to the users´ mission, they simply don't use it.

To increase user acceptance of a BI system, it can be advisable to consult business users at an early stage of the DW/BI lifecycle, for example at the requirements gathering phase. This can provide an insight into the business process and what the users need from the BI system. There are several methods for gathering this information, such as questionnaires and interview sessions.

When gathering the requirements from the business users, the local IT department should also be consulted in order to determine to which degree it is possible to fulfill the business's needs based on the available data.

Taking on a user-centered approach throughout the design and development stage may further increase the chance of rapid user adoption of the BI system.

Besides focusing on the user experience offered by the BI applications, it may also possibly motivate the users to utilize the system by adding an element of competition. Kimball suggests implementing a function on the Business Intelligence portal website where reports on system usage can be found. By doing so, managers can see how well their departments are doing and compare themselves to others and this may spur them to encourage their staff to utilize the BI system even more.

In a 2007 article, H. J. Watson gives an example of how the competitive element can act as an incentive. Watson describes how a large call centre implemented performance dashboards for all call agents, with monthly incentive bonuses tied to performance metrics. Also, agents could compare their performance to other team members. The implementation of this type of performance measurement and competition significantly improved agent performance.

BI chances of success can be improved by involving senior management to help make BI a part of the organizational culture, and by providing the users with necessary tools, training, and support. Training encourages more people to use the BI application.

Providing user support is necessary to maintain the BI system and resolve user problems. User support can be incorporated in many ways, for example by creating a website. The website should contain great content and tools for finding the necessary information. Furthermore, helpdesk support can be used. The help desk can be manned by power users or the DW/BI project team.

BI Portals

A **Business Intelligence portal** (BI portal) is the primary access interface for Data Warehouse (DW) and Business Intelligence (BI) applications. The BI portal is the users first impression of the DW/BI system. It is typically a browser application, from which the user has access to all the individual services of the DW/BI system, reports and other analytical functionality. The BI portal must be implemented in such a way that it is easy for the users of the DW/BI application to call on the functionality of the application.[11]

The BI portal's main functionality is to provide a navigation system of the DW/BI application. This means that the portal has to be implemented in a way that the user has access to all the functions of the DW/BI application.

The most common way to design the portal is to custom fit it to the business processes of the organization for which the DW/BI application is designed, in that way the portal can best fit the needs and requirements of its users.[12]

The BI portal needs to be easy to use and understand, and if possible have a look and feel similar to other applications or web content of the organization the DW/BI application is designed for (consistency).

The following is a list of desirable features for web portals in general and BI portals in particular:

Usable

: User should easily find what they need in the BI tool.

Content Rich

: The portal is not just a report printing tool, it should contain more functionality such as advice, help, support information and documentation.

Clean

: The portal should be designed so it is easily understandable and not over complex as to confuse the users

Current

: The portal should be updated regularly.

Interactive

: The portal should be implemented in a way that makes it easy for the user to use its functionality and encourage them to use the portal. Scalability and customization give the user the means to fit the portal to each user.

Value Oriented

: It is important that the user has the feeling that the DW/BI application is a valuable resource that is worth working on.

Marketplace

There are a number of business intelligence vendors, often categorized into the remaining independent "pure-play" vendors and consolidated "megavendors" that have entered the market through a recent trend of acquisitions in the BI industry.

Some companies adopting BI software decide to pick and choose from different product offerings (best-of-breed) rather than purchase one comprehensive integrated solution (full-service).

Industry-specific

Specific considerations for business intelligence systems have to be taken in some sectors such as governmental banking regulations. The information collected by banking institutions and analyzed with BI software must be protected from some groups or individuals, while being fully available to other groups or individuals. Therefore BI solutions must be sensitive to those needs and be flexible enough to adapt to new regulations and changes to existing law.

Semi-structured or unstructured data

Businesses create a huge amount of valuable information in the form of e-mails, memos, notes from call-centers, news, user groups, chats, reports, web-pages, presentations, image-files, video-files, and marketing material and news. According to Merrill Lynch, more than 85% of all business information exists in these forms. These information types are called either *semi-structured* or *unstructured* data. However, organizations often only use these documents once.

The management of semi-structured data is recognized as a major unsolved problem in the information technology industry. According to projections from Gartner (2003), white collar workers spend anywhere from 30 to 40 percent of their time searching, finding and assessing unstructured data. BI uses both structured and unstructured data, but the former is easy to search, and the latter contains a large quantity of the information needed for analysis and decision making. Because of the difficulty of properly searching, finding and assessing unstructured or semi-structured data, organizations may not draw upon these vast reservoirs of information, which could influence a particular decision, task or project. This can ultimately lead to poorly informed decision making.

Therefore, when designing a business intelligence/DW-solution, the specific problems associated with semi-structured and unstructured data must be accommodated for as well as those for the structured data.

Unstructured data vs. semi-structured data

Unstructured and semi-structured data have different meanings depending on their context. In the context of relational database systems, unstructured data cannot be stored in predictably ordered columns and rows. One type of unstructured data is typically stored in a BLOB (binary large object), a catch-all data type available in most relational database management systems. Unstructured data may also refer to irregularly or randomly repeated column patterns that vary from row to row within each file or document.

Many of these data types, however, like e-mails, word processing text files, PPTs, image-files, and video-files conform to a standard that offers the possibility of metadata. Metadata can include information such as author and time of creation, and this can be stored in a relational database. Therefore it may be more accurate to talk about this as semi-structured documents or data, but no specific consensus seems to have been reached.

Unstructured data can also simply be the knowledge that business users have about future business trends. Business forecasting naturally aligns with the BI system because business users think of their business in aggregate terms. Capturing the business knowledge that may only exist in the minds of business users provides some of the most important data points for a complete BI solution.

Problems with semi-structured or unstructured data

There are several challenges to developing BI with semi-structured data. According to Inmon & Nesavich,[13] some of those are:

1. Physically accessing unstructured textual data – unstructured data is stored in a huge variety of formats.
2. Terminology – Among researchers and analysts, there is a need to develop a standardized terminology.
3. Volume of data – As stated earlier, up to 85% of all data exists as semi-structured data. Couple that with the need for word-to-word and semantic analysis.
4. Searchability of unstructured textual data – A simple search on some data, e.g. apple, results in links where there is a reference to that precise search term. (Inmon & Nesavich, 2008) gives an example: "a search is made on the term felony. In a simple search, the term felony is used, and everywhere there is a reference to felony, a hit to an unstructured document is made. But a simple search is crude. It does not find references to crime, arson, murder, embezzlement, vehicular homicide, and such, even though these crimes are types of felonies."

The use of metadata

To solve problems with searchability and assessment of data, it is necessary to know something about the content. This can be done by adding context through the use of metadata. Many systems already capture some metadata (e.g. filename, author, size, etc.), but more useful would be metadata about the actual content – e.g. summaries, topics, people or companies mentioned. Two technologies designed for generating metadata about content are automatic categorization and information extraction.

Future

A 2009 Gartner paper predicted[14] these developments in the business intelligence market:

- Because of lack of information, processes, and tools, through 2012, more than 35 percent of the top 5,000 global companies regularly fail to make insightful decisions about significant changes in their business and markets.
- By 2012, business units will control at least 40 percent of the total budget for business intelligence.
- By 2012, one-third of analytic applications applied to business processes will be delivered through coarse-grained application mashups.

A 2009 *Information Management* special report predicted the top BI trends: "green computing, social networking, data visualization, mobile BI, predictive analytics, composite applications, cloud computing and multitouch."

Other business intelligence trends include the following:

- Third party SOA-BI products increasingly address ETL issues of volume and throughput.
- Companies embrace in-memory processing, 64-bit processing, and pre-packaged analytic BI applications.
- Operational applications have callable BI components, with improvements in response time, scaling, and concurrency.
- Near or real time BI analytics is a baseline expectation.
- Open source BI software replaces vendor offerings.

Other lines of research include the combined study of business intelligence and uncertain data.[15] In this context, the data used is not assumed to be precise, accurate and complete. Instead, data is considered uncertain and therefore this uncertainty is propagated to the results produced by BI.

According to a study by the Aberdeen Group, there has been increasing interest in Software-as-a-Service (SaaS) business intelligence over the past years, with twice as many organizations using this deployment approach as one year ago – 15% in 2009 compared to 7% in 2008.[*citation needed*]

An article by InfoWorld's Chris Kanaracus points out similar growth data from research firm IDC, which predicts the SaaS BI market will grow 22 percent each year through 2013 thanks to increased product sophistication, strained IT budgets, and other factors.[16]

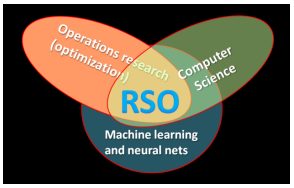
Reactive business intelligence

Reactive business intelligence (RBI) advocates an holistic approach that integrates data mining, modeling and interactive visualization, into an end-to-end discovery and continuous innovation process powered by human and automated learning.[1]

In the area of decision-making this approach has been used to adapt the decision method to the knowledge which is progressively acquired from the decision maker.

Relationships with reactive search optimization (RSO)

RSO is a multi-disciplinary research area between operations research (optimization), computer science, machine learning and neural networks that studies online learning schemes applied to problem-solving and optimization, according to a *learning while optimizing* principle . The word **reactive** hints at a ready response to events during the search through an internal feedback loop for online self-tuning and dynamic adaptation. Online adaptation and model revision is used in **reactive business intelligence** to adapt the data mining and interactive visualization techniques to the knowledge derived from a user in real time.



RSO is multi-disciplinary

Business analytics

Business analytics (**BA**) refers to the skills, technologies, applications and practices for continuous iterative exploration and investigation of past business performance to gain insight and drive business planning. Business analytics focuses on developing new insights and understanding of business performance based on data and statistical methods. In contrast, business intelligence traditionally focuses on using a consistent set of metrics to both measure past performance and guide business planning, which is also based on data and statistical methods.

Business analytics makes extensive use of data, statistical and quantitative analysis, explanatory and predictive modeling, and fact-based management to drive decision making. It is therefore closely related to management science. Analytics may be used as input for human decisions or may drive fully automated decisions. Business intelligence is querying, reporting, OLAP, and "alerts."

In other words, querying, reporting, OLAP, and alert tools can answer questions such as what happened, how many, how often, where the problem is, and what actions are needed. Business analytics can answer questions like why is this happening, what if these trends continue, what will happen next (that is, predict), what is the best that can happen (that is, optimize).

Examples of application

Banks, such as Capital One, use data analysis (or *analytics*, as it is also called in the business setting), to differentiate among customers based on credit risk, usage and other characteristics and then to match customer characteristics with appropriate product offerings. Harrah's, the gaming firm, uses analytics in its customer loyalty programs. E & J Gallo Winery quantitatively analyzes and predicts the appeal of its wines. Between 2002 and 2005, Deere & Company saved more than $1 billion by employing a new analytical tool to better optimize inventory.

Types of analytics

- Descriptive Analytics: Gain insight from historical data with reporting, scorecards, clustering etc.
- Predictive analytics (predictive modeling using statistical and machine learning techniques)
- Prescriptive analytics recommend decisions using optimization, simulation etc.
- Decisive analytics: supports human decisions with visual analytics the user models to reflect reasoning.

Basic domains within analytics

- Retail sales analytics
- Financial services analytics
- Risk & Credit analytics
- Talent analytics
- Marketing analytics
- Behavioral analytics
- Cohort Analysis
- Collections analytics
- Fraud analytics
- Pricing analytics
- Telecommunications
- Supply Chain analytics
- Transportation analytics
- Contextual data modeling - supports the human reasoning that occurs after viewing "executive dashboards" or any other visual analytics

History

Analytics have been used in business since the time management exercises that were initiated by Frederick Winslow Taylor in the late 19th century. Henry Ford measured pacing of assembly line. But analytics began to command more attention in the late 1960s when computers were used in decision support systems. Since then, analytics have evolved with the development of enterprise resource planning (ERP) systems, data warehouses, and a wide variety of other hardware and software tools and applications.

With the recent explosion of big data and intuitive BI tools, data is more accessible to business professionals and managers than ever before. Thus there is a big opportunity to make better decisions using that data to drive incremental revenue, decrease cost and loss by building better products, improving customer experience, catching fraud before it happens, improving customer engagement through targeting and customization- all with the power of data. More and more companies are now equipping their employees with the know-how of Business Analytics to drive efficiency in day-to-day decision making.

Challenges

Business analytics depends on sufficient volumes of high quality data. The difficulty in ensuring data quality is integrating and reconciling data across different systems, and then deciding what subsets of data to make available.

Previously, analytics was considered a type of after-the-fact method of forecasting consumer behavior by examining the number of units sold in the last quarter or the last year. This type of data warehousing required a lot more storage space than it did speed. Now business analytics is becoming a tool that can influence the outcome of customer interactions. When a specific customer type is considering a purchase, an analytics-enabled enterprise can modify the sales pitch to appeal to that consumer. This means the storage space for all that data must react extremely fast to provide the necessary data in real-time.

Competing on analytics

Davenport argues that businesses can optimize a distinct business capability via analytics and thus better compete. He identifies these characteristics of an organization that are apt to compete on analytics:

- One or more senior executives who strongly advocate fact-based decision making and, specifically, analytics
- Widespread use of not only descriptive statistics, but also predictive modeling and complex optimization techniques
- Substantial use of analytics across multiple business functions or processes
- Movement toward an enterprise level approach to managing analytical tools, data, and organizational skills and capabilities

Sales intelligence

Sales intelligence (SI) refers to technologies, applications and practices for the collection, integration, analysis, and presentation of information to help salespeople keep up to date with clients, prospect data and drive business. In addition to providing metrics for win-loss and sales confidence,[1] SI can present contextually relevant customer and product information.

The 2008 survey of 300 companies by the Aberdeen Group [2] show that the recent economic downturn has lengthened traditional sales cycles. As businesses have been forced to reduce spending, sales representatives have been challenged to meet quotas. Top performing companies have implemented sales intelligence programs to improve the quality and quantity of sales leads. SI contextualizes opportunities by providing relevant industry, corporate and personal information. Frequently SI's fact-based information is integrated or includes Customer Relationship Management (CRM).

Although some aspects of sales intelligence overlaps business intelligence (BI), SI is specifically designed for the use of salespeople and sales managers. Unlike customer relationship management (CRM) and traditional business intelligence (BI) applications, SI provides real-time analysis of current sales data and assists with suggesting and delivering actionable, relevant information.

Sales intelligence solutions are predominantly designed for companies in the manufacturing, distribution and wholesale sectors. These are highly competitive markets, where volumes are high, margins are low. (SI) solutions provide unique insight into customer buying patterns. By automatically analysing and evaluating these patterns, Sales Intelligence pro-actively identifies and delivers up-sell, cross-sell and switch-sell opportunities.

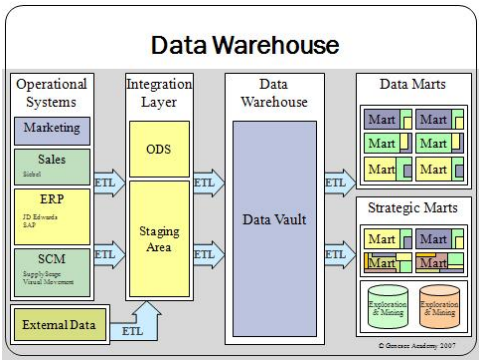
Performance intelligence

Performance Intelligence refers to technologies that utilize standard Business Intelligence techniques on performance-related IT metrics. Traditionally, the performance metrics are loaded into a set of tables that resemble the table structure of a data warehouse. Analysis is performed with standard Business Intelligence techniques such as slicing, dicing, drilling down and the trend analysis.

This type of analysis is useful, because it allows the user to quickly look at the data from several perspectives to see trends or anomalies that they might miss while looking at data in a more granular form.

Data warehouse

In computing, a **data warehouse** (**DW**, **DWH**), or an **enterprise data warehouse** (**EDW**), is a database used for reporting (1) and data analysis (2). Integrating data from one or more disparate sources creates a central repository of data, a data warehouse (DW). Data warehouses store current and historical data and are used for creating trending reports for senior management reporting such as annual and quarterly comparisons.



Data Warehouse Overview

The data stored in the warehouse is uploaded from the operational systems (such as marketing, sales, etc., shown in the figure to the right). The data may pass through an operational data store for additional operations before it is used in the DW for reporting.

The typical extract transform load (ETL)-based data warehouse uses staging, data integration, and access layers to house its key functions. The staging layer or staging database stores raw data extracted from each of the disparate source data systems. The integration layer integrates the disparate data sets by transforming the data from the staging layer often storing this transformed data in an operational data store (ODS) database. The integrated data are then moved to yet another database, often called the data warehouse database, where the data is arranged into hierarchical groups often called dimensions and into facts and aggregate facts. The combination of facts and dimensions is sometimes called a star schema. The access layer helps users retrieve data.

A data warehouse constructed from an integrated data source systems does not require ETL, staging databases, or operational data store databases. The integrated data source systems may be considered to be a part of a distributed operational data store layer. Data federation methods or data virtualization methods may be used to access the distributed integrated source data systems to consolidate and aggregate data directly into the data warehouse database tables. Unlike the ETL-based data warehouse, the integrated source data systems and the data warehouse are all integrated since there is no transformation of dimensional or reference data. This integrated data warehouse architecture supports the drill down from the aggregate data of the data warehouse to the transactional data of the integrated source data systems.

A data mart is a small data warehouse focused on a specific area of interest. Data warehouses can be subdivided into data marts for improved performance and ease of use within that area. Alternatively, an organization can create one or more data marts as first steps towards a larger and more complex enterprise data warehouse.

This definition of the data warehouse focuses on data storage. The main source of the data is cleaned, transformed, cataloged and made available for use by managers and other business professionals for data mining, online analytical processing, market research and decision support (Marakas & O'Brien 2009). However, the means to retrieve and analyze data, to extract, transform and load data, and to manage the data dictionary are also considered essential

components of a data warehousing system. Many references to data warehousing use this broader context. Thus, an expanded definition for data warehousing includes business intelligence tools, tools to extract, transform and load data into the repository, and tools to manage and retrieve metadata.

Benefits of a data warehouse

A data warehouse maintains a copy of information from the source transaction systems. This architectural complexity provides the opportunity to :

- Congregate data from multiple sources into a single database so a single query engine can be used to present data.
- Mitigate the problem of database isolation level lock contention in transaction processing systems caused by attempts to run large, long running, analysis queries in transaction processing databases.
- Maintain data history, even if the source transaction systems do not.
- Integrate data from multiple source systems, enabling a central view across the enterprise. This benefit is always valuable, but particularly so when the organization has grown by merger.
- Improve data quality, by providing consistent codes and descriptions, flagging or even fixing bad data.
- Present the organization's information consistently.
- Provide a single common data model for all data of interest regardless of the data's source.
- Restructure the data so that it makes sense to the business users.
- Restructure the data so that it delivers excellent query performance, even for complex analytic queries, without impacting the operational systems.
- Add value to operational business applications, notably customer relationship management (CRM) systems.
- Making decision–support queries easier to write.

Generic data warehouse environment

The environment for data warehouses and marts includes the following:

- Source systems that provide data to the warehouse or mart;
- Data integration technology and processes that are needed to prepare the data for use;
- Different architectures for storing data in an organization's data warehouse or data marts;
- Different tools and applications for the variety of users;
- Metadata, data quality, and governance processes must be in place to ensure that the warehouse or mart meets its purposes.

In regards to source systems listed above, Rainer states, “A common source for the data in data warehouses is the company’s operational databases, which can be relational databases”.

Regarding data integration, Rainer states, “It is necessary to extract data from source systems, transform them, and load them into a data mart or warehouse”.

Rainer discusses storing data in an organization’s data warehouse or data marts. “There are a variety of possible architectures to store decision-support data”.

Metadata are data about data. “IT personnel need information about data sources; database, table, and column names; refresh schedules; and data usage measures“.

Today, the most successful companies are those that can respond quickly and flexibly to market changes and opportunities. A key to this response is the effective and efficient use of data and information by analysts and managers. A “data warehouse” is a repository of historical data that are organized by subject to support decision makers in the organization. Once data are stored in a data mart or warehouse, they can be accessed.

History

The concept of data warehousing dates back to the late 1980s when IBM researchers Barry Devlin and Paul Murphy developed the "business data warehouse". In essence, the data warehousing concept was intended to provide an architectural model for the flow of data from operational systems to decision support environments. The concept attempted to address the various problems associated with this flow, mainly the high costs associated with it. In the absence of a data warehousing architecture, an enormous amount of redundancy was required to support multiple decision support environments. In larger corporations it was typical for multiple decision support environments to operate independently. Though each environment served different users, they often required much of the same stored data. The process of gathering, cleaning and integrating data from various sources, usually from long-term existing operational systems (usually referred to as legacy systems), was typically in part replicated for each environment. Moreover, the operational systems were frequently reexamined as new decision support requirements emerged. Often new requirements necessitated gathering, cleaning and integrating new data from "data marts" that were tailored for ready access by users.

Key developments in early years of data warehousing were:

- 1960s — General Mills and Dartmouth College, in a joint research project, develop the terms *dimensions* and *facts*.[1]
- 1970s — ACNielsen and IRI provide dimensional data marts for retail sales.
- 1970s — Bill Inmon begins to define and discuss the term: Data Warehouse
- 1975 — Sperry Univac Introduce MAPPER (MAintain, Prepare, and Produce Executive Reports) is a database management and reporting system that includes the world's first 4GL. It was the first platform designed for building Information Centers (a forerunner of contemporary Enterprise Data Warehousing platforms)
- 1983 — Teradata introduces a database management system specifically designed for decision support.
- 1983 — Sperry Corporation Martyn Richard Jones defines the Sperry Information Center approach, which while not being a true DW in the Inmon sense, did contain many of the characteristics of DW structures and process as defined previously by Inmon, and later by Devlin. First used at the TSB England & Wales
- 1984 — Metaphor Computer Systems, founded by David Liddle and Don Massaro, releases Data Interpretation System (DIS). DIS was a hardware/software package and GUI for business users to create a database management and analytic system.
- 1988 — Barry Devlin and Paul Murphy publish the article *An architecture for a business and information system* [2] in *IBM Systems Journal* where they introduce the term "business data warehouse".
- 1990 — Red Brick Systems, founded by Ralph Kimball, introduces Red Brick Warehouse, a database management system specifically for data warehousing.
- 1991 — Prism Solutions, founded by Bill Inmon, introduces Prism Warehouse Manager, software for developing a data warehouse.
- 1992 — Bill Inmon publishes the book *Building the Data Warehouse*.
- 1995 — The Data Warehousing Institute, a for-profit organization that promotes data warehousing, is founded.
- 1996 — Ralph Kimball publishes the book *The Data Warehouse Toolkit*.
- 2000 — Daniel Linstedt releases the *Data Vault*, enabling real time auditable Data Warehouses warehouse.

Information storage

Facts

A fact is a value or measurement, which represents a fact about the managed entity or system.

Facts as reported by the reporting entity are said to be at raw level.

E.g. if a BTS received 1,000 requests for traffic channel allocation, it allocates for 820 and rejects the remaining then it would report 3 **facts** or measurements to a management system:

- tch_req_total = 1000
- tch_req_success = 820
- tch_req_fail = 180

Facts at raw level are further aggregated to higher levels in various dimensions to extract more service or business-relevant information out of it. These are called aggregates or summaries or aggregated facts.

E.g. if there are 3 BTSs in a city, then facts above can be aggregated from BTS to city level in network dimension. E.g.

- $tch\_req\_success\_city = tch\_req\_success\_bts1 + tch\_req\_success\_bts2 + tch\_req\_success\_bts3$
- $avg\_tch\_req\_success\_city = (tch\_req\_success\_bts1 + tch\_req\_success\_bts2 + tch\_req\_success\_bts3)/3$

Dimensional vs. normalized approach for storage of data

There are three or more leading approaches to storing data in a data warehouse — the most important approaches are the dimensional approach and the normalized approach.

The dimensional approach, whose supporters are referred to as “Kimballites”, believe in Ralph Kimball's approach in which it is stated that the data warehouse should be modeled using a Dimensional Model/star schema. The normalized approach, also called the 3NF model (Third Normal Form), whose supporters are referred to as “Inmonites”, believe in Bill Inmon's approach in which it is stated that the data warehouse should be modeled using an E-R model/normalized model.

In a dimensional approach, transaction data are partitioned into "facts", which are generally numeric transaction data, and "dimensions", which are the reference information that gives context to the facts. For example, a sales transaction can be broken up into facts such as the number of products ordered and the price paid for the products, and into dimensions such as order date, customer name, product number, order ship-to and bill-to locations, and salesperson responsible for receiving the order.

A key advantage of a dimensional approach is that the data warehouse is easier for the user to understand and to use. Also, the retrieval of data from the data warehouse tends to operate very quickly.[*citation needed*] Dimensional structures are easy to understand for business users, because the structure is divided into measurements/facts and context/dimensions. Facts are related to the organization’s business processes and operational system whereas the dimensions surrounding them contain context about the measurement (Kimball, Ralph 2008).

The main disadvantages of the dimensional approach are the following:

1. In order to maintain the integrity of facts and dimensions, loading the data warehouse with data from different operational systems is complicated.
2. It is difficult to modify the data warehouse structure if the organization adopting the dimensional approach changes the way in which it does business.

In the normalized approach, the data in the data warehouse are stored following, to a degree, database normalization rules. Tables are grouped together by *subject areas* that reflect general data categories (e.g., data on customers, products, finance, etc.). The normalized structure divides data into entities, which creates several tables in a relational database. When applied in large enterprises the result is dozens of tables that are linked together by a web

of joins. Furthermore, each of the created entities is converted into separate physical tables when the database is implemented (Kimball, Ralph 2008)[*citation needed*]. The main advantage of this approach is that it is straightforward to add information into the database. Some disadvantages of this approach are that, because of the number of tables involved, it can be difficult for users to join data from different sources into meaningful information and to access the information without a precise understanding of the sources of data and of the data structure of the data warehouse.

It should be noted that both normalized and dimensional models can be represented in entity-relationship diagrams as both contain joined relational tables. The difference between the two models is the degree of normalization (also known as Normal Forms).

These approaches are not mutually exclusive, and there are other approaches. Dimensional approaches can involve normalizing data to a degree (Kimball, Ralph 2008).

In Information-Driven Business, Robert Hillard proposes an approach to comparing the two approaches based on the information needs of the business problem. The technique shows that normalized models hold far more information than their dimensional equivalents (even when the same fields are used in both models) but this extra information comes at the cost of usability. The technique measures information quantity in terms of Information Entropy and usability in terms of the Small Worlds data transformation measure.

Top-down versus bottom-up design methodologies

Bottom-up design

Ralph Kimball,[3] designed an approach to data warehouse design known as *bottom-up*.

In the *bottom-up* approach, data marts are first created to provide reporting and analytical capabilities for specific business processes.

Data marts contain, primarily, dimensions and facts. Facts can contain either atomic data and, if necessary, summarized data. The single data mart often models a specific business area such as "Sales" or "Production." These data marts can eventually be integrated to create a comprehensive data warehouse. The data warehouse bus architecture is primarily an implementation of "the bus", a collection of conformed dimensions and conformed facts, which are dimensions that are shared (in a specific way) between facts in two or more data marts.

The integration of the data marts in the data warehouse is centered on the conformed dimensions (residing in "the bus") that define the possible integration "points" between data marts. The actual integration of two or more data marts is then done by a process known as "Drill across". A drill-across works by grouping (summarizing) the data along the keys of the (shared) conformed dimensions of each fact participating in the "drill across" followed by a join on the keys of these grouped (summarized) facts.

Maintaining tight management over the data warehouse bus architecture is fundamental to maintaining the integrity of the data warehouse. The most important management task is making sure dimensions among data marts are consistent.

Business value can be returned as quickly as the first data marts can be created, and the method lends itself well to an exploratory and iterative approach to building data warehouses. For example, the data warehousing effort might start in the "Sales" department, by building a Sales-data mart. Upon completion of the Sales-data mart, the business might then decide to expand the warehousing activities into the, say, "Production department" resulting in a Production data mart. The requirement for the Sales data mart and the Production data mart to be integrable, is that they share the same "Bus", that will be, that the data warehousing team has made the effort to identify and implement the conformed dimensions in the bus, and that the individual data marts links that information from the bus. The Sales-data mart is good as it is (assuming that the bus is complete) and the Production-data mart can be constructed virtually independent of the Sales-data mart (but not independent of the Bus).

If integration via the bus is achieved, the data warehouse, through its two data marts, will not only be able to deliver the specific information that the individual data marts are designed to do, in this example either "Sales" or "Production" information, but can deliver integrated Sales-Production information, which, often, is of critical business value.

Top-down design

Bill Inmon, has defined a data warehouse as a centralized repository for the entire enterprise.[4] The *top-down* approach is designed using a normalized enterprise data model. "Atomic" data, that is, data at the lowest level of detail, are stored in the data warehouse. Dimensional data marts containing data needed for specific business processes or specific departments are created from the data warehouse. In the Inmon vision, the data warehouse is at the center of the "Corporate Information Factory" (CIF), which provides a logical framework for delivering business intelligence (BI) and business management capabilities. Gartner released a research note confirming Inmon's definition in 2005[5] with additional clarity plus they added one additional attribute.

The data warehouse is:

Subject-oriented

: The data in the data warehouse is organized so that all the data elements relating to the same real-world event or object are linked together.

Non-volatile

: Data in the data warehouse are never over-written or deleted — once committed, the data are static, read-only, and retained for future reporting.

Integrated

: The data warehouse contains data from most or all of an organization's operational systems and these data are made consistent.

Time-variant

: For an **operational system**, the stored data contains the current value. The data warehouse, however, contains the history of data values.

No virtualization

: A data warehouse is a physical repository.

The top-down design methodology generates highly consistent dimensional views of data across data marts since all data marts are loaded from the centralized repository. Top-down design has also proven to be robust against business changes. Generating new dimensional data marts against the data stored in the data warehouse is a relatively simple task. The main disadvantage to the top-down methodology is that it represents a very large project with a very broad scope. The up-front cost for implementing a data warehouse using the top-down methodology is significant, and the duration of time from the start of project to the point that end users experience initial benefits can be substantial. In addition, the top-down methodology can be inflexible and unresponsive to changing departmental needs during the implementation phases.

Hybrid design

Data warehouse (DW) solutions often resemble the hub and spokes architecture. Legacy systems feeding the DW/BI solution often include customer relationship management (CRM) and enterprise resource planning solutions (ERP), generating large amounts of data. To consolidate these various data models, and facilitate the extract transform load (ETL) process, DW solutions often make use of an operational data store (ODS). The information from the ODS is then parsed into the actual DW. To reduce data redundancy, larger systems will often store the data in a normalized way. Data marts for specific reports can then be built on top of the DW solution.

It is important to note that the DW database in a hybrid solution is kept on third normal form to eliminate data redundancy. A normal relational database however, is not efficient for business intelligence reports where dimensional modelling is prevalent. Small data marts can shop for data from the consolidated warehouse and use the filtered, specific data for the fact tables and dimensions required. The DW effectively provides a single source of information from which the data marts can read, creating a highly flexible solution from a BI point of view. The hybrid architecture allows a DW to be replaced with a master data management solution where operational, not static information could reside.

The Data Vault Modeling components follow hub and spokes architecture. This modeling style is a hybrid design, consisting of the best practices from both 3rd normal form and star schema. The Data Vault model is not a true 3rd normal form, and breaks some of the rules that 3NF dictates be followed. It is however, a top-down architecture with a bottom up design. The Data Vault model is geared to be strictly a data warehouse. It is not geared to be end-user accessible, which when built, still requires the use of a data mart or star schema based release area for business purposes.

Data warehouses versus operational systems

Operational systems are optimized for preservation of data integrity and speed of recording of business transactions through use of database normalization and an entity-relationship model. Operational system designers generally follow the Codd rules of database normalization in order to ensure data integrity. Codd defined five increasingly stringent rules of normalization. Fully normalized database designs (that is, those satisfying all five Codd rules) often result in information from a business transaction being stored in dozens to hundreds of tables. Relational databases are efficient at managing the relationships between these tables. The databases have very fast insert/update performance because only a small amount of data in those tables is affected each time a transaction is processed. Finally, in order to improve performance, older data are usually periodically purged from operational systems.

Evolution in organization use

These terms refer to the level of sophistication of a data warehouse:

Offline operational data warehouse

> Data warehouses in this stage of evolution are updated on a regular time cycle (usually daily, weekly or monthly) from the operational systems and the data is stored in an integrated reporting-oriented data

Offline data warehouse

> Data warehouses at this stage are updated from data in the operational systems on a regular basis and the data warehouse data are stored in a data structure designed to facilitate reporting.

On time data warehouse

> Online Integrated Data Warehousing represent the real time Data warehouses stage data in the warehouse is updated for every transaction performed on the source data

Integrated data warehouse

> These data warehouses assemble data from different areas of business, so users can look up the information they need across other systems.

Data warehouse architectures

–

The technical architecture of data warehouses is somewhat similar to other systems, but does have some special characteristics. There are two border areas in data warehouse architecture - the single-layer architecture and the N-layer architecture. The difference here is the number of middleware between the operational systems and the analytical tools. The data warehouse architecture described here is a high level architecture and the parts in the architectures mentioned are full bodied systems and not system-parts.

Single-layer architecture

A simple architecture is the single-layer architecture. There is no physical data warehouse or data mart between the operation data and the analytic tools. The middleware in this type of system should be considered a virtual data warehouse, which consists of a software layer and not a data based layer. The single-layer model is light weight as it minimises redundancies and thereby the amount of data stored. It has, however, no separation between analytical and operational processing. The analysis are based directly on the operational data.[1]

Three-layer architecture

The three-layer architecture consists of the source layer (containing multiple source systems), the reconciled layer and the data warehouse layer (containing both data warehouses and data marts). The reconciled layer sits between the source data and data warehouse. It is populated with data from the source systems through an ETL process and the data stored in it is published further through another ETL process. In the reconciled layer the data has been cleaned up once and integrated to a common standardised form from multiple different source systems. The ETL process that feeds the data warehouse then only gets already integrated data that has less need for transformation. This architecture is especially useful for the very large, enterprise-wide systems. A disadvantage of this architecture is the extra data storage space used through the extra redundant reconciled layer. It also makes the analytical tools a little further away from being real-time.

Data mart

A **data mart** is the access layer of the data warehouse environment that is used to get data out to the users. The data mart is a subset of the data warehouse that is usually oriented to a specific business line or team. Data marts are small slices of the data warehouse. Whereas data warehouses have an enterprise-wide depth, the information in data marts pertains to a single department. In some deployments, each department or business unit is considered the *owner* of its data mart including all the *hardware*, *software* and *data*.[1] This enables each department to use, manipulate and develop their data any way they see fit; without altering information inside other data marts or the data warehouse. In other deployments where conformed dimensions are used, this business unit ownership will not hold true for shared dimensions like customer, product, etc.

The related term spreadmart is a derogatory label describing the situation that occurs when one or more business analysts develop a system of linked spreadsheets to perform a business analysis, then grow it to a size and degree of complexity that makes it nearly impossible to maintain.

The primary use for a data mart is business intelligence (BI) applications. BI is used to gather, store, access and analyze data. The data mart can be used by smaller businesses to utilize the data they have accumulated. A data mart can be less expensive than implementing a data warehouse, thus making it more practical for the small business. A data mart can also be set up in much less time than a data warehouse, being able to be set up in less than 90 days. Since most small businesses only have use for a small number of BI applications, the low cost and quick set up of the data mart makes it a suitable method for storing data.

Design schemas

- Star schema - fairly popular design choice; enables a relational database to emulate the analytical functionality of a multidimensional database
- Snowflake schema

Reasons for creating a data mart

- Easy access to frequently needed data
- Creates collective view by a group of users
- Improves end-user response time
- Ease of creation
- Lower cost than implementing a full data warehouse
- Potential users are more clearly defined than in a full data warehouse
- Contains only business essential data and is less cluttered.

Dependent data mart

According to the Inmon school of data warehousing, a **dependent data mart** is a logical subset (view) or a physical subset (extract) of a larger data warehouse, isolated for one of the following reasons:

- A need refreshment for a special data model or schema: e.g., to restructure for OLAP
- Performance: to offload the data mart to a separate computer for greater efficiency or to obviate the need to manage that workload on the centralized data warehouse.
- Security: to separate an authorized data subset selectively
- Expediency: to bypass the data governance and authorizations required to incorporate a new application on the Enterprise Data Warehouse

- Proving Ground: to demonstrate the viability and ROI (return on investment) potential of an application prior to migrating it to the Enterprise Data Warehouse
- Politics: a coping strategy for IT (Information Technology) in situations where a user group has more influence than funding or is not a good citizen on the centralized data warehouse.
- Politics: a coping strategy for consumers of data in situations where a data warehouse team is unable to create a usable data warehouse.

According to the Inmon school of data warehousing, tradeoffs inherent with data marts include limited scalability, duplication of data, data inconsistency with other silos of information, and inability to leverage enterprise sources of data.

The alternative school of data warehousing is that of Ralph Kimball. In his view, a data warehouse is nothing more than the union of all the data marts. This view helps to reduce costs and provides fast development, but can create an inconsistent data warehouse, especially in large organizations. Therefore, Kimball's approach is more suitable for small-to-medium corporations.[2]

The Kimball Lifecycle

The Kimball Lifecycle is a methodology for developing data warehouses, and has been developed over many years by Ralph Kimball and a variety of colleagues.

Program/Project planning

According to Kimball et al., this phase is the start of the Lifecycle. It is a planning-phase in which project is a single iteration of the Lifecycle while program is the broader coordination of resources. When launching a project/program Kimball et al. suggests following three focus areas:

- Define and Scope project
- Plan project
- Manage project

Program/Project Management

This is an ongoing discipline in the project. The purpose is to keep the project/program on course, develop a communication plan and manage expectations.

Business Requirements Definition

This phase/milestone of the project is about making the project team understand the business requirements. Its purpose is to establish a foundation for all the following activities in the Lifecycle. Kimball et al. makes it very clear that it is extremely important for the project team to talk with the business users. It is important to be prepared, to focus on listening and to document the interview with the business users.

Technology Track

This is the top track in the diagram. It holds two milestones:

Technical Architecture Design is supposed to create a framework for the DW/BI system. The main focus in this phase is to create a plan for the application architecture, while considering business requirements, technical environment and the planned strategic technical directions.

Product Selection & Installation use the architecture plan to identify what components are needed to complete the DW/BI project. This phase then selects, installs and tests the products.

Data Track

Dimensional Modeling is a process in which the business requirements are used to design dimensional models for the system.

Physical Design is the phase where the database is designed. It involves the database environment as well as security.

ETL Design & Development is the design of some of the heavy procedures in the DW/BI-system. Kimball et al. suggests four parts to this process, which are further divided into 34 subsystems (Kimball et al., 2008):

- Extracting data
- Cleaning and conforming data
- Delivering data for Presentation
- Managing the ETL system

Business Intelligence Application Track

BI Application Design deals with designing and selecting some applications to support the business requirements. BI Application Development use the design to develop and validate applications to support the business requirements.

Deployment

When the three tracks are complete they all end up in the final deployment. This phase requires planning and should include pre-deployment testing, documentation, training and maintenance and support.

Maintenance

When the deployment has finished the system will need proper maintenance to stay alive. This includes data reconciliation, execution and monitoring and performance tuning.

Growth

As the project can be seen as part of the larger iterative program, it is very likely that the system will want to expand. There will be projects to add new data as well as reaching new segments of the business areas. The Lifecycle then starts over again.

Time variance

Time variance is the ability to remember historic perspectives. The requirement is to be able to know how something was classified or who owned something and how this changed as time passed.

For the context of time and frequency and qualification of oscillators and amplifiers the technical terms time deviation and time variance is defined.

Understanding time variance

Future change, be it organizational, regulatory or geographical is hard to conceive. In 1988, who imagined that within a few years, Yugoslavia and East Germany would cease to exist? Enabling a data warehouse to report pre- and post-change information together in a meaningful context is very expensive and time-consuming. Couple that with the pressure to rapidly meet other business requirements, and with the inability for any of us to predict change (especially at system design time!), and you can see why the time-variant reporting requirement is often ignored. But at what expense? The real-life case below illustrates the value of time-variant reporting: A beverage company paid rebates to customers at year-end, based on ownership of customer sites at year end. The sales data warehouse did not reflect customers selling sites to one another throughout the year, resulting in mis-payments and a multi-million dollar customer service dilemma. For regulatory compliance and other reasons, data warehouses must remember how things were in the past because at some point business people will expect to be able to be report on them that way.So it is one of the important characteristic of data warehouse

Federated database system

A **federated database system** is a type of meta-database management system (DBMS), which transparently maps multiple autonomous database systems into a single **federated database**. The constituent databases are interconnected via a computer network and may be geographically decentralized. Since the constituent database systems remain autonomous, a federated database system is a contrastable alternative to the (sometimes daunting) task of merging several disparate databases. A federated database, or **virtual database**, is a composite of all constituent databases in a federated database system. There is no actual data integration in the constituent disparate databases as a result of data federation.

McLeod and Heimbigner were among the first to define a federated database system, as one which "define[s] the architecture and interconnect[s] databases that minimize central authority yet support partial sharing and coordination among database systems".

Through data abstraction, federated database systems can provide a uniform user interface, enabling users and clients to store and retrieve data in multiple noncontiguous databases with a single query -- even if the constituent databases are heterogeneous. To this end, a federated database system must be able to decompose the query into subqueries for submission to the relevant constituent DBMS's, after which the system must composite the result sets of the subqueries. Because various database management systems employ different query languages, federated database systems can apply wrappers to the subqueries to translate them into the appropriate query languages.

- Note: this description of federated databases does not accurately reflect the McLeod/Heimbigner definition of a federated database. Rather, this description fits what McLeod/Heimbinger called a *composite* database. McLeod/Heimbigner's federated database is a collection of autonomous components that make their data available to other members of the federation through the publication of an export schema and access operations; there is no unified, central schema that encompasses the information available from the members of the federation.

Among other surveys, defines a Federated Database as a collection of cooperating component systems which are autonomous and are possibly heterogeneous. The three important components of an FDBS as pointed out in are autonomy, heterogeneity and distribution. Another dimension which has also been considered is the Networking Environment Computer Network, e.g., many DBSs over a LAN or many DBSs over a WAN update related functions of participating DBSs (e.g., no updates, nonatomic transitions, atomic updates).

FDBS architecture

A DBMS can be classified as either centralized or distributed. A centralized system manages a single database while distributed manages multiple databases. A component DBS in a DBMS may be centralized or distributed. A multiple DBS (MDBS) can be classified into two types depending on the autonomy of the component DBS as federated and non federated. A nonfederated database system is an integration of component DBMS that are not autonomous. A federated database system consists of component DBS that are autonomous yet participate in a federation to allow partial and controlled sharing of their data.

Federated architectures differ based on levels of integration with the component database systems and the extent of services offered by the federation. A FDBS can be categorized as loosely or tightly coupled systems.

- Loosely Coupled require component databases to construct their own federated schema. A user will typically access other component database systems by using a multidatabase language but this removes any levels of location transparency, forcing the user to have direct knowledge of the federated schema. A user imports the data they require from other component databases and integrates it with their own to form a federated schema.
- Tightly coupled system consists of component systems that use independent processes to construct and publicize an integrated federated schema.

Multiple DBS of which FDBS are a specific type can be characterized along three dimensions: Distribution, Heterogeneity and Autonomy. Another characterization could be based on the dimension of networking, for example single databases or multiple databases in a LAN or WAN.

Distribution

Distribution of data in an FDBS is due to the existence of a multiple DBS before an FDBS is built. Data can be distributed among multiple DB which could be stored in a single computer or multiple computers. These computers could be geographically located in different places but interconnected by a network. The benefits of data distribution help in increased availability and reliability as well as improved access times.

Heterogeneity

Heterogeneities in databases arise due to factors such as differences in structures, semantics of data, the constraints supported or query language. Differences in structure occur when two data models provide different primitives such as object oriented (OO) models that support specialization and inheritance and relational models that do not. Differences due to constraints occur when two models support two different constraints. For example the set type in CODASYL schema may be partially modeled as a referential integrity constraint in a relationship schema. CODASYL supports insertion and retention that are not captured by referential integrity alone. The query language supported by one DBMS can also contribute to heterogeneity between other component DBMSs. For example, differences in query languages with the same data models or different versions of query languages could contribute to heterogeneity.

Semantic heterogeneities arise when there is a disagreement about meaning, interpretation or intended use of data. At the schema and data level, classification of possible heterogeneities include:

- Naming conflicts e.g. databases using different names to represent the same concept.
- Domain conflicts or data representation conflicts e.g. databases using different values to represent same concept.
- Precision conflicts e.g. databases using same data values from domains of different cardinalities for same data.
- Metadata conflicts e.g. same concepts are represented at schema level and instance level.
- Data conflicts e.g. missing attributes
- Schema conflicts e.g. table versus table conflict which includes naming conflicts, data conflicts etc.

In creating a federated schema, one has to resolve such heterogeneities before integrating the component DB schemas.

Schema matching, schema mapping

Dealing with incompatible data types or query syntax is not the only obstacle to a concrete implementation of an FDBS. In systems that are not planned top-down, a generic problem lies in matching semantically equivalent, but differently named parts from different schemas (=data models) (tables, attributes). A pairwise mapping between n attributes would result in $\frac{n(n-1)}{2}$ mapping rules (given equivalence mappings) - a number that quickly gets too large for practical purposes. A common way out is to provide a global schema that comprises the relevant parts of all member schemas and provide mappings in the form of database views. Two principal solutions can be realized, depending on the direction of the mapping:

1. Global as View (GaV): the global schema is defined in terms of the underlying schemas
2. Local as View (LaV): the local schemas are defined in terms of the global schema

Both are explained in more detail in the article Data integration. Alternate approaches to the schema matching problem and a classification of the same are explained in more detail in the article Schema Matching

Autonomy

Fundamental to the difference between an MDBS and an FDBS is the concept of autonomy. It is important to understand the aspects of autonomy for component databases and how they can be addressed when a component DBS participates in an FDBS. There are four kinds of autonomies addressed:

- Design Autonomy which refers to ability to choose its design irrespective of data, query language or conceptualization, functionality of the system implementation.

Heterogeneities in an FDBS are primarily due to design autonomy.

- Communication autonomy refers to the general operation of the DBMS to communicate with other DBMS or not.
- Execution autonomy allows a component DBMS to control the operations requested by local and external operations.
- Association autonomy gives a power to component DBS to disassociate itself from a federation which means FDBS can operate independently of any single DBS.

The ANSI/X3/SPARC Study Group outlined a three level data description architecture, the components of which are the conceptual schema, internal schema and external schema of databases. The three level architecture is however inadequate to describing the architectures of an FDBS. It was therefore extended to support the three dimensions of the FDBS namely Distribution, Autonomy and Heterogeneity. The five level schema architecture is explained below.

Concurrency control

The *Heterogeneity* and *Autonomy* requirements pose special challenges concerning concurrency control in an FDBS, which is crucial for the correct execution of its concurrent transactions (see also Global concurrency control). Achieving global serializability, the major correctness criterion, under these requirements has been characterized as very difficult and unsolved. Commitment ordering, introduced in 1991, has provided a general solution for this issue (See Global serializability; See Commitment ordering also for the architectural aspects of the solution).

Five Level Schema Architecture for FDBSs

The five level schema architecture includes the following:

- Local Schema is the conceptual concept *[unclear]* expressed in primary data model of component DBMS.
- Component Schema is derived by translating local schema into a model called the canonical data model or common data model. They are useful when semantics missed in local schema are incorporated in the component. They help in integration of data for tightly coupled FDBS.
- Export Schema represents a subset of a component schema that is available to the FDBS. It may include access control information regarding its use by specific federation user. The export schema help in managing flow of control of data.
- Federated Schema is an integration of multiple export schema. It includes information on data distribution that is generated when integrating export schemas.
- External Schema defines a schema for a user/applications or a class of users/applications.

While accurately representing the state of the art in data integration, the Five Level Schema Architecture above does suffer from a major drawback, namely IT imposed look and feel. Modern data users demand control over how data is presented; their needs are somewhat in conflict with such bottom-up approaches to data integration.

Single Source of Truth

In Information Systems design and theory, as instantiated at the *Enterprise Level*, **Single Source Of Truth** (SSOT) refers to the practice of structuring information models and associated schemata such that every data element is stored exactly once (e.g., in no more than a single row of a single table). Any possible linkages to this data element (possibly in other areas of the relational schema or even in distant federated databases) are by reference only. Thus, when any such data element is updated, this update propagates to the enterprise at large, without the possibility of a duplicate value somewhere in the distant enterprise not being updated (because there would be no duplicate values that *needed* updating).[*citation needed*]

Deployment of an SSOT architecture is becoming increasingly important in enterprise settings where incorrectly linked duplicate or de-normalized data elements (a direct consequence of intentional or unintentional denormalization of any explicit data model) poses a risk for retrieval of outdated, and therefore incorrect, information. A common example would be the electronic health record, where it is imperative to accurately validate patient identity against a single referential repository, which serves as the SSOT. Duplicate representations of data within the enterprise would be implemented by the use of pointers rather than duplicate database tables, rows, or cells. This ensures that data updates to elements in the authoritative location are comprehensively distributed to all federated database constituencies in the larger overall enterprise architecture.[*citation needed*]

SSOT systems provide data that is authentic, relevant, and referable.Wikipedia:Please clarify[*citation needed*]

Implementing a Single Source of Truth

The "ideal" implementation of SSOT as described above is rarely possible in most enterprises. This is because many organisations have multiple information systems, each of which needs access to data relating to the same entities (e.g., customer). Often these systems are purchased "off-the-shelf" from vendors and cannot be modified in non-trivial ways. Each of these various systems therefore needs to store its own version of common data or entities, and therefore each system must retain its own copy of a record (hence immediately violating the SSOT approach defined above). For example, an ERP (Enterprise Resource Planning) system (such as SAP or Oracle e-Business Suite) may store a customer record; the CRM (Customer Relationship Management) system also needs a copy of the customer record (or part of it) and the warehouse despatch system might also need a copy of some or all of the customer data (e.g., shipping address). In cases where vendors do not support such modifications, it is not always possible to replace these records with pointers to the SSOT.

For organisations (with more than one information system) wishing to implement a Single Source of Truth (without modifying all but one master system to store pointers to other systems for all entities), three supporting technologies are commonly used:[*citation needed*]

- Enterprise Service Bus (ESB)
- Master Data Management (MDM)
- Data Warehouse (DW)

Enterprise Service Bus (ESB)

An Enterprise Service Bus (ESB) allows any number of systems in an organisation to receive updates of data that has changed in another system. To implement a Single Source of Truth, a single source system of correct data for any entity must be identified. Changes to this entity (creates, updates, and deletes) are then published via the ESB; other systems which need to retain a copy of that data subscribe to this update, and update their own records accordingly. For any given entity, the master source must be identified (sometimes called the Golden Record). It should be noted that any given system could publish (be the source of truth for) information on a particular entity (e.g., customer) and also subscribe to updates from another system for information on some other entity (e.g., product).[*citation needed*]

An alternative approach is point-to-point data updates, but these become exponentially more expensive to maintain as the number of systems increases, and this approach is increasingly out of favour as an IT architecture.[*citation needed*]

Master Data Management (MDM)

An MDM system can act as the source of truth for any given entity that might not necessarily have an alternative "source of truth" in another system. Typically the MDM acts as a hub for multiple systems, many of which could allow (be the source of truth for) updates to different aspects of information on a given entity. For example, the CRM system may be the "source of truth" for most aspects of the customer, and is updated by a call centre operator. However, a customer may (for example) also update their address via a customer service web site, with a different back-end database from the CRM system. The MDM application receives updates from multiple sources, acts as a broker to determine which updates are to be regarded as authoritative (the Golden Record) and then syndicates this updated data to all subscribing systems. The MDM application normally requires an ESB to syndicate its data to multiple subscribing systems.[*citation needed*]

Customer Data Integration (CDI), as a common application of Master Data Management, is sometimes abbreviated CDI-MDM.[*citation needed*]

Data Warehouse (DW)

While the primary purpose of a data warehouse is to support reporting and analysis of data that has been combined from multiple sources, the fact that such data has been combined (according to business logic embedded in the data transformation and integration processes) means that the data warehouse is often used as a *de facto* SSOT. Generally, however, the data available from the data warehouse is not used to update other systems; rather the DW becomes the "single source of truth" for reporting to multiple stakeholders. In this context, the Data Warehouse is more correctly referred to as a "Single Version of the Truth" since other versions of the truth exist in its operational data sources (no data originates in the DW; it is simply a reporting mechanism for data loaded from operational systems).[*citation needed*]

XLeratorDB

XLeratorDB is a suite of database function libraries that enable Microsoft SQL Server to perform a wide range of additional (non-native) business intelligence and ad hoc analytics. The libraries, which are embedded and run centrally on the database, include more than 450 individual functions similar to those found in Microsoft Excel spreadsheets. The individual functions are grouped and sold as six separate libraries based on usage: finance, statistics, math, engineering, unit conversions and strings. WestClinTech, the company that developed **XLeratorDB**, claims it is "the first commercial function package add-in for Microsoft SQL Server."[1]

Company history

WestClinTech (LLC), founded by software industry veterans Charles Flock and Joe Stampf in 2008, is located in Irvington, New York, USA. Flock was a co-founder of The Frustum Group, developer of the OPICS enterprise banking and trading platform, which was acquired by London-based Misys, PLC in 1996.[2] Stampf joined Frustum in 1994 and with Flock remained active with the company after acquisition, helping to develop successive generations of OPICS now employed by over 150 leading financial institutions worldwide.[3]

Following a full year of research, development and testing, WestClinTech introduced and recorded its first commercial sale of **XLeratorDB** in April 2009.[4][5] In September 2009, **XLeratorDB** became available to all Federal agencies through NASA's Strategic Enterprise-Wide Procurement (SEWP-IV) program, a government-wide acquisition contract.[6]

Technology

XLeratorDB uses Microsoft SQL CLR(Common Language Runtime) technology.[7] SQL CLR allows managed code to be hosted by, and run in, the Microsoft SQL Server environment. SQL CLR relies on the creation, deployment and registration of .NET Framework assemblies that are physically stored in managed code dynamic-link libraries (DLL). The assemblies may contain .NET namespaces, classes, functions, and properties. Because managed code compiles to native code prior to execution, functions using SQL CLR can achieve significant performance increases versus the equivalent functions written in T-SQL in some scenarios.[8]

XLeratorDB requires Microsoft SQL Server 2005 or SQL Server 2005 Express editions, or later (compatibility mode 90 or higher).[9] The product installs with PERMISSION_SET=SAFE. SAFE mode, the most restrictive permission set, is accessible by all users. Code executed by an assembly with SAFE permissions cannot access external system resources such as files, the network, the internet, environment variables, or the registry.[10]

Functions

In computer science, a function is a portion of code within a larger program which performs a specific task and is relatively independent of the remaining code. As used in database and spreadsheet applications these functions generally represent mathematical formulas widely used across a variety of fields. While this code may be user-generated, it is also embedded as a pre-written sub-routine in applications. These functions are typically identified by common nomenclature which corresponds to their underlying operations: e.g. **IRR** identifies the function which calculates Internal Rate of Return on a series of periodic cash flows.

Function uses

As sub-routines functions can be integrated and used in a variety of ways, and in a wide variety of larger, more complicated applications. Within large enterprise applications they may, for example, play an important role in defining business rules or risk management parameters, while remaining virtually undetected by end users. Within database management systems and spreadsheets, however, these kinds of functions also represent discrete sets of tools; they can be accessed directly and utilized on a stand-alone basis, or in more complex, user-defined configurations. In this context, functions can be used for business intelligence and ad hoc analysis of data in fields such as finance, statistics, engineering, math, etc.

Function types

XLeratorDB uses three kinds of functions to perform analytic operations: scalar, aggregate, and a hybrid form which WestClinTech calls ***Range Queries***. Scalar functions take a single value, perform an operation and return a single value.[11] An example of this type of function is **LOG**, which returns the logarithm of a number to a specified base.[12] Aggregate functions operate on a series of values but return a single, summarizing value. An example of this type of function is **AVG**, which returns the average of values in a specified group.[13]

In **XLeratorDB** there are some functions which have characteristics of aggregate functions (operating on multiple series of values) but cannot be processed in SQL CLR using single column inputs, such as **AVG** does. For example, irregular internal rate of return (**XIRR**), a financial function, operates on a collection of cash flow values from one column, but must also apply variable period lengths from another column and an initial iterative assumption from a third, in order to return a single, summarizing value. WestClinTech documentation notes that ***Range Queries*** specify the data to be included in the result set of the function independently of the WHERE clause associated with the T-SQL statement, by incorporating a SELECT statement into the function as a string argument; the function then traps that SELECT statement, executes it internally and processes the result.[14]

Some **XLeratorDB** functions that employ ***Range Queries*** are: **NPV**, **XNPV**, **IRR**, **XIRR**, **MIRR**, **MULTINOMIAL**, and **SERIESSUM**. Within the application these functions are identified by a "**_q**" naming convention: e.g. **NPV_q**, **IRR_q**, etc.[15]

Analytic functions

SQL Server functions

Microsoft SQL Server is the #3 selling database management system (DBMS), behind Oracle and IBM.[16] (While versions of SQL Server have been on the market since 1987,[17] **XLeratorDB** is compatible with only the 2005 edition and later.) Like all major DBMS, SQL Server performs a variety of data mining operations by returning or arraying data in different views (also known as drill-down). In addition, SQL Server uses Transact-SQL (T-SQL) [18] to execute four major classes of pre-defined functions in native mode.[19] Functions operating on the DBMS offer several advantages over client layer applications like Excel: they utilize the most up-to-date data available; they can process far larger quantities of data; and, the data is not subject to exporting and transcription errors.[20]

SQL Server 2008 includes a total of 58 functions that perform relatively basic aggregation (12), math (23) and string manipulation (23) operations useful for analytics; it includes no native functions that perform more complex operations directly related to finance, statistics or engineering.[21]

Excel functions

Microsoft Excel, a component of Microsoft Office suite, is one of the most widely used spreadsheet applications on the market today.[22] In addition to its inherent utility as a stand-alone desktop application, Excel overlaps and complements the functionality of DBMS in several ways: storing and arraying data in rows and columns; performing certain basic tasks such as pivot table[23] and aggregating values; and facilitating sharing, importing and exporting of database data. Excel's chief limitation relative to a true database is capacity; Excel 2003 is limited to some 65k rows and 256 columns; Excel 2007 extends this capacity to roughly 1million rows and 16k columns.[24] By comparison, SQL Server is able to manage over 500k terabytes of memory.[25]

Excel offers, however, an extensive library of specialized pre-written functions which are useful for performing ad hoc analysis on database data. Excel 2007 includes over 300 of these pre-defined functions, although customized functions can also be created by users, or imported from third party developers as add-ons. Excel functions are grouped by type:[26]

Excel Functions

Financial	Statistical	Engineering	Math and trig
Information	Date and time	Text and data	Logical
Add-ins and automation	Lookup and reference	Cube	Database and list management

Excel business intelligence functions

Operating on the client computing layer Excel plays an important role as a business intelligence tool [27] because it:

- performs a wide array of complex analytic functions not native to most DBMS software
- offers far greater ad hoc reporting and analytic flexibility than most enterprise software
- provides a medium for sharing and collaborating because of its ubiquity throughout the enterprise

Microsoft reinforces this positioning with Business Intelligence documentation that positions Excel in a clearly pivotal role.[28]

XLeratorDB vs. Excel functions

While operating within the database environment, **XLeratorDB** functions utilize the same naming conventions and input formats, and in most cases, return the same calculation results as Excel functions.[29] **XLeratorDB**, coupled with SQL Server's native capabilities, compares to Excel's function sets as follows:

Excel 2007		**XLeratorDB + SQL Server**			
Function Type	**Total**	**Total**	**Match**	**New**	**Native**
Financial	52	93	50	43	0
Statistics	83	171	65	94	12
Math	59	76	34	19	23
Engineering	39	44	38	6	0
Conversions*	49	78	0	78	0
Strings	26	63	11	29	23
**Microsoft includes these functions within Engineering using variable input configurations*

Design

Dimension (data warehouse)

In a data warehouse, **Dimensions** provide structured labeling information to otherwise unordered numeric measures. The dimension is a data set composed of individual, non-overlapping data elements. The primary functions of dimensions are threefold: to provide filtering, grouping and labelling.

These functions are often described as "slice and dice". Slicing refers to filtering data. Dicing refers to grouping data. A common data warehouse example involves sales as the measure, with customer and product as dimensions. In each sale a customer buys a product. The data can be sliced by removing all customers except for a group under study, and then diced by grouping by product.

A dimensional data element is similar to a categorical variable in statistics.

Typically dimensions in a data warehouse are organized internally into one or more hierarchies. "Date" is a common dimension, with several possible hierarchies:

- "Days (are grouped into) Months (which are grouped into) Years",
- "Days (are grouped into) Weeks (which are grouped into) Years"
- "Days (are grouped into) Months (which are grouped into) Quarters (which are grouped into) Years"
- etc.

Types

Conformed dimension

A conformed dimension is a set of data attributes that have been physically referenced in multiple database tables using the same key value to refer to the same structure, attributes, domain values, definitions and concepts. A conformed dimension cuts across many facts.

Dimensions are conformed when they are either exactly the same (including keys) or one is a perfect subset of the other. Most important, the row headers produced in two different answer sets from the same conformed dimension(s) must be able to match perfectly.

Conformed dimensions are either identical or strict mathematical subsets of the most granular, detailed dimension. Dimension tables are not conformed if the attributes are labeled differently or contain different values. Conformed dimensions come in several different flavors. At the most basic level, conformed dimensions mean exactly the same thing with every possible fact table to which they are joined. The date dimension table connected to the sales facts is identical to the date dimension connected to the inventory facts.[1]

Junk dimension

A junk dimension is a convenient grouping of typically low-cardinality flags and indicators. By creating an abstract dimension, these flags and indicators are removed from the fact table while placing them into a useful dimensional framework.[2] A Junk Dimension is a dimension table consisting of attributes that do not belong in the fact table or in any of the existing dimension tables. The nature of these attributes is usually text or various flags, e.g. non-generic comments or just simple yes/no or true/false indicators. These kinds of attributes are typically remaining when all the obvious dimensions in the business process have been identified and thus the designer is faced with the challenge of where to put these attributes that do not belong in the other dimensions.

One solution is to create a new dimension for each of the remaining attributes, but due to their nature, it could be necessary to create a vast number of new dimensions resulting in a fact table with a very large number of foreign keys. The designer could also decide to leave the remaining attributes in the fact table but this could make the row length of the table unnecessarily large if, for example, the attributes is a long text string.

The solution to this challenge is to identify all the attributes and then put them into one or several Junk Dimensions. One Junk Dimension can hold several true/false or yes/no indicators that have no correlation with each other, so it would be convenient to convert the indicators into a more describing attribute. An example would be an indicator about whether a package had arrived, instead of indicating this as “yes” or “no”, it would be converted into “arrived” or “pending” in the junk dimension. The designer can choose to build the dimension table so it ends up holding all the indicators occurring with every other indicator so that all combinations are covered. This sets up a fixed size for the table itself which would be 2^x rows, where x is the number of indicators. This solution is appropriate in situations where the designer would expect to encounter a lot of different combinations and where the possible combinations are limited to an acceptable level. In a situation where the number of indicators are large, thus creating a very big table or where the designer only expect to encounter a few of the possible combinations, it would be more appropriate to build each row in the junk dimension as new combinations are encountered. To limit the size of the tables, multiple junk dimensions might be appropriate in other situations depending on the correlation between various indicators.

Junk dimensions are also appropriate for placing attributes like non-generic comments from the fact table. Such attributes might consist of data from an optional comment field when a customer places an order and as a result will probably be blank in many cases. Therefore the junk dimension should contain a single row representing the blanks as a surrogate key that will be used in the fact table for every row returned with a blank comment field[3]

Degenerate dimension

A degenerate dimension is a key, such as a transaction number, invoice number, ticket number, or bill-of-lading number, that has no attributes and hence does not join to an actual dimension table. Degenerate dimensions are very common when the grain of a fact table represents a single transaction item or line item because the degenerate dimension represents the unique identifier of the parent. Degenerate dimensions often play an integral role in the fact table's primary key.[4]

Role-playing dimension

Dimensions are often recycled for multiple applications within the same database. For instance, a "Date" dimension can be used for "Date of Sale", as well as "Date of Delivery", or "Date of Hire". This is often referred to as a "role-playing dimension".

Use of ISO representation terms

When referencing data from a metadata registry such as ISO/IEC 11179, representation terms such as **Indicator** (a boolean true/false value), **Code** (a set of non-overlapping enumerated values) are typically used as dimensions. For example using the National Information Exchange Model (NIEM) the data element name would be **PersonGenderCode** and the enumerated values would be **male**, **female** and **unknown**.

Common patterns

Date and time[5]

Since many fact tables in a data warehouse are time series of observations, one or more date dimensions are often needed. One of the reasons to have date dimensions is to place calendar knowledge in the data warehouse instead of hard coded in an application. While a simple SQL date/timestamp is useful for providing accurate information about the time a fact was recorded, it can not give information about holidays, fiscal periods, etc. An SQL date/timestamp can still be useful to store in the fact table, as it allows for precise calculations.

Having both the date and time of day in the same dimension, may easily result in a huge dimension with millions of rows. If a high amount of detail is needed it is usually a good idea to split date and time into two or more separate dimensions. A time dimension with a grain of seconds in a day will only have 86400 rows. A more or less detailed grain for date/time dimensions can be chosen depending on needs. As examples, date dimensions can be accurate to year, quarter, month or day and time dimensions can be accurate to hours, minutes or seconds.

As a rule of thumb, time of day dimension should only be created if hierarchical groupings are needed or if there are meaningful textual descriptions for periods of time within the day (ex. “evening rush” or “first shift”).

If the rows in a fact table are coming from several timezones, it might be useful to store date and time in both local time and a standard time. This can be done by having two dimensions for each date/time dimension needed – one for local time, and one for standard time. Storing date/time in both local and standard time, will allow for analysis on when facts are created in a local setting and in a global setting as well. The standard time chosen can be a global standard time (ex. UTC), it can be the local time of the business' headquarter, or any other time zone that would make sense to use.

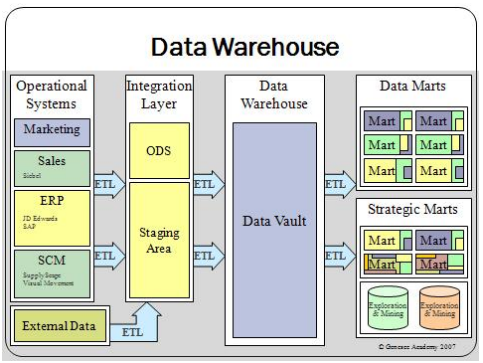
Fact (data warehouse)

In computing, a **data warehouse** (**DW**, **DWH**), or an **enterprise data warehouse** (**EDW**), is a database used for reporting (1) and data analysis (2). Integrating data from one or more disparate sources creates a central repository of data, a data warehouse (DW). Data warehouses store current and historical data and are used for creating trending reports for senior management reporting such as annual and quarterly comparisons.



Data Warehouse Overview

The data stored in the warehouse is uploaded from the operational systems (such as marketing, sales, etc., shown in the figure to the right). The data may pass through an operational data store for additional operations before it is used in the DW for reporting.

The typical extract transform load (ETL)-based data warehouse uses staging, data integration, and access layers to house its key functions. The staging layer or staging database stores raw data extracted from each of the disparate source data systems. The integration layer integrates the disparate data sets by transforming the data from the staging layer often storing this transformed data in an operational data store (ODS) database. The integrated data are then moved to yet another database, often called the data warehouse database, where the data is arranged into hierarchical groups often called dimensions and into facts and aggregate facts. The combination of facts and dimensions is sometimes called a star schema. The access layer helps users retrieve data.

A data warehouse constructed from an integrated data source systems does not require ETL, staging databases, or operational data store databases. The integrated data source systems may be considered to be a part of a distributed operational data store layer. Data federation methods or data virtualization methods may be used to access the distributed integrated source data systems to consolidate and aggregate data directly into the data warehouse database tables. Unlike the ETL-based data warehouse, the integrated source data systems and the data warehouse are all integrated since there is no transformation of dimensional or reference data. This integrated data warehouse architecture supports the drill down from the aggregate data of the data warehouse to the transactional data of the integrated source data systems.

A data mart is a small data warehouse focused on a specific area of interest. Data warehouses can be subdivided into data marts for improved performance and ease of use within that area. Alternatively, an organization can create one or more data marts as first steps towards a larger and more complex enterprise data warehouse.

This definition of the data warehouse focuses on data storage. The main source of the data is cleaned, transformed, cataloged and made available for use by managers and other business professionals for data mining, online analytical processing, market research and decision support (Marakas & O'Brien 2009). However, the means to retrieve and analyze data, to extract, transform and load data, and to manage the data dictionary are also considered essential components of a data warehousing system. Many references to data warehousing use this broader context. Thus, an expanded definition for data warehousing includes business intelligence tools, tools to extract, transform and load data into the repository, and tools to manage and retrieve metadata.

Benefits of a data warehouse

A data warehouse maintains a copy of information from the source transaction systems. This architectural complexity provides the opportunity to :

- Congregate data from multiple sources into a single database so a single query engine can be used to present data.
- Mitigate the problem of database isolation level lock contention in transaction processing systems caused by attempts to run large, long running, analysis queries in transaction processing databases.
- Maintain data history, even if the source transaction systems do not.
- Integrate data from multiple source systems, enabling a central view across the enterprise. This benefit is always valuable, but particularly so when the organization has grown by merger.
- Improve data quality, by providing consistent codes and descriptions, flagging or even fixing bad data.
- Present the organization's information consistently.
- Provide a single common data model for all data of interest regardless of the data's source.
- Restructure the data so that it makes sense to the business users.
- Restructure the data so that it delivers excellent query performance, even for complex analytic queries, without impacting the operational systems.
- Add value to operational business applications, notably customer relationship management (CRM) systems.
- Making decision–support queries easier to write.

Generic data warehouse environment

The environment for data warehouses and marts includes the following:

- Source systems that provide data to the warehouse or mart;
- Data integration technology and processes that are needed to prepare the data for use;
- Different architectures for storing data in an organization's data warehouse or data marts;
- Different tools and applications for the variety of users;
- Metadata, data quality, and governance processes must be in place to ensure that the warehouse or mart meets its purposes.

In regards to source systems listed above, Rainer states, “A common source for the data in data warehouses is the company’s operational databases, which can be relational databases”.

Regarding data integration, Rainer states, “It is necessary to extract data from source systems, transform them, and load them into a data mart or warehouse”.

Rainer discusses storing data in an organization’s data warehouse or data marts. “There are a variety of possible architectures to store decision-support data”.

Metadata are data about data. “IT personnel need information about data sources; database, table, and column names; refresh schedules; and data usage measures“.

Today, the most successful companies are those that can respond quickly and flexibly to market changes and opportunities. A key to this response is the effective and efficient use of data and information by analysts and managers. A “data warehouse” is a repository of historical data that are organized by subject to support decision makers in the organization. Once data are stored in a data mart or warehouse, they can be accessed.

History

The concept of data warehousing dates back to the late 1980s when IBM researchers Barry Devlin and Paul Murphy developed the "business data warehouse". In essence, the data warehousing concept was intended to provide an architectural model for the flow of data from operational systems to decision support environments. The concept attempted to address the various problems associated with this flow, mainly the high costs associated with it. In the absence of a data warehousing architecture, an enormous amount of redundancy was required to support multiple decision support environments. In larger corporations it was typical for multiple decision support environments to operate independently. Though each environment served different users, they often required much of the same stored data. The process of gathering, cleaning and integrating data from various sources, usually from long-term existing operational systems (usually referred to as legacy systems), was typically in part replicated for each environment. Moreover, the operational systems were frequently reexamined as new decision support requirements emerged. Often new requirements necessitated gathering, cleaning and integrating new data from "data marts" that were tailored for ready access by users.

Key developments in early years of data warehousing were:

- 1960s — General Mills and Dartmouth College, in a joint research project, develop the terms *dimensions* and *facts*.[1]
- 1970s — ACNielsen and IRI provide dimensional data marts for retail sales.
- 1970s — Bill Inmon begins to define and discuss the term: Data Warehouse
- 1975 — Sperry Univac Introduce MAPPER (MAintain, Prepare, and Produce Executive Reports) is a database management and reporting system that includes the world's first 4GL. It was the first platform designed for building Information Centers (a forerunner of contemporary Enterprise Data Warehousing platforms)
- 1983 — Teradata introduces a database management system specifically designed for decision support.
- 1983 — Sperry Corporation Martyn Richard Jones defines the Sperry Information Center approach, which while not being a true DW in the Inmon sense, did contain many of the characteristics of DW structures and process as defined previously by Inmon, and later by Devlin. First used at the TSB England & Wales
- 1984 — Metaphor Computer Systems, founded by David Liddle and Don Massaro, releases Data Interpretation System (DIS). DIS was a hardware/software package and GUI for business users to create a database management and analytic system.
- 1988 — Barry Devlin and Paul Murphy publish the article *An architecture for a business and information system* [2] in *IBM Systems Journal* where they introduce the term "business data warehouse".
- 1990 — Red Brick Systems, founded by Ralph Kimball, introduces Red Brick Warehouse, a database management system specifically for data warehousing.
- 1991 — Prism Solutions, founded by Bill Inmon, introduces Prism Warehouse Manager, software for developing a data warehouse.
- 1992 — Bill Inmon publishes the book *Building the Data Warehouse*.
- 1995 — The Data Warehousing Institute, a for-profit organization that promotes data warehousing, is founded.
- 1996 — Ralph Kimball publishes the book *The Data Warehouse Toolkit*.
- 2000 — Daniel Linstedt releases the *Data Vault*, enabling real time auditable Data Warehouses warehouse.

Information storage

Facts

A fact is a value or measurement, which represents a fact about the managed entity or system.

Facts as reported by the reporting entity are said to be at raw level.

E.g. if a BTS received 1,000 requests for traffic channel allocation, it allocates for 820 and rejects the remaining then it would report 3 **facts** or measurements to a management system:

- tch_req_total = 1000
- tch_req_success = 820
- tch_req_fail = 180

Facts at raw level are further aggregated to higher levels in various dimensions to extract more service or business-relevant information out of it. These are called aggregates or summaries or aggregated facts.

E.g. if there are 3 BTSs in a city, then facts above can be aggregated from BTS to city level in network dimension. E.g.

- $tch\_req\_success\_city = tch\_req\_success\_bts1 + tch\_req\_success\_bts2 + tch\_req\_success\_bts3$
- $avg\_tch\_req\_success\_city = (tch\_req\_success\_bts1 + tch\_req\_success\_bts2 + tch\_req\_success\_bts3)/3$

Dimensional vs. normalized approach for storage of data

There are three or more leading approaches to storing data in a data warehouse — the most important approaches are the dimensional approach and the normalized approach.

The dimensional approach, whose supporters are referred to as “Kimballites”, believe in Ralph Kimball's approach in which it is stated that the data warehouse should be modeled using a Dimensional Model/star schema. The normalized approach, also called the 3NF model (Third Normal Form), whose supporters are referred to as “Inmonites”, believe in Bill Inmon's approach in which it is stated that the data warehouse should be modeled using an E-R model/normalized model.

In a dimensional approach, transaction data are partitioned into "facts", which are generally numeric transaction data, and "dimensions", which are the reference information that gives context to the facts. For example, a sales transaction can be broken up into facts such as the number of products ordered and the price paid for the products, and into dimensions such as order date, customer name, product number, order ship-to and bill-to locations, and salesperson responsible for receiving the order.

A key advantage of a dimensional approach is that the data warehouse is easier for the user to understand and to use. Also, the retrieval of data from the data warehouse tends to operate very quickly.[*citation needed*] Dimensional structures are easy to understand for business users, because the structure is divided into measurements/facts and context/dimensions. Facts are related to the organization’s business processes and operational system whereas the dimensions surrounding them contain context about the measurement (Kimball, Ralph 2008).

The main disadvantages of the dimensional approach are the following:

1. In order to maintain the integrity of facts and dimensions, loading the data warehouse with data from different operational systems is complicated.
2. It is difficult to modify the data warehouse structure if the organization adopting the dimensional approach changes the way in which it does business.

In the normalized approach, the data in the data warehouse are stored following, to a degree, database normalization rules. Tables are grouped together by *subject areas* that reflect general data categories (e.g., data on customers, products, finance, etc.). The normalized structure divides data into entities, which creates several tables in a relational database. When applied in large enterprises the result is dozens of tables that are linked together by a web

of joins. Furthermore, each of the created entities is converted into separate physical tables when the database is implemented (Kimball, Ralph 2008)[*citation needed*]. The main advantage of this approach is that it is straightforward to add information into the database. Some disadvantages of this approach are that, because of the number of tables involved, it can be difficult for users to join data from different sources into meaningful information and to access the information without a precise understanding of the sources of data and of the data structure of the data warehouse.

It should be noted that both normalized and dimensional models can be represented in entity-relationship diagrams as both contain joined relational tables. The difference between the two models is the degree of normalization (also known as Normal Forms).

These approaches are not mutually exclusive, and there are other approaches. Dimensional approaches can involve normalizing data to a degree (Kimball, Ralph 2008).

In Information-Driven Business, Robert Hillard proposes an approach to comparing the two approaches based on the information needs of the business problem. The technique shows that normalized models hold far more information than their dimensional equivalents (even when the same fields are used in both models) but this extra information comes at the cost of usability. The technique measures information quantity in terms of Information Entropy and usability in terms of the Small Worlds data transformation measure.

Top-down versus bottom-up design methodologies

Bottom-up design

Ralph Kimball,[2] designed an approach to data warehouse design known as *bottom-up*.

In the *bottom-up* approach, data marts are first created to provide reporting and analytical capabilities for specific business processes.

Data marts contain, primarily, dimensions and facts. Facts can contain either atomic data and, if necessary, summarized data. The single data mart often models a specific business area such as "Sales" or "Production." These data marts can eventually be integrated to create a comprehensive data warehouse. The data warehouse bus architecture is primarily an implementation of "the bus", a collection of conformed dimensions and conformed facts, which are dimensions that are shared (in a specific way) between facts in two or more data marts.

The integration of the data marts in the data warehouse is centered on the conformed dimensions (residing in "the bus") that define the possible integration "points" between data marts. The actual integration of two or more data marts is then done by a process known as "Drill across". A drill-across works by grouping (summarizing) the data along the keys of the (shared) conformed dimensions of each fact participating in the "drill across" followed by a join on the keys of these grouped (summarized) facts.

Maintaining tight management over the data warehouse bus architecture is fundamental to maintaining the integrity of the data warehouse. The most important management task is making sure dimensions among data marts are consistent.

Business value can be returned as quickly as the first data marts can be created, and the method lends itself well to an exploratory and iterative approach to building data warehouses. For example, the data warehousing effort might start in the "Sales" department, by building a Sales-data mart. Upon completion of the Sales-data mart, the business might then decide to expand the warehousing activities into the, say, "Production department" resulting in a Production data mart. The requirement for the Sales data mart and the Production data mart to be integrable, is that they share the same "Bus", that will be, that the data warehousing team has made the effort to identify and implement the conformed dimensions in the bus, and that the individual data marts links that information from the bus. The Sales-data mart is good as it is (assuming that the bus is complete) and the Production-data mart can be constructed virtually independent of the Sales-data mart (but not independent of the Bus).

If integration via the bus is achieved, the data warehouse, through its two data marts, will not only be able to deliver the specific information that the individual data marts are designed to do, in this example either "Sales" or "Production" information, but can deliver integrated Sales-Production information, which, often, is of critical business value.

Top-down design

Bill Inmon, has defined a data warehouse as a centralized repository for the entire enterprise.[3] The *top-down* approach is designed using a normalized enterprise data model. "Atomic" data, that is, data at the lowest level of detail, are stored in the data warehouse. Dimensional data marts containing data needed for specific business processes or specific departments are created from the data warehouse. In the Inmon vision, the data warehouse is at the center of the "Corporate Information Factory" (CIF), which provides a logical framework for delivering business intelligence (BI) and business management capabilities. Gartner released a research note confirming Inmon's definition in 2005[4] with additional clarity plus they added one additional attribute.

The data warehouse is:

Subject-oriented

> The data in the data warehouse is organized so that all the data elements relating to the same real-world event or object are linked together.

Non-volatile

> Data in the data warehouse are never over-written or deleted — once committed, the data are static, read-only, and retained for future reporting.

Integrated

> The data warehouse contains data from most or all of an organization's operational systems and these data are made consistent.

Time-variant

> For an **operational system**, the stored data contains the current value. The data warehouse, however, contains the history of data values.

No virtualization

> A data warehouse is a physical repository.

The top-down design methodology generates highly consistent dimensional views of data across data marts since all data marts are loaded from the centralized repository. Top-down design has also proven to be robust against business changes. Generating new dimensional data marts against the data stored in the data warehouse is a relatively simple task. The main disadvantage to the top-down methodology is that it represents a very large project with a very broad scope. The up-front cost for implementing a data warehouse using the top-down methodology is significant, and the duration of time from the start of project to the point that end users experience initial benefits can be substantial. In addition, the top-down methodology can be inflexible and unresponsive to changing departmental needs during the implementation phases.

Hybrid design

Data warehouse (DW) solutions often resemble the hub and spokes architecture. Legacy systems feeding the DW/BI solution often include customer relationship management (CRM) and enterprise resource planning solutions (ERP), generating large amounts of data. To consolidate these various data models, and facilitate the extract transform load (ETL) process, DW solutions often make use of an operational data store (ODS). The information from the ODS is then parsed into the actual DW. To reduce data redundancy, larger systems will often store the data in a normalized way. Data marts for specific reports can then be built on top of the DW solution.

It is important to note that the DW database in a hybrid solution is kept on third normal form to eliminate data redundancy. A normal relational database however, is not efficient for business intelligence reports where dimensional modelling is prevalent. Small data marts can shop for data from the consolidated warehouse and use the filtered, specific data for the fact tables and dimensions required. The DW effectively provides a single source of information from which the data marts can read, creating a highly flexible solution from a BI point of view. The hybrid architecture allows a DW to be replaced with a master data management solution where operational, not static information could reside.

The Data Vault Modeling components follow hub and spokes architecture. This modeling style is a hybrid design, consisting of the best practices from both 3rd normal form and star schema. The Data Vault model is not a true 3rd normal form, and breaks some of the rules that 3NF dictates be followed. It is however, a top-down architecture with a bottom up design. The Data Vault model is geared to be strictly a data warehouse. It is not geared to be end-user accessible, which when built, still requires the use of a data mart or star schema based release area for business purposes.

Data warehouses versus operational systems

Operational systems are optimized for preservation of data integrity and speed of recording of business transactions through use of database normalization and an entity-relationship model. Operational system designers generally follow the Codd rules of database normalization in order to ensure data integrity. Codd defined five increasingly stringent rules of normalization. Fully normalized database designs (that is, those satisfying all five Codd rules) often result in information from a business transaction being stored in dozens to hundreds of tables. Relational databases are efficient at managing the relationships between these tables. The databases have very fast insert/update performance because only a small amount of data in those tables is affected each time a transaction is processed. Finally, in order to improve performance, older data are usually periodically purged from operational systems.

Evolution in organization use

These terms refer to the level of sophistication of a data warehouse:

Offline operational data warehouse

> Data warehouses in this stage of evolution are updated on a regular time cycle (usually daily, weekly or monthly) from the operational systems and the data is stored in an integrated reporting-oriented data

Offline data warehouse

> Data warehouses at this stage are updated from data in the operational systems on a regular basis and the data warehouse data are stored in a data structure designed to facilitate reporting.

On time data warehouse

> Online Integrated Data Warehousing represent the real time Data warehouses stage data in the warehouse is updated for every transaction performed on the source data

Integrated data warehouse

> These data warehouses assemble data from different areas of business, so users can look up the information they need across other systems.

Measure (data warehouse)

In a data warehouse, a **measure** is a property on which calculations (e.g., sum, count, average, minimum, maximum) can be made.

Example

For example if a retail store sold a specific product, the quantity and prices of each item sold could be added or averaged to find the total number of items sold and total or average price of the goods.

Use of ISO representation terms

When entering data into a metadata registry such as ISO/IEC 11179, representation terms such as **Number**, **Value** and **Measure** are typically used as measures.

Fact table

In data warehousing, a **fact table** consists of the measurements, metrics or facts of a business process. It is located at the center of a star schema or a snowflake schema surrounded by dimension tables. Where multiple fact tables are used, these are arranged as a fact constellation schema. A fact table typically has two types of columns: those that contain facts and those that are foreign keys to dimension tables. The primary key of a fact table is usually a composite key that is made up of all of its foreign keys. Fact tables contain the content of the data warehouse and store different types of measures like additive, non additive, and semi additive measures.

Fact tables provide the (usually) additive values that act as independent variables by which dimensional attributes are analyzed. Fact tables are often defined by their *grain*. The grain of a fact table represents the most atomic level by which the facts may be defined. The grain of a SALES fact table might be stated as "Sales volume by Day by Product by Store". Each record in this fact table is therefore uniquely defined by a day, product and store. Other dimensions might be members of this fact table (such as location/region) but these add nothing to the uniqueness of the fact records. These "affiliate dimensions" allow for additional slices of the independent facts but generally provide insights at a higher level of aggregation (a region contains many stores).

Example

If the business process is SALES, then the corresponding fact table will typically contain columns representing both raw facts and aggregations in rows such as:

- *$12,000*, being "sales for New York store for 15-Jan-2005"
- *$34,000*, being "sales for Los Angeles store for 15-Jan-2005"
- *$22,000*, being "sales for New York store for 16-Jan-2005"
- *$50,000*, being "sales for Los Angeles store for 16-Jan-2005"
- *$21,000*, being "average daily sales for Los Angeles Store for Jan-2005"
- *$65,000*, being "average daily sales for Los Angeles Store for Feb-2005"
- *$33,000*, being "average daily sales for Los Angeles Store for year 2005"

"average daily sales" is a measurement which is stored in the fact table. The fact table also contains foreign keys from the dimension tables, where time series (e.g. dates) and other dimensions (e.g. store location, salesperson, product) are stored.

All foreign keys between fact and dimension tables should be surrogate keys, not reused keys from operational data.

Measure types

- Additive - Measures that can be added across any dimension.
- Non Additive - Measures that cannot be added across any dimension.
- Semi Additive - Measures that can be added across some dimensions.

A fact table might contain either detail level facts or facts that have been aggregated (fact tables that contain aggregated facts are often instead called summary tables).

Special care must be taken when handling ratios and percentage. One good design rule[1] is to never store percentages or ratios in fact tables but only calculate these in the data access tool. Thus only store the numerator and denominator in the fact table, which then can be aggregated and the aggregated stored values can then be used for calculating the ratio or percentage in the data access tool.

In the real world, it is possible to have a fact table that contains no measures or facts. These tables are called "factless fact tables", or "junction tables".

The "Factless fact tables" can for example be used for modeling many-to-many relationships or capture events.

Types of fact tables

There are basically three fundamental measurement events, which characterizes all fact tables.

- Transactional

  A transactional table is the most basic and fundamental. The grain associated with a transactional fact table is usually specified as "one row per line in a transaction", e.g., every line on a receipt. Typically a transactional fact table holds data of the most detailed level, causing it to have a great number of dimensions associated with it.

- Periodic snapshots

  The periodic snapshot, as the name implies, takes a "picture of the moment", where the moment could be any defined period of time, e.g. a performance summary of a salesman over the previous month. A periodic snapshot table is dependent on the transactional table, as it needs the detailed data held in the transactional fact table in order to deliver the chosen performance output.

- Accumulating snapshots

  This type of fact table is used to show the activity of a process that has a well-defined beginning and end, e.g., the processing of an order. An order moves through specific steps until it is fully processed. As steps towards fulfilling the order are completed, the associated row in the fact table is updated. An accumulating snapshot table often has multiple date columns, each representing a milestone in the process. Therefore, it's important to have an entry in the associated date dimension that represents an unknown date, as many of the milestone dates are unknown at the time of the creation of the row.

- Temporal snapshots

  By applying Temporal Database theory and modelling techniques the Temporal Snapshot Fact Table allows to have the equivalent of daily snapshots without really having daily snapshots. It introduces the concept of Time Intervals into a fact table, allowing to save a lot of space, optimizing performances while allowing the end user to have the logical equivalent of the "picture of the moment" he is interested in.

Steps in designing a fact table

- Identify a business process for analysis (like sales).
- Identify measures of facts (sales dollar), by asking questions like 'What number of XX are relevant for the business process?', replacing the XX with various options that make sense within the context of the business.
- Identify dimensions for facts (product dimension, location dimension, time dimension, organization dimension), by asking questions that make sense within the context of the business, like 'Analyse by XX', where XX is replaced with the subject to test.
- List the columns that describe each dimension (region name, branch name, business unit name).
- Determine the lowest level (granularity) of summary in a fact table (e.g. sales dollars).

An alternative approach is the four step design process described in Kimball.

Degenerate dimension

The Kimball definition

According to Ralph Kimball, in a data warehouse, a **degenerate dimension** is a dimension key in the fact table that does not have its own dimension table, because all the interesting attributes have been placed in analytic dimensions. The term "degenerate dimension" was originated by Ralph Kimball.

As Bob Becker says,

> Degenerate dimensions commonly occur when the fact table's grain is a single transaction (or transaction line). Transaction control header numbers assigned by the operational business process are typically degenerate dimensions, such as order, ticket, credit card transaction, or check numbers. These degenerate dimensions are natural keys of the "parents" of the line items.
>
> Even though there is no corresponding dimension table of attributes, degenerate dimensions can be quite useful for grouping together related fact tables rows. For example, retail point-of-sale transaction numbers tie all the individual items purchased together into a single market basket. In health care, degenerate dimensions can group the claims items related to a single hospital stay or episode of care.

Other uses of the term

Although most writers and practitioners use the term **degenerate dimension** correctly, it is very easy to find misleading definitions in online and printed sources. For example, the Oracle FAQ defines a degenerate dimension as a "data dimension that is stored in the fact table rather than a separate dimension table. This eliminates the need to join to a dimension table. You can use the data in the degenerate dimension to limit or 'slice and dice' your fact table measures."

This common interpretation implies that it is good dimensional modeling practice to place dimension attributes in the fact table, as long as you call them a degenerate dimension. This is not the case; the concept of **degenerate dimension** was developed by Kimball to support a specific, well-defined exception to the otherwise ironclad rule that dimension attributes are always pulled out into dimension tables.

Slowly changing dimension

Dimension is a term in data management and data warehousing. It's the logical groupings of data such as geographical location, customer or product information. With **Slowly Changing Dimensions (SCDs)** data changes slowly, rather than changing on a time-based, regular schedule.

For example, you may have a dimension in your database that tracks the sales records of your company's salespeople. Creating sales reports seems simple enough, until a salesperson is transferred from one regional office to another. How do you record such a change in your sales dimension?

You could calculate the sum or average of each salesperson's sales, but if you use that to compare the performance of salespeople, that might give misleading information. If the salesperson was transferred and used to work in a hot market where sales were easy, and now works in a market where sales are infrequent, his/her totals will look much stronger than the other salespeople in their new region. Or you could create a second salesperson record and treat the transferred person as a new sales person, but that creates problems.

Dealing with these issues involves SCD management methodologies referred to as Type 0 through 6. Type 6 SCDs are also sometimes called Hybrid SCDs.

Type 0

The **Type 0** method is passive. It manages dimensional changes and no action is performed. Values remain as they were at the time the dimension record was first inserted. In certain circumstances history is preserved with a Type 0. High order types are employed to guarantee the preservation of history whereas Type 0 provides the least or no control.

The most common types are I, II, and III.

Type 1

This methodology overwrites old with new data, and therefore does not track historical data.

Example of a supplier table:

Supplier_Key	Supplier_Code	Supplier_Name	Supplier_State
123	ABC	Acme Supply Co	CA

In the above example, Supplier_Code is the natural key and Supplier_Key is a surrogate key. Technically, the surrogate key is not necessary, since the row will be unique by the natural key (Supplier_Code). However, to

optimize performance on joins use integer rather than character keys.

If the supplier relocates the headquarters to Illinois the record would be overwritten:

Supplier_Key	Supplier_Code	Supplier_Name	Supplier_State
123	ABC	Acme Supply Co	IL

The disadvantage of the Type I method is that there is no history in the data warehouse. It has the advantage however that it's easy to maintain.

If you have calculated an aggregate table summarizing facts by state, it will need to be recalculated when the Supplier_State is changed.

Type 2

This method tracks historical data by creating multiple records for a given natural key in the dimensional tables with separate surrogate keys and/or different version numbers. Unlimited history is preserved for each insert.

For example, if the supplier relocates to Illinois the version numbers will be incremented sequentially:

Supplier_Key	Supplier_Code	Supplier_Name	Supplier_State	Version.
123	ABC	Acme Supply Co	CA	0
124	ABC	Acme Supply Co	IL	1

Another method is to add 'effective date' columns.

Supplier_Key	Supplier_Code	Supplier_Name	Supplier_State	Start_Date	End_Date
123	ABC	Acme Supply Co	CA	01-Jan-2000	21-Dec-2004
124	ABC	Acme Supply Co	IL	22-Dec-2004	

The null End_Date in row two indicates the current tuple version. In some cases, a standardized surrogate high date (e.g. 9999-12-31) may be used as an end date, so that the field can be included in an index, and so that null-value substitution is not required when querying.

Transactions that reference a particular surrogate key (Supplier_Key) are then permanently bound to the time slices defined by that row of the slowly changing dimension table. An aggregate table summarizing facts by state continues to reflect the historical state, i.e. the state the supplier was in at the time of the transaction; no update is needed.

If there are retrospective changes made to the contents of the dimension, or if new attributes are added to the dimension (for example a Sales_Rep column) which have different effective dates from those already defined, then this can result in the existing transactions needing to be updated to reflect the new situation. This can be an expensive database operation, so Type 2 SCDs are not a good choice if the dimensional model is subject to change.

Type 3

This method tracks changes using separate columns and preserves limited history. The Type 3 preserves limited history as it's limited to the number of columns designated for storing historical data. The original table structure in Type 1 and Type 2 is the same but Type III adds additional columns. In the following example, an additional column has been added to the table to record the supplier's original state - only the previous history is stored.

Supplier_Key	Supplier_Code	Supplier_Name	Original_Supplier_State	Effective_Date	Current_Supplier_State
123	ABC	Acme Supply Co	CA	22-Dec-2004	IL

This record contains a column for the original state and current state—cannot track the changes if the supplier relocates a second time.

One variation of this is to create the field Previous_Supplier_State instead of Original_Supplier_State which would track only the most recent historical change.

Type 4

The **Type 4** method is usually referred to as using "history tables", where one table keeps the current data, and an additional table is used to keep a record of some or all changes. Both the surrogate keys are referenced in the Fact table to enhance query performance.For the above example the original table name is **Supplier** and the history table is **Supplier_History.**

Supplier

Supplier_key	Supplier_Code	Supplier_Name	Supplier_State
123	ABC	Acme Supply Co	IL

Supplier_History

Supplier_key	Supplier_Code	Supplier_Name	Supplier_State	Create_Date
123	ABC	Acme Supply Co	CA	22-Dec-2004

This method resembles how database audit tables and change data capture techniques function.

Type 6 / hybrid

The **Type 6** method combines the approaches of types 1, 2 and 3 (1 + 2 + 3 = 6). One possible explanation of the origin of the term was that it was coined by Ralph Kimball during a conversation with Stephen Pace from Kalido[*citation needed*]. Ralph Kimball calls this method "Unpredictable Changes with Single-Version Overlay" in *The Data Warehouse Toolkit*.

The Supplier table starts out with one record for our example supplier:

Supplier_Key	Supplier_Code	Supplier_Name	Current_State	Historical_State	Start_Date	End_Date	Current_Flag
123	ABC	Acme Supply Co	CA	CA	01-Jan-2000	31-Dec-9999	Y

The Current_State and the Historical_State are the same. The Current_Flag attribute indicates that this is the current or most recent record for this supplier.

When Acme Supply Company moves to Illinois, we add a new record, as in Type 2 processing:

Supplier_Key	Supplier_Code	Supplier_Name	Current_State	Historical_State	Start_Date	End_Date	Current_Flag
123	ABC	Acme Supply Co	IL	CA	01-Jan-2000	21-Dec-2004	N
124	ABC	Acme Supply Co	IL	IL	22-Dec-2004	31-Dec-9999	Y

We overwrite the Current_State information in the first record (Supplier_Key = 123) with the new information, as in Type 1 processing. We create a new record to track the changes, as in Type 2 processing. And we store the history in a second State column (Historical_State), which incorporates Type 3 processing.

For example if the supplier were to relocate again, we would add another record to the Supplier dimension, and we would overwrite the contents of the Current_State column:

Supplier_Key	Supplier_Code	Supplier_Name	Current_State	Historical_State	Start_Date	End_Date	Current_Flag
123	ABC	Acme Supply Co	NY	CA	01-Jan-2000	21-Dec-2004	N
124	ABC	Acme Supply Co	NY	IL	22-Dec-2004	03-Feb-2008	N
125	ABC	Acme Supply Co	NY	NY	04-Feb-2008	31-Dec-9999	Y

Note that, for the current record (Current_Flag = 'Y'), the Current_State and the Historical_State are always the same.

Type 2 / Type 6 fact implementation

Type 2 surrogate key with Type 3 attribute

In many Type 2 and Type 6 SCD implementations, the surrogate key from the dimension is put into the fact table in place of the natural key when the fact data is loaded into the data repository. The surrogate key is selected for a given fact record based on its effective date and the Start_Date and End_Date from the dimension table. This allows the fact data to be easily joined to the correct dimension data for the corresponding effective date.

Here is the Supplier table as we created it above using Type 6 Hybrid methodology:

Supplier_Key	Supplier_Code	Supplier_Name	Current_State	Historical_State	Start_Date	End_Date	Current_Flag
123	ABC	Acme Supply Co	NY	CA	01-Jan-2000	21-Dec-2004	N
124	ABC	Acme Supply Co	NY	IL	22-Dec-2004	03-Feb-2008	N
125	ABC	Acme Supply Co	NY	NY	04-Feb-2008	31-Dec-9999	Y

Once the Delivery table contains the correct Supplier_Key, it can easily be joined to the Supplier table using that key. The following SQL retrieves, for each fact record, the current supplier state and the state the supplier was located in at the time of the delivery:

```
SELECT
  delivery.delivery_cost,
  supplier.supplier_name,
  supplier.historical_state,
  supplier.current_state
FROM delivery
INNER JOIN supplier
  ON delivery.supplier_key = supplier.supplier_key
```

Pure Type 6 implementation

Having a Type 2 surrogate key for each time slice can cause problems if the dimension is subject to change.

A pure Type 6 implementation does not use this, but uses a Surrogate Key for each master data item (e.g. each unique supplier has a single surrogate key).

This avoids any changes in the master data having an impact on the existing transaction data.

It also allows more options when querying the transactions.

Here is the Supplier table using the pure Type 6 methodology:

Supplier_Key	Supplier_Code	Supplier_Name	Supplier_State	Start_Date	End_Date
456	ABC	Acme Supply Co	CA	01-Jan-2000	21-Dec-2004
456	ABC	Acme Supply Co	IL	22-Dec-2004	03-Feb-2008
456	ABC	Acme Supply Co	NY	04-Feb-2008	31-Dec-9999

The following example shows how the query must be extended to ensure a single supplier record is retrieved for each transaction.

```
SELECT
  supplier.supplier_code,
  supplier.supplier_state
FROM supplier
INNER JOIN delivery
  ON supplier.supplier_key = delivery.supplier_key
 AND delivery.delivery_date >= supplier.start_date
 AND delivery.delivery_date <= supplier.end_date
```

A fact record with an effective date (Delivery_Date) of August 9, 2001 will be linked to Supplier_Code of ABC, with a Supplier_State of 'CA'. A fact record with an effective date of October 11, 2007 will also be linked to the same Supplier_Code ABC, but with a Supplier_State of 'IL'.

Whilst more complex, there are a number of advantages of this approach, including:

1. If there is more than one date on the fact (e.g. Order Date, Delivery Date, Invoice Payment Date) you can choose which date to use for a query.
2. You can do "as at now", "as at transaction time" or "as at a point in time" queries by changing the date filter logic.
3. You don't need to reprocess the Fact table if there is a change in the dimension table (e.g. adding additional fields retrospectively which change the time slices, or if you make a mistake in the dates on the dimension table you can correct them easily).
4. You can introduce bi-temporal dates in the dimension table.
5. You can join the fact to the multiple versions of the dimension table to allow reporting of the same information with different effective dates, in the same query.

The following example shows how a specific date such as '2012-01-01 00:00:00' (which could be the current datetime) can be used.

```
SELECT
  supplier.supplier_code,
  supplier.supplier_state
FROM supplier
INNER JOIN delivery
  ON supplier.supplier_key = delivery.supplier_key
```

```
 AND '2012-01-01 00:00:00' >= supplier.start_date
 AND '2012-01-01 00:00:00' <= supplier.end_date
```

Both surrogate and natural key

An alternative implementation is to place *both* the surrogate key and the natural key into the fact table. This allows the user to select the appropriate dimension records based on:

- the primary effective date on the fact record (above),
- the most recent or current information,
- any other date associated with the fact record.

This method allows more flexible links to the dimension, even if you have used the Type 2 approach instead of Type 6.

Here is the Supplier table as we might have created it using Type 2 methodology:

Supplier_Key	Supplier_Code	Supplier_Name	Supplier_State	Start_Date	End_Date	Current_Flag
123	ABC	Acme Supply Co	CA	01-Jan-2000	21-Dec-2004	N
124	ABC	Acme Supply Co	IL	22-Dec-2004	03-Feb-2008	N
125	ABC	Acme Supply Co	NY	04-Feb-2008	31-Dec-9999	Y

The following SQL retrieves the most current Supplier_Name and Supplier_State for each fact record:

```
SELECT
  delivery.delivery_cost,
  supplier.supplier_name,
  supplier.supplier_state
FROM delivery
INNER JOIN supplier
  ON delivery.supplier_code = supplier.supplier_code
WHERE supplier.current_flag = 'Y'
```

If there are multiple dates on the fact record, the fact can be joined to the dimension using another date instead of the primary effective date. For instance, the Delivery table might have a primary effective date of Delivery_Date, but might also have an Order_Date associated with each record.

The following SQL retrieves the correct Supplier_Name and Supplier_State for each fact record based on the Order_Date:

```
SELECT
  delivery.delivery_cost,
  supplier.supplier_name,
  supplier.supplier_state
FROM delivery
INNER JOIN supplier
  ON delivery.supplier_code = supplier.supplier_code
 AND delivery.order_date >= supplier.start_date
 AND delivery.order_date <= supplier.end_date
```

Some cautions:

- If the join query is not written correctly, it may return duplicate rows and/or give incorrect answers.
- The date comparison might not perform well.

- Some Business Intelligence tools do not handle generating complex joins well.
- The ETL processes needed to create the dimension table needs to be carefully designed to ensure that there are no overlaps in the time periods for each distinct item of reference data.

Combining types

Different SCD Types can be applied to different columns of a table. For example, we can apply Type 1 to the Supplier_Name column and Type 2 to the Supplier_State column of the same table.

Star schema

In computing, the **Star Schema** (also called **star-join schema**) is the simplest style of data mart schema. The star schema consists of one or more fact tables referencing any number of dimension tables. The star schema is an important special case of the snowflake schema, and is more effective for handling simpler queries.

The star schema gets its name from the physical model's[1] resemblance to a star with a fact table at its center and the dimension tables surrounding it representing the star's points.

Model

The star schema separates business process data into facts, which hold the measurable, quantitative data about a business, and dimensions which are descriptive attributes related to fact data. Examples of fact data include sales price, sale quantity, and time, distance, speed, and weight measurements. Related dimension attribute examples include product models, product colors, product sizes, geographic locations, and salesperson names.

A star schema that has many dimensions is sometimes called a *centipede schema*.[2] Having dimensions of only a few attributes, while simpler to maintain, results in queries with many table joins and makes the star schema less easy to use.

Fact tables

Fact tables record measurements or metrics for a specific event. Fact tables generally consist of numeric values, and foreign keys to dimensional data where descriptive information is kept. Fact tables are designed to a low level of uniform detail (referred to as "granularity" or "grain"), meaning facts can record events at a very atomic level. This can result in the accumulation of a large number of records in a fact table over time. Fact tables are defined as one of three types:

- Transaction fact tables record facts about a specific event (e.g., sales events)
- Snapshot fact tables record facts at a given point in time (e.g., account details at month end)

- Accumulating snapshot tables record aggregate facts at a given point in time (e.g., total month-to-date sales for a product)

Fact tables are generally assigned a surrogate key to ensure each row can be uniquely identified.

Dimension tables

Dimension tables usually have a relatively small number of records compared to fact tables, but each record may have a very large number of attributes to describe the fact data. Dimensions can define a wide variety of characteristics, but some of the most common attributes defined by dimension tables include:

- Time dimension tables describe time at the lowest level of time granularity for which events are recorded in the star schema
- Geography dimension tables describe location data, such as country, state, or city
- Product dimension tables describe products
- Employee dimension tables describe employees, such as sales people
- Range dimension tables describe ranges of time, dollar values, or other measurable quantities to simplify reporting

Dimension tables are generally assigned a surrogate primary key, usually a single-column integer data type, mapped to the combination of dimension attributes that form the natural key.

Benefits

Star schemas are denormalized, meaning the normal rules of normalization applied to transactional relational databases are relaxed during star schema design and implementation. The benefits of star schema denormalization are:

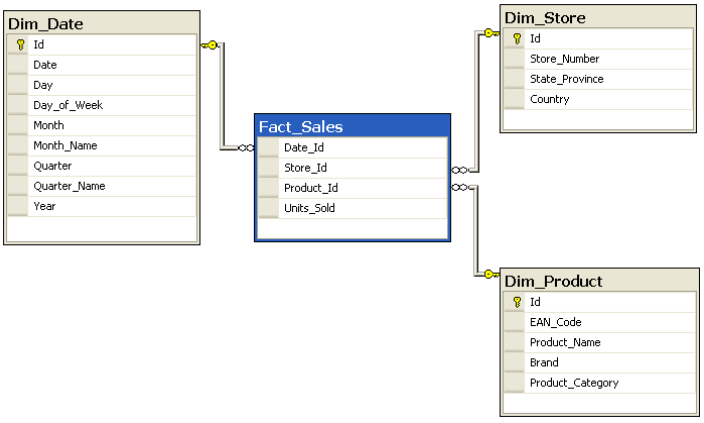
- Simpler queries - star schema join logic is generally simpler than the join logic required to retrieve data from a highly normalized transactional schemas.
- Simplified business reporting logic - when compared to highly normalized schemas, the star schema simplifies common business reporting logic, such as period-over-period and as-of reporting.
- Query performance gains - star schemas can provide performance enhancements for read-only reporting applications when compared to highly normalized schemas.
- Fast aggregations - the simpler queries against a star schema can result in improved performance for aggregation operations.
- Feeding cubes - star schemas are used by all OLAP systems to build proprietary OLAP cubes efficiently; in fact, most major OLAP systems provide a ROLAP mode of operation which can use a star schema directly as a source without building a proprietary cube structure.

Disadvantages

The main disadvantage of the star schema is that data integrity is not enforced as well as it is in a highly normalized database. One-off inserts and updates can result in data anomalies which normalized schemas are designed to avoid. Generally speaking, star schemas are loaded in a highly controlled fashion via batch processing or near-real time "trickle feeds", to compensate for the lack of protection afforded by normalization.

Example

Consider a database of sales, perhaps from a store chain, classified by date, store and product. The image of the schema to the right is a star schema version of the sample schema provided in the snowflake schema article.



Star schema used by example query.

`Fact_Sales` is the fact table and there are three dimension tables `Dim_Date`, `Dim_Store` and `Dim_Product`.

Each dimension table has a primary key on its `Id` column, relating to one of the columns (viewed as rows in the example schema) of the `Fact_Sales` table's three-column (compound) primary key (`Date_Id`, `Store_Id`, `Product_Id`). The non-primary key `Units_Sold` column of the fact table in this example represents a measure or metric that can be used in calculations and analysis. The non-primary key columns of the dimension tables represent additional attributes of the dimensions (such as the `Year` of the `Dim_Date` dimension).

For example, the following query answers how many TV sets have been sold, for each brand and country, in 1997:

```
SELECT
      P.Brand,
      S.Country as Countries,
      SUM(F.Units_Sold)
FROM Fact_Sales F
INNER JOIN Dim_Date D    ON F.Date_Id = D.Id
INNER JOIN Dim_Store S   ON F.Store_Id = S.Id
INNER JOIN Dim_Product P ON F.Product_Id = P.Id
WHERE
      D.Year = 1997
AND P.Product_Category = 'tv'
GROUP BY
      P.Brand,
      S.Country
```

Dimension table

In data warehousing, a **dimension table** is one of the set of companion tables to a fact table.

The fact table contains business facts (or *measures*), and foreign keys which refer to candidate keys (normally primary keys) in the dimension tables.

Contrary to *fact* tables, *dimension* tables contain descriptive attributes (or fields) that are typically textual fields (or discrete numbers that behave like text). These attributes are designed to serve two critical purposes: query constraining and/or filtering, and query result set labeling.

Dimension attributes should be:

- Verbose (labels consisting of full words)
- Descriptive
- Complete (having no missing values)
- Discretely valued (having only one value per dimension table row)
- Quality assured (having no misspellings or impossible values)

Dimension table rows are uniquely identified by a single key field. It is recommended that the key field be a simple integer because a key value is meaningless, used only for joining fields between the fact and dimension tables.

The use of surrogate dimension keys brings several advantages, including:

- Performance. Join processing is made much more efficient by using a single field (the surrogate key)
- Buffering from operational key management practices. This prevents situations where removed data rows might reappear when their natural keys get reused or reassigned after a long period of dormancy
- Mapping to integrate disparate sources
- Handling unknown or not-applicable connections
- Tracking changes in dimension attribute values

Although surrogate key use places a burden put on the ETL system, pipeline processing can be improved, and ETL tools have built-in improved surrogate key processing.

The goal of a dimension table is to create standardized, conformed dimensions that can be shared across the enterprise's data warehouse environment, and enable joining to multiple fact tables representing various business processes.

Conformed dimensions are important to the enterprise nature of DW/BI systems because they promote:

- Consistency. Every fact table is filtered consistently, so that query answers are labeled consistently.

- Integration. Queries can drill into different process fact tables separately for each individual fact table, then join the results on common dimension attributes.
- Reduced development time to market. The common dimensions are available without recreating them.

Over time, the attributes of a given row in a dimension table may change. For example, the shipping address for a company may change. Kimball refers to this phenomenon as Slowly Changing Dimensions. Strategies for dealing with this kind of change are divided into three categories:

- Type One. Simply overwrite the old value(s).
- Type Two. Add a new row containing the new value(s), and distinguish between the rows using Tuple-versioning techniques.
- Type Three. Add a new attribute to the existing row.

Dimensional Fact Model

The *Dimensional Fact Model* (DFM) is an ad hoc formalism specifically devised to support the conceptual modeling phase in a DW project.

Data Warehouses (DWs) are databases used by decision makers to analyze the status and the development of an organization. DWs are based on large amounts of data integrated from heterogeneous sources into multidimensional databases, and they are optimized for accessing data in a way that comes natural to human analysts (e.g., OLAP applications).

Data in a DW are organized according to the multidimensional model, that hinges on the concepts of fact (a focus of interest for the decision-making process, such as sales and orders) and dimension (a coordinate for analyzing a fact, such as time, customer, and product). Each fact is quantified through a set of numerical measures, such as the quantity of product sold, the price of products, etc.

DW design and development require ad hoc methodologies and an appropriate life-cycle.[][1][2]

Overview

The DFM is a graphical conceptual model, specifically devised for multidimensional design, in order to:

- lend effective support to conceptual design
- create an environment in which user queries may be formulated intuitively
- make communication possible between designers and end users with the goal of formalizing requirement specifications
- build a stable platform for logical design
- provide clear and expressive design documentation.

The conceptual representation generated by the DFM consists of a set of fact schemata. Fact schemata model facts, measures, dimensions, and hierarchies (see Figure 1). Besides these basic elements, the DFM includes a large set of constructs for expressing the multitude of conceptual nuances that characterize actual modeling scenarios in projects of small to large complexity. A multidimensional schema modeled with the DFM can easily (i.e., semi-automatically) be implemented on both ROLAP and MOLAP platforms.

Basic concepts

A *fact* is a concept relevant to decision-making processes. It typically models a set of events taking place within a company. Examples of facts in the commercial domain are sales, shipments, purchases, and complaints.

A *measure* is a numerical property of a fact and describes a quantitative attribute that is relevant to analysis. For example, each sale is measured by the number of units sold, the unit price, and the total receipts.

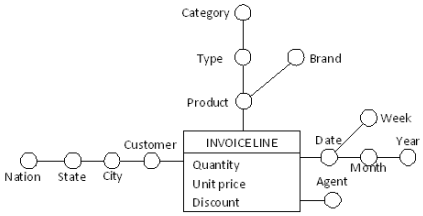

Figure 1: a simple fact schema for the invoice fact

A *dimension* is a property, with a finite domain, that describes an analysis coordinate of the fact. A fact generally has multiple dimensions that define its minimum representation granularity. Typical dimensions for the sales fact are products, stores, and dates; in which case, the basic information that can be represented is product sales in one store in one day.

A *fact* is represented by a box that displays the fact name along with the measure names. Small circles represent the dimensions, which are linked to the fact by straight lines (see Figure 1).

A *dimensional attribute* is a property, with a finite domain, of a dimension. Like dimensions, a dimensional attribute is represented by a circle. For instance, a product may be described by its type, category, and brand; a customer may be represented by city and nation. The relationships among the dimensional attributes are expressed by hierarchies.

A *hierarchy* is a directed tree whose nodes are dimensional attributes and whose arcs model many-to-one associations between dimensional attribute pairs. A hierarchy includes a dimension, positioned at the tree's root, and all of the dimensional attributes that describe it. Arcs are graphically represented by straight lines that connect dimensional attributes. Hierarchies define the way elemental business events can be selected and aggregated for decision-making processes.

Advanced concepts

A *descriptive attribute* specifies a property of a dimension attribute, to which it is related by a x-to-one association. Descriptive attributes cannot be used for aggregation; they are always leaves of a hierarchy and are graphically represented by horizontal lines, like Telephone number in Figure 2.

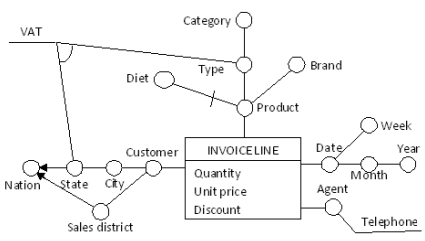

Figure 2: a more complex fact schema for the invoice fact

A *cross-dimensional attribute* is a dimensional or descriptive attribute whose value is defined by the combination of two or more dimensional attributes, possibly belonging to different hierarchies. For example, if a product value added tax (VAT) depends both on the product category and on the country where the product is sold, you can use a cross-dimensional attribute to represent it. Figure 2 shows this example by joining the arcs that define a product VAT with a circular arc.

A *convergence* takes place when two dimensional attributes within a hierarchy are connected by two or more alternative paths of many-to-one associations. Convergences are represented by letting two or more arcs reach the same dimensional attribute. For instance, in Figure 2 the geographic hierarchy on the customer dimension contains a convergence if we assume that, though no inclusion relationships exists between districts and cities/states, sales districts never cross the nation boundaries. In this case, each customer belongs to exactly one nation whichever of the two paths is followed.

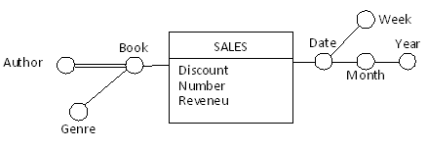

Figure 3: a fact schema for the book sales fact

Optional arcs are used to model scenarios for which an association represented in a fact schema is not defined for a subset of events. Optional arcs are marked with a dash. For instance, attribute *diet* in Figure 2 takes a value (such as cholesterol-free, gluten-free, or sugar-free) only for food products; for the other products, it is undefined.

A *multiple arc* models a many-to-many association between the two dimensional attributes it connects. Graphically, it is denoted by doubling the line that represents the arc. Consider the fact schema modeling the sales of books, represented in Figure 3, whose dimensions are date and book. It would certainly be interesting to aggregate and select sales on the basis of book authors. However, it would not be accurate to model author as a dimensional child attribute of book because a book may have more than one author, and authors can write more than one book. Hence, the relationship between books and authors is modeled as a multiple arc.

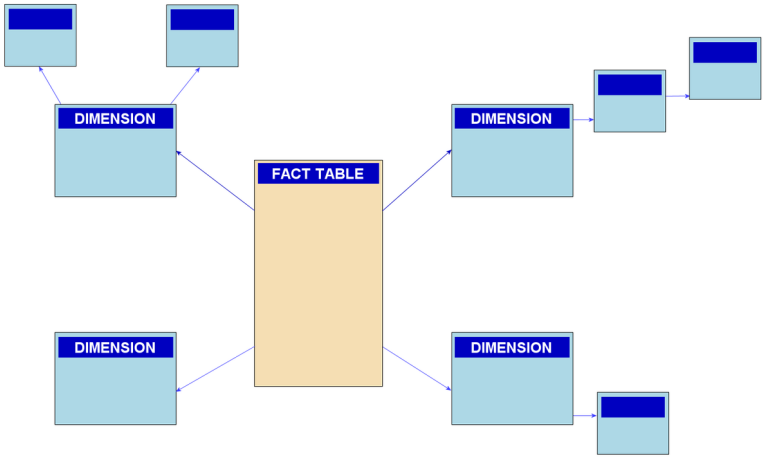
Snowflake schema

In computing, a **snowflake schema** is a logical arrangement of tables in a multidimensional database such that the entity relationship diagram resembles a snowflake shape. The snowflake schema is represented by centralized fact tables which are connected to multiple dimensions.[*citation needed*]. "Snowflaking" is a method of normalising the dimension tables in a star schema. When it is completely normalised along all the dimension tables, the resultant structure resembles a snowflake with the fact table in the middle. The principle behind snowflaking is normalisation of the dimension tables by removing low cardinality attributes and forming separate tables.[1]



The snowflake schema is a variation of the star schema, featuring normalization of dimension tables.

The snowflake schema is similar to the star schema. However, in the snowflake schema, dimensions are normalized into multiple related tables, whereas the star schema's dimensions are denormalized with each dimension represented by a single table. A complex snowflake shape emerges when the dimensions of a snowflake schema are elaborate, having multiple levels of relationships, and the child tables have multiple parent tables ("forks in the road").

Common uses

Star and snowflake schemas are most commonly found in dimensional data warehouses and data marts where speed of data retrieval is more important than the efficiency of data manipulations. As such, the tables in these schemas are not normalized much, and are frequently designed at a level of normalization short of third normal form.[*citation needed*]

Deciding whether to employ a star schema or a snowflake schema should involve considering the relative strengths of the database platform in question and the query tool to be employed. Star schemas should be favored with query tools that largely expose users to the underlying table structures, and in environments where most queries are simpler in nature. Snowflake schemas are often better with more sophisticated query tools that create a layer of abstraction between the users and raw table structures for environments having numerous queries with complex criteria.[*citation needed*]

Data normalization and storage

Normalization splits up data to avoid redundancy (duplication) by moving commonly repeating groups of data into new tables. Normalization therefore tends to increase the number of tables that need to be joined in order to perform a given query, but reduces the space required to hold the data and the number of places where it needs to be updated if the data changes.[*citation needed*]

From a space storage point of view, the dimensional tables are typically small compared to the fact tables. This often removes the storage space benefit of snowflaking the dimension tables, as compared with a star schema.[*citation needed*]

Some database developers compromise by creating an underlying snowflake schema with views built on top of it that perform many of the necessary joins to simulate a star schema. This provides the storage benefits achieved through the normalization of dimensions with the ease of querying that the star schema provides. The tradeoff is that requiring the server to perform the underlying joins automatically can result in a performance hit when querying as well as extra joins to tables that may not be necessary to fulfill certain queries.[*citation needed*]

Benefits

The snowflake schema is in the same family as the star schema logical model. In fact, the star schema is considered a special case of the snowflake schema. The snowflake schema provides some advantages over the star schema in certain situations, including:

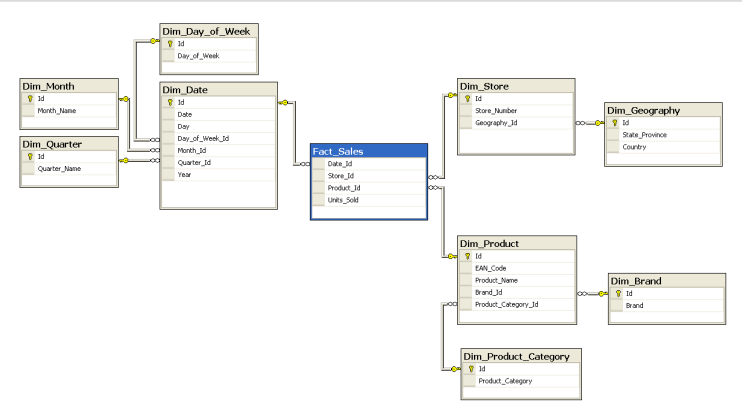
- Some OLAP multidimensional database modeling tools are optimized for snowflake schemas.
- Normalizing attributes results in storage savings, the tradeoff being additional complexity in source query joins.

Disadvantages

The primary disadvantage of the snowflake schema is that the additional levels of attribute normalization adds complexity to source query joins, when compared to the star schema. When compared to a highly normalized transactional schema, the snowflake schema's denormalization removes the data integrity assurances provided by normalized schemas. Data loads into the snowflake schema must be highly controlled and managed to avoid update and insert anomalies.

Examples

The example schema shown to the right is a snowflaked version of the star schema example provided in the star schema article.[*citation needed*]



Snowflake schema used by example query.

The following example query is the snowflake schema equivalent of the star schema example code which returns the total number of units sold by brand and by country for 1997. Notice that the snowflake schema query requires many more joins than the star schema version in order to fulfill even a simple query. The benefit of using the snowflake schema in this example is that the storage requirements are lower since the snowflake schema eliminates many duplicate values from the dimensions themselves.[*citation needed*]

```
SELECT
      B.Brand,
      G.Country,
      SUM(F.Units_Sold)
FROM Fact_Sales F
INNER JOIN Dim_Date D             ON F.Date_Id = D.Id
INNER JOIN Dim_Store S            ON F.Store_Id = S.Id
INNER JOIN Dim_Geography G        ON S.Geography_Id = G.Id
INNER JOIN Dim_Product P          ON F.Product_Id = P.Id
INNER JOIN Dim_Brand B            ON P.Brand_Id = B.Id
INNER JOIN Dim_Product_Category C ON P.Product_Category_Id = C.Id
WHERE
      D.Year = 1997 AND
      C.Product_Category = 'tv'
GROUP BY
      B.Brand,
      G.Country
```

Denormalization

In computing, **denormalization** is the process of attempting to optimize the read performance of a database by adding redundant data or by grouping data.[1][2] In some cases, denormalization is a means of addressing performance or scalability in relational database software.

A normalized design will often store different but related pieces of information in separate logical tables (called relations). If these relations are stored physically as separate disk files, completing a database query that draws information from several relations (a *join operation*) can be slow. If many relations are joined, it may be prohibitively slow. There are two strategies for dealing with this. The preferred method is to keep the logical design normalized, but allow the database management system (DBMS) to store additional redundant information on disk to optimise query response. In this case it is the DBMS software's responsibility to ensure that any redundant copies are kept consistent. This method is often implemented in SQL as indexed views (Microsoft SQL Server) or materialised views (Oracle). A view represents information in a format convenient for querying, and the index ensures that queries against the view are optimised.

The more usual approach is to denormalize the logical data design. With care this can achieve a similar improvement in query response, but at a cost—it is now the database designer's responsibility to ensure that the denormalized database does not become inconsistent. This is done by creating rules in the database called *constraints*, that specify how the redundant copies of information must be kept synchronised. It is the increase in logical complexity of the database design and the added complexity of the additional constraints that make this approach hazardous. Moreover, constraints introduce a trade-off, speeding up reads (`SELECT` in SQL) while slowing down writes (`INSERT`, `UPDATE`, and `DELETE`). This means a denormalized database under heavy write load may actually offer *worse* performance than its functionally equivalent normalized counterpart.

A denormalized data model is not the same as a data model that has not been normalized, and denormalization should only take place after a satisfactory level of normalization has taken place and that any required constraints and/or rules have been created to deal with the inherent anomalies in the design. For example, all the relations are in third normal form and any relations with join and multi-valued dependencies are handled appropriately.

Examples of denormalization techniques include:

- Materialised views, which may implement the following:
  - Storing the count of the "many" objects in a one-to-many relationship as an attribute of the "one" relation
  - Adding attributes to a relation from another relation with which it will be joined

- Star schemas, which are also known as fact-dimension models and have been extended to snowflake schemas
- Prebuilt summarisation or OLAP cubes

Denormalization techniques are often used to improve the scalability of Web applications.[3]

Single version of the truth

In computerized business management, **SVOT**, or **Single Version of the Truth**, is a technical concept describing the data warehousing ideal of having either a single centralised database, or at least a distributed synchronised database, which stores all of an organisation's data in a consistent and non-redundant form. This contrasts with the related concept of Single Source of Truth (SSOT), which refers to is a data storage principle to always source a particular piece of information from one place.[*citation needed*]

SVOT applied to message sequencing

In some systems and in the context of message processing systems (often realtime systems), this term also refers to the goal of establishing a single agreed sequence of messages within a database formed by a particular but arbitrary sequencing of records. The key concept is that data combined in a certain sequence is a "truth" which may be analyzed and processed giving particular results, and that although the sequence is arbitrary (and thus another correct but equally arbitrary sequencing would ultimately provide different results in any analysis), it is desirable to agree that the sequence enshrined in the "single version of the truth" is the version that will be considered "the truth", and that any conclusions drawn from analysis of the database are valid and unarguable, and (in a technical context) the database may be duplicated to a backup environment to ensure a persistent record is kept of the "single version of the truth".

The key point is when the database is created using an external data source (such as a sequence of trading messages from a stock exchange) an arbitrary selection is made of one possibility from two or more equally valid representations of the input data, but henceforth the decision sets "in stone" one and only one version of the truth.

Critique of SVOT as applied to message sequencing

Critics of "SVOT as applied to message sequencing" argue that this concept is not scalable. As the world moves towards systems spread over many processing nodes, the effort involved in negotiating a single agreed-upon sequence becomes prohibitive.

Transaction data

Transaction data are data describing an event (the change as a result of a transaction) and is usually described with verbs. Transaction data always has a time dimension, a numerical value and refers to one or more objects (i.e. the reference data).

Typical transactions are:

- Financial: orders, invoices, payments
- Work: Plans, activity records
- Logistics: Deliveries, storage records, travel records, etc.

Typical transaction processing systems (systems generating transactions) are SAP and Oracle Financials.

Records management

Recording and retaining transactions is called records management. The record of the transaction is stored in a place where the retention can be guaranteed and where data are archived/removed following a retention period. The format of the transaction can be data (to be stored in a database), but it can also be a document.

Data Warehousing

Transaction data can be summarised in a Data warehouse, which helps accessibility and analysis of the data.

Enterprise bus matrix

The *'Enterprise Bus Matrix* is a Data Warehouse planning tool and model created by Ralph Kimball, and is part of the Data Warehouse Bus Architecture. The Matrix is the logical definition of one of the core concepts of Kimball's approach to Dimensional Modeling – Conformed dimensions.[1]

The Bus Matrix defines part of the Data Warehouse Bus Architecture and is an output of the Business Requirements phase in The Kimball Lifecycle. It is applied in the following phases of dimensional modeling and development of the Data Warehouse . The matrix can be categorized as a hybrid model, being part technical design tool, part project management tool and part communication tool [2]

Background

The Enterprise Bus Matrix stems from the issue of how one goes about creating the overall Data Warehouse environment. Historically there has been the structure of the centralized and planned approach and the more loosely defined, department specific, solutions developed in a more independent matter. Autonomous projects can result in a range of isolated stove pipe data marts. Naturally each approach has its issues; the overall visionary approach often struggles with long delivery cycles and lack of reaction time as the formalities and scope issues is evident. On the other hand the development of isolated data marts, leading to Stovepipe systems that lacks synergy in development. Over time this approach will lead to a so-called data-mart-in-a-box architecture [3] where interoperability and lack of cohesion is apparent, and can hinder the realization of an overall enterprise Data Warehouse. As an attempt to handle this matter Ralph Kimball introduced the enterprise bus.

The Bus Matrix

In short words the bus matrix purpose is one of high abstraction and visionary planning on the Data Warehouse architectural level. By dictating coherency in the development and implementation of an overall Data Warehouse the Bus Architecture approach enables an overall vision of the broader enterprise integration and consistency while at the same time dividing the problem into more manageable parts – all in a technology and software independent manner .[4]

The bus matrix and architecture builds upon the concept of conformed dimensions - creating a structure of common dimensions that ideally can be used across the enterprise by all business processes related to the DW and the corresponding fact tables from which they derive their context. According to Kimball and Marg Rosses article "Differences of Opinion" [5] "*The Enterprise Data warehouse built on the bus architecture "identifies and enforces the relationship between business process metrics (facts) and descriptive attributes (dimensions)*".

The concept of a bus[6] is well known in the language of Information Technology, and is what reflects the conformed dimension concept in the Data Warehouse, creating the skeletal structure where all parts of a system connect, ensuring interoperability and consistency of data, and at the same time considers future expansion. This makes the conformed dimensions act as the integration 'glue', creating a robust backbone of the enterprise Data Warehouse.[7]

Establishment and applicability

Figure 1[8] shows the base for a single document planning tool for the whole of the DW implementation - a graphical overview of the enterprises core business processes or events each correspond to a measurement table of facts, that typically is complemented by a major source system in the horizontal rows. In the vertical columns the groups of contextual data is found as the common, conformed dimensions.

In this way the shared dimensions are defined, as each process indicates what dimensions it applies to through the cells figure 2. By this definition and coordination of conformed dimensions and processes the development of the overall data DW bus architecture is realized. The matrix identifies the shared dimensions related to processes and fact tables, and can be a tool for planning, prioritizing what needs to be approached, coordinating implementation and communicating the importance for conformed dimensions .

Kimball extends the matrix bus in detail as seen in figure 3 by introducing the other steps of the Datawarehouse Methodology; The Fact tables, Granularity, and at last the description of the needed facts. description of the fact tables, granularity and fact instances of each process, structuring and specifying what is needed across the enterprise in a more specific matter, further exemplifying how the matrix can be used as a planning too.

OLAP

Statistical database

A **statistical database** is a database used for statistical analysis purposes. It is an OLAP (online analytical processing), instead of OLTP (online transaction processing) system. Modern decision, and classical statistical databases are often closer to the relational model than the multidimensional model commonly used in OLAP systems today.

Statistical databases typically contain parameter data and the measured data for these parameters. For example, parameter data consists of the different values for varying conditions in an experiment (e.g., temperature, time). The measured data (or variables) are the measurements taken in the experiment under these varying conditions.

Many statistical databases are sparse with many null or zero values. It is not uncommon for a statistical database to be 40% to 50% sparse. There are two options for dealing with the sparseness: (1) leave the null values in there and use compression techniques to squeeze them out or (2) remove the entries that only have null values.

Statistical databases often incorporate support for advanced statistical analysis techniques, such as correlations, which go beyond SQL. They also pose unique security concerns, which were the focus of much research, particularly in the late 1970s and early to mid-1980s.

Security in statistical databases

In a statistical database, it is often desired to allow query access only to aggregate data, not individual records. Securing such a database is a difficult problem, since intelligent users can use a combination of aggregate queries to derive information about a single individual.

Some common approaches are:

- only allowing aggregate queries (SUM, COUNT, AVG, STDEV, etc.)
- rather than returning exact values for sensitive data like income, only return which partition it belongs to (e.g. 35k-40k)
- return imprecise counts (e.g. rather than 141 records met query, only indicate 130-150 records met it.)
- don't allow overly selective WHERE clauses
- audit all users queries, so users using system incorrectly can be investigated
- use intelligent agents to detect automatically inappropriate system use

Research in this area has largely stalled; reference 3 below showed that, in general, securing statistical databases was an impossible aim: if they were open to legitimate use, they were also open to abuse; and if they were restricted so tightly as to be incapable of abuse, they would then be useless for practical statistical purposes. To quote:

> The conclusion is that statistical databases are almost always subject to compromise. Severe restrictions on allowable query set sizes will render the database useless as a source of statistical information but will not secure the confidential records.[1]

Online transaction processing

Online transaction processing, or **OLTP**, is a class of information systems that facilitate and manage transaction-oriented applications, typically for data entry and retrieval transaction processing. The term is somewhat ambiguous; some understand a "transaction" in the context of computer or database transactions, while others (such as the Transaction Processing Performance Council) define it in terms of business or commercial transactions.[1] OLTP has also been used to refer to processing in which the system responds immediately to user requests. An automated teller machine (ATM) for a bank is an example of a commercial transaction processing application.

Requirements

Online transaction processing increasingly requires support for transactions that span a network and may include more than one company. For this reason, new online transaction processing software uses client or server processing and brokering software that allows transactions to run on different computer platforms in a network.

In large applications, efficient OLTP may depend on sophisticated transaction management software (such as CICS) and/or database optimization tactics to facilitate the processing of large numbers of concurrent updates to an OLTP-oriented database.

For even more demanding decentralized database systems, OLTP brokering programs can distribute transaction processing among multiple computers on a network. OLTP is often integrated into service-oriented architecture (SOA) and Web services.

Online Transaction Processing (OLTP) involves gathering input information, processing the information and updating existing information to reflect the gathered and processed information. As of today, most organizations use a database management system to support OLTP. OLTP is carried in a client server system.

Benefits

Online Transaction Processing has two key benefits: simplicity and efficiency. Reduced paper trails and the faster, more accurate forecasts for revenues and expenses are both examples of how OLTP makes things simpler for businesses.

Disadvantages

Additionally, like many modern online information technology solutions, some systems require offline maintenance which further affects the cost-benefit analysis.

Operational system

An **operational system** is a term used in data warehousing to refer to a system that is used to process the day-to-day transactions of an organization. These systems are designed in a manner that processing of day-to-day transactions is performed efficiently and the integrity of the transactional data is preserved.

Synonyms

Sometimes operational systems are referred to as operational databases, transaction processing systems, or online transaction processing systems (OLTP). However, the use of the last two terms as synonyms may be confusing, because operational systems can be batch processing systems as well.

Any Enterprise must necessarily maintain a lot of data about its operation. This is its "Operational Data".

Organization	Probably
Manufacturing Company	Product data
Bank	Account Data
Hospital	Patient Data
University	Student Data
Government Department	Planning data

Operational data store

An **operational data store** (or "**ODS**") is a database designed to integrate data from multiple sources for additional operations on the data. The data is then passed back to operational systems for further operations and to the data warehouse for reporting.

Because the data originates from multiple sources, the integration often involves cleaning, resolving redundancy and checking against business rules for integrity. An ODS is usually designed to contain low-level or atomic (indivisible) data (such as transactions and prices) with limited history that is captured "real time" or "near real time" as opposed to the much greater volumes of data stored in the data warehouse generally on a less-frequent basis.

General Use

The general purpose of an ODS is to integrate data from disparate source systems in a single structure, using data integration technologies like data virtualization, data federation, or extract, transform, and load. This will allow operational access to the data for operational reporting, master data or reference data management.

An ODS is not a replacement or substitute for a data warehouse but in turn could become a source.

Operational database

An **operational database** stores information about the activities of an organization, for example customer relationship management transactions, in a computer database. Operational databases can be known as **production database**, especially when distinguishing from a "test database" or "development database" used by programmers.

Use in business

Operational databases allow a business to enter, gather, and retrieve large quantities of specific information, such as training status, personal employee information, sales, customer complaints, and previous proposal information. Storing information in a centralized area can increase retrieval time for users. An important feature of storing information in an operational database is the ability to share information across the company. Operational databases can be used to monitor activities, to audit suspicious transactions, or to review the history of dealings with a particular customer. They can also be part of the actual process of making and fulfilling a purchase, for example in e-commerce.

Data warehouse terminology

In data warehousing, the term is even more specific: the operational database is the one which is accessed by an operational system (for example a customer-facing website or the application used by the customer service department) to carry out regular operations of an organization. Operational databases usually use an online transaction processing database which is optimized for faster transaction processing (create, read, update and delete operations).

The contents of the data warehouse are deleted from the operational database, but not necessarily updated in real time (if the machines are separate). Data warehouses tend to be optimized for faster read-only queries as an online analytical processing database to be used for back-office applications like business intelligence.

Online analytical processing

In computing, **online analytical processing**, or **OLAP** /ˈoʊlæp/, is an approach to answering multi-dimensional analytical (MDA) queries swiftly. OLAP is part of the broader category of business intelligence, which also encompasses relational database, report writing and data mining. Typical applications of OLAP include business reporting for sales, marketing, management reporting, business process management (BPM), budgeting and forecasting, financial reporting and similar areas, with new applications coming up, such as agriculture. The term *OLAP* was created as a slight modification of the traditional database term OLTP (Online Transaction Processing).

OLAP tools enable users to analyze multidimensional data interactively from multiple perspectives. OLAP consists of three basic analytical operations: consolidation (roll-up), drill-down, and slicing and dicing.[1] Consolidation involves the aggregation of data that can be accumulated and computed in one or more dimensions. For example, all sales offices are rolled up to the sales department or sales division to anticipate sales trends. By contrast, the drill-down is a technique that allows users to navigate through the details. For instance, users can view the sales by individual products that make up a region's sales. Slicing and dicing is a feature whereby users can take out (slicing) a specific set of data of the OLAP cube and view (dicing) the slices from different viewpoints.

Databases configured for OLAP use a multidimensional data model, allowing for complex analytical and ad hoc queries with a rapid execution time. They borrow aspects of navigational databases, hierarchical databases and relational databases.

Overview of OLAP systems

The core of any OLAP system is an OLAP cube (also called a 'multidimensional cube' or a hypercube). It consists of numeric facts called *measures* which are categorized by *dimensions*. The measures are placed at the intersections of the hypercube, which is spanned by the dimensions as a Vector space. The usual interface to manipulate an OLAP cube is a matrix interface like Pivot tables in a spreadsheet program, which performs projection operations along the dimensions, such as aggregation or averaging.

The cube metadata is typically created from a star schema or snowflake schema or fact constellation of tables in a relational database. Measures are derived from the records in the fact table and dimensions are derived from the dimension tables.

Each *measure* can be thought of as having a set of *labels*, or meta-data associated with it. A *dimension* is what describes these *labels*; it provides information about the *measure*.

A simple example would be a cube that contains a store's sales as a *measure*, and Date/Time as a *dimension*. Each Sale has a Date/Time *label* that describes more about that sale.

Any number of *dimensions* can be added to the structure such as Store, Cashier, or Customer by adding a foreign key column to the fact table. This allows an analyst to view the *measures* along any combination of the *dimensions*.

For example:

```
 Sales Fact Table
+-------------+----------+
| sale_amount | time_id  |
+-------------+----------+            Time Dimension
|      2008.10|     1234 |---+     +---------+-------------------+
+-------------+----------+   |     | time_id | timestamp         |
                             |     +---------+-------------------+
                             +---->|   1234  | 20080902 12:35:43 |
                                   +---------+-------------------+
```

Multidimensional databases

Multidimensional structure is defined as “a variation of the relational model that uses multidimensional structures to organize data and express the relationships between data”.[2] The structure is broken into cubes and the cubes are able to store and access data within the confines of each cube. “Each cell within a multidimensional structure contains aggregated data related to elements along each of its dimensions”.[3] Even when data is manipulated it remains easy to access and continues to constitute a compact database format. The data still remains interrelated. Multidimensional structure is quite popular for analytical databases that use online analytical processing (OLAP) applications.[4] Analytical databases use these databases because of their ability to deliver answers to complex business queries swiftly. Data can be viewed from different angles, which gives a broader perspective of a problem unlike other models.[5]

Aggregations

It has been claimed that for complex queries OLAP cubes can produce an answer in around 0.1% of the time required for the same query on OLTP relational data. The most important mechanism in OLAP which allows it to achieve such performance is the use of *aggregations*. Aggregations are built from the fact table by changing the granularity on specific dimensions and aggregating up data along these dimensions. The number of possible aggregations is determined by every possible combination of dimension granularities.

The combination of all possible aggregations and the base data contains the answers to every query which can be answered from the data.

Because usually there are many aggregations that can be calculated, often only a predetermined number are fully calculated; the remainder are solved on demand. The problem of deciding which aggregations (views) to calculate is known as the view selection problem. View selection can be constrained by the total size of the selected set of aggregations, the time to update them from changes in the base data, or both. The objective of view selection is typically to minimize the average time to answer OLAP queries, although some studies also minimize the update time. View selection is NP-Complete. Many approaches to the problem have been explored, including greedy algorithms, randomized search, genetic algorithms and A* search algorithm.

Types

OLAP systems have been traditionally categorized using the following taxonomy.

Multidimensional

MOLAP is a "multi-dimensional online analytical processing". 'MOLAP' is the 'classic' form of OLAP and is sometimes referred to as just OLAP. MOLAP stores this data in an optimized multi-dimensional array storage, rather than in a relational database. Therefore it requires the pre-computation and storage of information in the cube - the operation known as processing. MOLAP tools generally utilize a pre-calculated data set referred to as a data cube. The data cube contains all the possible answers to a given range of questions. MOLAP tools have a very fast response time and the ability to quickly write back data into the data set.

Advantages of MOLAP

- Fast query performance due to optimized storage, multidimensional indexing and caching.
- Smaller on-disk size of data compared to data stored in relational database due to compression techniques.
- Automated computation of higher level aggregates of the data.
- It is very compact for low dimension data sets.
- Array models provide natural indexing.
- Effective data extraction achieved through the pre-structuring of aggregated data.

Disadvantages of MOLAP

- Within some MOLAP Solutions the processing step (data load) can be quite lengthy, especially on large data volumes. This is usually remedied by doing only incremental processing, i.e., processing only the data which have changed (usually new data) instead of reprocessing the entire data set.
- MOLAP tools traditionally have difficulty querying models with dimensions with very high cardinality (i.e., millions of members).
- Some MOLAP products have difficulty updating and querying models with more than ten dimensions. This limit differs depending on the complexity and cardinality of the dimensions in question. It also depends on the number of facts or measures stored. Other MOLAP products can handle hundreds of dimensions.
- Some MOLAP methodologies introduce data redundancy.

Relational

ROLAP works directly with relational databases. The base data and the dimension tables are stored as relational tables and new tables are created to hold the aggregated information. Depends on a specialized schema design. This methodology relies on manipulating the data stored in the relational database to give the appearance of traditional OLAP's slicing and dicing functionality. In essence, each action of slicing and dicing is equivalent to adding a "WHERE" clause in the SQL statement. ROLAP tools do not use pre-calculated data cubes but instead pose the query to the standard relational database and its tables in order to bring back the data required to answer the question. ROLAP tools feature the ability to ask any question because the methodology does not limit to the contents of a cube. ROLAP also has the ability to drill down to the lowest level of detail in the database.

Hybrid

There is no clear agreement across the industry as to what constitutes "Hybrid OLAP", except that a database will divide data between relational and specialized storage. For example, for some vendors, a HOLAP database will use relational tables to hold the larger quantities of detailed data, and use specialized storage for at least some aspects of the smaller quantities of more-aggregate or less-detailed data. HOLAP addresses the shortcomings of MOLAP and ROLAP by combining the capabilities of both approaches. HOLAP tools can utilize both pre-calculated cubes and relational data sources.

Comparison

Each type has certain benefits, although there is disagreement about the specifics of the benefits between providers.

- Some MOLAP implementations are prone to database explosion, a phenomenon causing vast amounts of storage space to be used by MOLAP databases when certain common conditions are met: high number of dimensions, pre-calculated results and sparse multidimensional data.
- MOLAP generally delivers better performance due to specialized indexing and storage optimizations. MOLAP also needs less storage space compared to ROLAP because the specialized storage typically includes compression techniques.
- ROLAP is generally more scalable. However, large volume pre-processing is difficult to implement efficiently so it is frequently skipped. ROLAP query performance can therefore suffer tremendously.
- Since ROLAP relies more on the database to perform calculations, it has more limitations in the specialized functions it can use.
- HOLAP encompasses a range of solutions that attempt to mix the best of ROLAP and MOLAP. It can generally pre-process swiftly, scale well, and offer good function support.

Other types

The following acronyms are also sometimes used, although they are not as widespread as the ones above:

- **WOLAP** - Web-based OLAP
- **DOLAP** - **Desktop** OLAP
- **RTOLAP** - Real-Time OLAP

APIs and query languages

Unlike relational databases, which had SQL as the standard query language, and widespread APIs such as ODBC, JDBC and OLEDB, there was no such unification in the OLAP world for a long time. The first real standard API was OLE DB for OLAP specification from Microsoft which appeared in 1997 and introduced the MDX query language. Several OLAP vendors - both server and client - adopted it. In 2001 Microsoft and Hyperion announced the XML for Analysis specification, which was endorsed by most of the OLAP vendors. Since this also used MDX as a query language, MDX became the de facto standard. Since September-2011 LINQ can be used to query SSAS OLAP cubes from Microsoft .NET.

Products

History

The first product that performed OLAP queries was *Express,* which was released in 1970 (and acquired by Oracle in 1995 from Information Resources). However, the term did not appear until 1993 when it was coined by Edgar F. Codd, who has been described as "the father of the relational database". Codd's paper resulted from a short consulting assignment which Codd undertook for former Arbor Software (later Hyperion Solutions, and in 2007 acquired by Oracle), as a sort of marketing coup. The company had released its own OLAP product, *Essbase*, a year earlier. As a result Codd's "twelve laws of online analytical processing" were explicit in their reference to Essbase. There was some ensuing controversy and when Computerworld learned that Codd was paid by Arbor, it retracted the article. OLAP market experienced strong growth in late 90s with dozens of commercial products going into market. In 1998, Microsoft released its first OLAP Server - Microsoft Analysis Services, which drove wide adoption of OLAP technology and moved it into mainstream.

Market structure

Below is a list of top OLAP vendors in 2006, with figures in millions of US Dollars.

Vendor	Global Revenue	Consolidated company
Microsoft Corporation	1,806	Microsoft
Hyperion Solutions Corporation	1,077	Oracle
Cognos	735	IBM
Business Objects	416	SAP
MicroStrategy	416	MicroStrategy
SAP AG	330	SAP
Cartesis (SAP)	210	SAP
Applix	205	IBM
Infor	199	Infor
Oracle Corporation	159	Oracle
Others	152	Others

Total	**5,700**

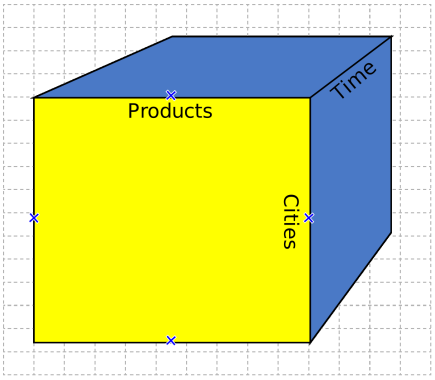
OLAP cube

An **OLAP cube** is an array of data understood in terms of its 0 or more dimensions. *OLAP* is an acronym for online analytical processing. OLAP is a computer-based technique for analyzing business data in the search for business intelligence.



An example of an OLAP cube

Terminology

A cube can be considered a generalization of a three-dimensional spreadsheet. For example, a company might wish to summarize financial data by product, by time-period, and by city to compare actual and budget expenses. Product, time, city and scenario (actual and budget) are the data's dimensions.

Cube is a shortcut for *multidimensional dataset*, given that data can have an arbitrary number of *dimensions*. The term hypercube is sometimes used, especially for data with more than three dimensions.

Each cell of the cube holds a number that represents some *measure* of the business, such as sales, profits, expenses, budget and forecast.

OLAP data is typically stored in a star schema or snowflake schema in a relational data warehouse or in a special-purpose data management system. Measures are derived from the records in the fact table and dimensions are derived from the dimension tables.

Hierarchy

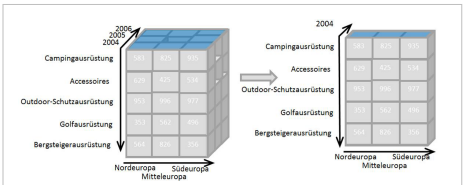
The elements of a dimension can be organized as a hierarchy, a set of parent-child relationships, typically where a parent member summarizes its children. Parent elements can further be aggregated as the children of another parent.

For example May 2005's parent is Second Quarter 2005 which is in turn the child of Year 2005. Similarly cities are the children of regions; products roll into product groups and individual expense items into types of expenditure.

Operations

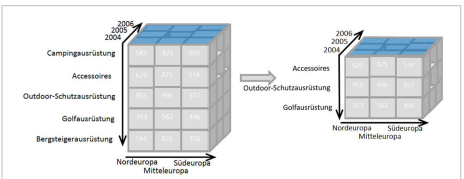
Conceiving data as a cube with hierarchical dimensions leads to conceptually straightforward operations to facilitate analysis. Aligning the data content with a familiar visualization enhances analyst learning and productivity. The user-initiated process of navigating by calling for page displays interactively, through the specification of slices via rotations and drill down/up is sometimes called "slice and dice". Common operations include slice and dice, drill down, roll up, and pivot.

Slice is the act of picking a rectangular subset of a cube by choosing a single value for one of its dimensions, creating a new cube with one fewer dimension. The picture shows a slicing operation: The sales figures of all sales regions and all product categories of the company in the year 2004 are "sliced" out of the data cube.



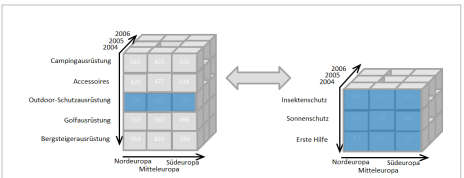
OLAP slicing

Dice: The dice operation produces a subcube by allowing the analyst to pick specific values of multiple dimensions. The picture shows a dicing operation: The new cube shows the sales figures of a limited number of product categories, the time and region dimensions cover the same range as before.



OLAP dicing

Drill Down/Up allows the user to navigate among levels of data ranging from the most summarized (up) to the most detailed (down). The picture shows a drill-down operation: The analyst moves from the summary category "Outdoor-Schutzausrüstung" to see the sales figures for the individual products.

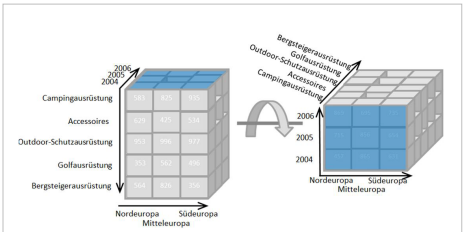


OLAP Drill-up and drill-down

Roll-up: A roll-up involves summarizing the data along a dimension. The summarization rule might be computing totals along a hierarchy or applying a set of formulas such as "profit = sales - expenses".

Pivot allows an analyst to rotate the cube in space to see its various faces. For example, cities could be arranged vertically and products horizontally while viewing data for a particular quarter. Pivoting could replace products with time periods to see data across time for a single product.

The picture shows a pivoting operation: The whole cube is rotated, giving another perspective on the data.



OLAP pivoting

Mathematical definition

In database theory, an OLAP cube is an abstract representation of a projection of an RDBMS relation. Given a relation of order N, consider a projection that subtends X, Y, and Z as the key and W as the residual attribute. Characterizing this as a function,

$$f : (X,Y,Z) \rightarrow W,$$

the attributes X, Y, and Z correspond to the axes of the cube, while the W value into which each (X, Y, Z) triple maps corresponds to the data element that populates each cell of the cube.

Insofar as two-dimensional output devices cannot readily characterize four dimensions, it is more practical to project "slices" of the data cube (we say *project* in the classic vector analytic sense of dimensional reduction, not in the SQL sense, although the two are conceptually similar),

$$g : (X,Y) \rightarrow W$$

which may suppress a primary key, but still have some semantic significance, perhaps a slice of the triadic functional representation for a given Z value of interest.

The motivation behind OLAP displays harks back to the *cross-tabbed report* paradigm of 1980s DBMS. The resulting spreadsheet-style display, where values of X populate row $1; values of Y populate column $A; and values of $g : (X, Y) \rightarrow W$ populate the individual cells "southeast of" $B2, so to speak, $B2 itself included.

Aggregate (data warehouse)

Aggregates are used in dimensional models of the data warehouse to produce dramatic positive effects on the time it takes to query large sets of data. At the simplest form an **aggregate** is a simple summary table that can be derived by performing a *Group by* SQL query. A more common use of aggregates is to take a dimension and change the granularity of this dimension. When changing the granularity of the dimension the fact table has to be partially summarized to fit the new grain of the new dimension, thus creating new dimensional and fact tables, fitting this new level of grain. Aggregates are sometimes referred to as pre-calculated summary data, since aggregations are usually precomputed, partially summarized data, that are stored in new aggregated tables. When facts are aggregated, it is either done by eliminating dimensionality or by associating the facts with a rolled up dimension. Rolled up dimensions should be shrunken versions of the dimensions associated with the granular base facts. This way, the aggregated dimension tables should conform to the base dimension tables.[1] So the reason why aggregates can make such a dramatic increase in the performance of the data warehouse is the reduction of the number of rows to be accessed when responding to a query.[2]

Ralph Kimball, who is widely regarded as one of the original architects of data warehousing, says:

> *The single most dramatic way to affect performance in a large data warehouse is to provide a proper set of aggregate (summary) records that coexist with the primary base records. Aggregates can have a very significant effect on performance, in some cases speeding queries by a factor of one hundred or even one thousand. No other means exist to harvest such spectacular gains.*

Having aggregates and atomic data increases the complexity of the dimensional model. This complexity should be transparent to the users of the data warehouse, thus when a request is made, the data warehouse should return data from the table with the correct grain. So when requests to the data warehouse are made, aggregate navigator functionality should be implemented, to help determine the correct table with the correct grain. The number of possible aggregations is determined by every possible combination of dimension granularities. Since it would produce a lot of overhead to build all possible aggregations, it is a good idea to choose a subset of tables on which to make aggregations. The best way to choose this subset and decide which aggregations to build is to monitor queries and design aggregations to match query patterns.[3]

Aggregate navigator

Having aggregate data in the dimensional model makes the environment more complex. To make this extra complexity transparent to the user, functionality known as aggregate navigation is used to query the dimensional and fact tables with the correct grain level. The aggregate navigation essentially examines the query to see if it can be answered using a smaller, aggregate table.[4]

Implementations of aggregate navigators can be found in a range of technologies:

- OLAP engines
- Materialized views
- Relational OLAP (ROLAP) services
- BI application servers or query tools

It is generally recommended to use either of the first three technologies, since the benefits in the latter case is restricted to a single front end BI tool[5]

Problems/challenges

- Since dimensional models only gains from aggregates on large data sets, at what size of the data sets should one start considering using aggregates?
- Similarly, is a data warehouses always handling data sets that are too large for direct queries, or is it sometimes a good idea to omit the aggregate tables, when starting a new data warehouse project. Thus will, omitting aggregates in the first iteration of building a new data warehouse, make the structure of the dimensional model simpler?

MOLAP

MOLAP stands for **M**ultidimensional **O**n**l**ine **A**nalytical **P**rocessing.

MOLAP is an alternative to the ROLAP (Relational OLAP) technology. While both ROLAP and MOLAP analytic tools are designed to allow analysis of data through the use of a multidimensional data model, MOLAP differs significantly in that (in some software) it requires the pre-computation and storage of information in the cube — the operation known as *processing*. Most MOLAP solutions store these data in an optimized multidimensional array storage, rather than in a relational database (i.e. in ROLAP).

There are many methodologies and algorithms for efficient data storage, aggregation and *implementation specific* business logic with a MOLAP Solution. As a result there are many misconceptions to what the term specifically implies.

MOLAP vs. ROLAP

Advantages of MOLAP

- Fast query performance due to optimized storage, multidimensional indexing and caching.
- Smaller on-disk size of data compared to data stored in relational database due to compression techniques.
- Automated computation of higher level aggregates of the data.
- It is very compact for low dimension data sets.
- Array models provide natural indexing.
- Effective data extraction achieved through the pre-structuring of aggregated data.

Disadvantages of MOLAP

- Within some MOLAP Solutions the processing step (data load) can be quite lengthy, especially on large data volumes. This is usually remedied by doing only incremental processing, i.e., processing only the data which have changed (usually new data) instead of reprocessing the entire data set.
- MOLAP tools traditionally have difficulty querying models with dimensions with very high cardinality (i.e., millions of members).
- Some MOLAP products have difficulty updating and querying models with more than ten dimensions. This limit differs depending on the complexity and cardinality of the dimensions in question. It also depends on the number of facts or measures stored. Other MOLAP products can handle hundreds of dimensions.
- Some MOLAP methodologies introduce data redundancy.

Trends

Many commercial OLAP tools now use a "Hybrid OLAP" (HOLAP) approach, which allows the model designer to decide which portion of the data will be stored in MOLAP .

Products

Examples of commercial products that use MOLAP are Cognos Powerplay, Oracle Database OLAP Option, MicroStrategy, Microsoft Analysis Services, Essbase, TM1, Board Toolkit, Lilith Hicare and Daptech Keystone. There is also an open source MOLAP server Palo.

Not all MOLAP are generic databases. Some commercial products focus on a specific business function or type, such as Oracle© RPAS (Retail Predictive Application Server)[1]

ROLAP

ROLAP stands for **R**elational **Onl**ine **A**nalytical **P**rocessing.

ROLAP is an alternative to the MOLAP (Multidimensional OLAP) technology. While both ROLAP and MOLAP analytic tools are designed to allow analysis of data through the use of a multidimensional data model, ROLAP differs significantly in that it does not require the pre-computation and storage of information. Instead, ROLAP tools access the data in a relational database and generate SQL queries to calculate information at the appropriate level when an end user requests it. With ROLAP, it is possible to create additional database tables (*summary tables* or *aggregations*) which summarize the data at any desired combination of dimensions.

While ROLAP uses a relational database source, generally the database must be carefully designed for ROLAP use. A database which was designed for OLTP will not function well as a ROLAP database. Therefore, ROLAP still involves creating an additional copy of the data. However, since it is a database, a variety of technologies can be used to populate the database.

ROLAP vs. MOLAP

The discussion of the advantages and disadvantages of ROLAP below, focus on those things that are true of the most widely used ROLAP and MOLAP tools available today. In some cases there will be tools which are exceptions to any generalization made.

Advantages of ROLAP

- ROLAP is considered to be more scalable in handling large data volumes, especially models with dimensions with very high cardinality (i.e., millions of members).
- With a variety of data loading tools available, and the ability to fine tune the ETL code to the particular data model, load times are generally much shorter than with the automated MOLAP loads.
- The data are stored in a standard relational database and can be accessed by any SQL reporting tool (the tool does not have to be an OLAP tool).
- ROLAP tools are better at handling *non-aggregatable facts* (e.g., textual descriptions). MOLAP tools tend to suffer from slow performance when querying these elements.
- By decoupling the data storage from the multi-dimensional model, it is possible to successfully model data that would not otherwise fit into a strict dimensional model.
- The ROLAP approach can leverage database authorization controls such as row-level security, whereby the query results are filtered depending on preset criteria applied, for example, to a given user or group of users (SQL WHERE clause).

Disadvantages of ROLAP

- There is a consensus in the industry that ROLAP tools have slower performance than MOLAP tools. However, see the discussion below about ROLAP performance.
- The loading of *aggregate tables* must be managed by custom ETL code. The ROLAP tools do not help with this task. This means additional development time and more code to support.
- When the step of creating aggregate tables is skipped, the query performance then suffers because the larger detailed tables must be queried. This can be partially remedied by adding additional aggregate tables, however it is still not practical to create aggregate tables for all combinations of dimensions/attributes.
- ROLAP relies on the general purpose database for querying and caching, and therefore several special techniques employed by MOLAP tools are not available (such as special hierarchical indexing). However, modern ROLAP

tools take advantage of latest improvements in SQL language such as CUBE and ROLLUP operators, DB2 Cube Views, as well as other SQL OLAP extensions. These SQL improvements can mitigate the benefits of the MOLAP tools.

- Since ROLAP tools rely on SQL for all of the computations, they are not suitable when the model is heavy on calculations which don't translate well into SQL. Examples of such models include budgeting, allocations, financial reporting and other scenarios.

Performance of ROLAP

OLAP Survey

In the OLAP industry ROLAP is usually perceived as being able to scale for large data volumes, but suffering from slower query performance as opposed to MOLAP. The OLAP Survey [1], the largest independent survey across all major OLAP products, being conducted for 6 years (2001 to 2006) have consistently found that companies using ROLAP report slower performance than those using MOLAP even when data volumes were taken into consideration.

However, as with any survey there are a number of subtle issues that must be taken into account when interpreting the results.

- The survey shows that ROLAP tools have 7 times more users than MOLAP tools within each company. Systems with more users will tend to suffer more performance problems at peak usage times.
- There is also a question about complexity of the model, measured both in number of dimensions and richness of calculations. The survey does not offer a good way to control for these variations in the data being analyzed.

Downside of flexibility

Some companies select ROLAP because they intend to re-use existing relational database tables—these tables will frequently not be optimally designed for OLAP use. The superior flexibility of ROLAP tools allows this less than optimal design to work, but performance suffers. MOLAP tools in contrast would force the data to be re-loaded into an optimal OLAP design.

Trends

The undesirable trade-off between additional ETL cost and slow query performance has ensured that most commercial OLAP tools now use a "Hybrid OLAP" (HOLAP) approach, which allows the model designer to decide which portion of the data will be stored in MOLAP and which portion in ROLAP.

Products

Examples of commercial products using ROLAP include Microsoft Analysis Services, MicroStrategy, SAP Business Objects [2], Oracle Business Intelligence Suite Enterprise Edition (the former Siebel Analytics) and Tableau Software [3]. There is also an open source ROLAP server, Mondrian. ROLAP is also a company that operates in the detection of anatocism and usury in the current accounts. Rolap website [4]

HOLAP

HOLAP (**H**ybrid **Onl**ine **A**nalytical **P**rocessing) is a combination of ROLAP (Relational OLAP) and MOLAP (Multidimensional OLAP) which are other possible implementations of OLAP. HOLAP allows storing part of the data in a MOLAP store and another part of the data in a ROLAP store, allowing a tradeoff of the advantages of each. The degree of control that the cube designer has over this partitioning varies from product to product.

Vertical partitioning

In this mode HOLAP stores *aggregations* in MOLAP for fast query performance, and detailed data in ROLAP to optimize time of cube *processing*.

Horizontal partitioning

In this mode HOLAP stores some slice of data, usually the more recent one (i.e. sliced by Time dimension) in MOLAP for fast query performance, and older data in ROLAP. Moreover, we can store some dices in MOLAP and others in ROLAP, leveraging the fact that in a large cuboid, there will be dense and sparse subregions.[1]

Products

The first product to provide HOLAP storage was Holos, but the technology also became available in other commercial products such as Microsoft Analysis Services, Oracle Database OLAP Option, MicroStrategy and SAP AG BI Accelerator. The hybrid OLAP approach combines ROLAP and MOLAP technology, benefiting from the greater scalability of ROLAP and the faster computation of MOLAP. For example, a HOLAP server may allow large volumes of detail data to be stored in a relational database, while aggregations are kept in a separate MOLAP store. The Microsoft SQL Server 7.0 OLAP Services supports a hybrid OLAP server

Thomsen Diagrams

Thomsen Diagrams are the diagrammatic methodology developed by Erik Thomsen in 1997[1] is essentially a metaphor for describing multi-dimensional data spaces in the OLAP system. In effect, it may be thought of as a multi-dimensional domain structure. In the structure, each dimension is represented by a vertical line, and hence each dimension is described independently.

Every member of a dimension is represented by a unit interval on the line. A multi-dimensional model is built by combining the resultant lines for the particular dimensions.

The Thomsen diagrammatical technique is not based on angular defined dimensions, and is thus able to represent any number of dimensions. It may be referred to as a multi-dimensional type structure[2] (MTS). The MTS permits the viewing of information about hierarchies and data flows, both within and between structures, hence enhancing the capabilities of the OLAP system.

Spreadmart

A **spreadmart** is a concept describing the tendency of spreadsheets to "run amok" in organizations. The definition of a spreadmart as used by The Data Warehousing Institute (TDWI) in a 2008 survey is:

> A spreadmart is a reporting or analysis system running on a desktop database (e.g., spreadsheet, Access database, or dashboard) that is created and maintained by an individual or group that performs all the tasks normally done by a data mart or data warehouse, such as extracting, transforming, and formatting data as well as defining metrics, submitting queries, and formatting and publishing reports to others. Also known as data shadow systems, human data warehouses, or IT shadow systems.

Note that this definition also includes situations where Business Intelligence tools are used in the manner as described above.

Critics like Stephen Samild argue that the definition stems from a biased view that sees a Data Warehouse as desirable end-result, whereas *One might more accurately define data marts and data warehouses as "scaled-up systems which perform some of the tasks normally done by a spreadmart"*.[1] In the rest of the article Stephen Samild argues that a spreadmart fulfills a number of roles that a data warehouse cannot fulfill as easily or as cheaply due to the lack of integration with unstructured data, the lack of read-write capabilities, the long time span needed for integration of new sources in the data warehouse and the inherent 'free form' of many analytical presentations done in Word, PowerPoint or Excel.

Typically a spreadmart is created by individuals at different times using different data sources and rules for defining metrics in an organization, creating a fractured view of the enterprise. The concept was coined in 2002 by Wayne Eckerson at TDWI in his article *Taming Spreadsheet Jockeys*.[2]

Usually, spreadmarts grow where standard Business Intelligence (BI) reporting is too inflexible and too slow. A Business analyst uses the "export to Microsoft Excel" button in his BI software and creates his own report with the exported data table. By this, the number of independently generated spreadsheets dealing with a particular group of analyses grows inside the company, and the data inside each spreadsheet is uncoupled from its source. When this happens, the data reflected in the spreadsheets is no longer verifiable and is not automatically kept up to date. Usually these spreadsheet files are distributed via email to colleagues resulting in even more copies of the data roaming through the enterprise. With Microsoft PowerPivot for Microsoft SharePoint, Excel spreadsheets can be distributed as dashboards throughout the entire company, giving even more users the tools to create spreadmarts.

The growth of spreadmarts poses a real risk for a company, since undefined and uncoupled data is floating from spreadsheet to spreadsheet, and can be used to draw false conclusions that lead to wrong decisions, which will cost time and money to discover and correct. Although Business Intelligence 2.0 software vendors claim to have overcome this issue, locally installed spreadsheet and graphing software continues to be easier to access and use, giving the business analyst the freedom to create the needed analysis quickly, and choose to live with the risk of data inconsistency that goes with it.

Related technologies

- Microsoft Excel with PowerPivot as the standard
- OpenOffice.org Calc, the open source alternative to Excel
- A whole host of Business Intelligence software vendors, for example Cognos, provide software that couples spreadsheets to the data in a more persistent manner.

MultiDimensional eXpressions

Multidimensional Expressions (MDX) is a query language for OLAP databases, much like SQL is a query language for relational databases. It is also a calculation language, with syntax similar to spreadsheet formulas.

Background

The *MultiDimensional eXpressions (MDX) language* provides a specialized syntax for querying and manipulating the multidimensional data stored in OLAP cubes. While it is possible to translate some of these into traditional SQL, it would frequently require the synthesis of clumsy SQL expressions even for very simple MDX expressions. MDX has been embraced by a wide majority of OLAP vendors and has become the standard for OLAP systems.

History

MDX was first introduced as part of the OLE DB for OLAP specification in 1997 from Microsoft. It was invented by the group of SQL Server engineers including Mosha Pasumansky. The specification was quickly followed by commercial release of Microsoft OLAP Services 7.0 in 1998 and later by Microsoft Analysis Services. The latest version of the OLE DB for OLAP specification was issued by Microsoft in 1999.

While it was not an open standard, but rather a Microsoft-owned specification, it was adopted by the wide range of OLAP vendors. This included both vendors on the server side such as Applix, icCube, MicroStrategy, NCR, Oracle Corporation, SAS, SAP, Teradata, Symphony Teleca, and vendors on the client side such as Panorama Software, PowerOLAP, XLCubed, Proclarity, AppSource, Jaspersoft, Cognos, Business Objects, Brio Technology, Crystal Reports, Microsoft Excel, Tagetik, and Microsoft Reporting Services.

With the invention of XML for Analysis, which standardized MDX as a query language, even more companies - such as Hyperion Solutions - began supporting MDX.

The XML for Analysis specification referred back to the OLE DB for OLAP specification for details on the MDX Query Language. In Analysis Services 2005, Microsoft has added some MDX Query Language extensions like subselects. Products like Microsoft Excel 2007 have started to use these new MDX Query Language extensions. Some refer to this newer variant of MDX as MDX 2005.

mdXML

In 2001 the XMLA Council released the XML for Analysis standard, which included mdXML as a query language. In the current XMLA 1.1 specification, mdXML is essentially MDX wrapped in the XML `<Statement>` tag.

MDX data types

There are six primary data types in MDX

- **Scalar**. Scalar is either a number or a string. It can be specified as a literal, e.g. number 5 or string "OLAP" or it can be returned by an MDX function, e.g. `Aggregate` (number), `UniqueName` (string), `.Value` (number or string) etc.
- **Dimension/Hierarchy**. Dimension is a dimension of a cube. A dimension is a primary organizer of measure and attribute information in a cube. MDX does not know of, nor does it assume any, dependencies between dimensions- they are assumed to be mutually independent. A dimension will contain some members (see below) organized in some hierarchy or hierarchies containing levels. It can be specified by its unique name, e.g. `[Time]` or it can be returned by an MDX function, e.g. `.Dimension`. Hierarchy is a dimension hierarchy of a cube. It can be specified by its unique name, e.g. `[Time].[Fiscal]` or it can be returned by an MDX function, e.g. `.Hierarchy`. Hierarchies are contained within dimensions. (*OLEDB for OLAP MDX*

specification does not distinguish between dimension and hierarchy data types. Some implementations, such as Microsoft Analysis Services, treat them differently.)

- **Level**. Level is a level in a dimension hierarchy. It can be specified by its unique name, e.g. `[Time].[Fiscal].[Month]` or it can be returned by an MDX function, e.g. `.Level`.
- **Member**. Member is a member in a dimension hierarchy. It can be specified by its unique name, e.g. `[Time].[Fiscal].[Month].[August 2006]`, by qualified name, e.g. `[Time].[Fiscal].[2006].[Q2].[August 2006]` or returned by an MDX function, e.g. `.PrevMember`, `.Parent`, `.FirstChild` etc. Note that all members are specific to a hierarchy. If the self-same product is a member of two different hierarchies (`[Product].[ByManufacturer]` and `[Product].[ByCategory]`), there will be two different members visible that may need to be coordinated in sets and tuples (see below).
- **Tuple**. Tuple is an ordered collection of one or more members from different dimensions. Tuples can be specified by enumerating the members, e.g. `([Time].[Fiscal].[Month].[August], [Customer].[By Geography].[All Customers].[USA], [Measures].[Sales])` or returned by an MDX function, e.g. `.Item`.
- **Set**. Set is an ordered collection of tuples with the same dimensionality, or hierarchality in the case of Microsoft's implementation. It can be specified enumerating the tuples, e.g. `{([Measures].[Sales], [Time].[Fiscal].[2006]), ([Measures].[Sales], [Time].[Fiscal].[2007])}` or returned by MDX function or operator, e.g. `Crossjoin`, `Filter`, `Order`, `Descendants` etc.
- Other data types. Member properties are equivalent to *attributes* in the data warehouse sense. They can be retrieved by name in a query through an axis PROPERTIES clause of a query. The scalar data value of a member property for some member can be accessed in an expression through MDX, either by naming the property (for example, `[Product].CurrentMember.[Sales Price]`) or by using a special access function (for example, `[Product].CurrentMember.Properties("Sales Price")`). In limited contexts, MDX allows other data types as well - for example Array can be used inside the `SetToArray` function to specify an array that is not processed by MDX but passed to a user-defined function in an ActiveX library. Objects of other data types are represented as scalar strings indicating the object names, such as measure group name in Microsoft's `MeasureGroupMeasures` function or KPI name in for example Microsoft's `KPIValue` or `KPIGoal` functions.

Example query

The following example, adapted from the SQL Server 2000 Books Online, shows a basic MDX query that uses the SELECT statement. This query returns a result set that contains the 2002 and 2003 store sales amounts for stores in the state of California.

```
SELECT
   { [Measures].[Store Sales] } ON COLUMNS,
   { [Date].[2002], [Date].[2003] } ON ROWS
FROM Sales
WHERE ( [Store].[USA].[CA] )
```

In this example, the query defines the following result set information:

- The SELECT clause sets the query axes as the Store Sales member of the Measures dimension, and the 2002 and 2003 members of the Date dimension.
- The FROM clause indicates that the data source is the Sales cube.
- The WHERE clause defines the "slicer axis" as the California member of the Store dimension.

Note: You can specify up to 128 query axes in an MDX query.

If you create two axes, one must be the column axis and one must be the row axis, although it doesn't matter in which order they appear within the query. if you create a query that has only one axis, it must be the column axis. The square brackets around the particular object identifier are optional as long as the object identifier: is not one of reserved words, does not otherwise contain any characters other than letters, numbers or underscores.

```
SELECT
    [Measures].[Store Sales] ON COLUMNS,
    [Date].Members ON ROWS
FROM Sales
WHERE ( [Store].[USA].[CA] )
```

The Members() function returns the set of members in a dimension, level or hierarchy.

Applix

Applix Inc.

Industry	Computer Software
Fate	Acquired by Cognos, October 25, 2007; Acquired by IBM, January 31, 2008
Founded	1983
Headquarters	Westborough, Massachusetts, USA
Area served	Worldwide
Products	• Applix TM1 • Applix Web • Applix Executive Viewer • Applix Business Analytics Platform
Owner(s)	IBM
Website	www-01.ibm.com/software/analytics/cognos/ [1]

Applix Inc. was a computer software company founded in 1983 based in Westborough, Massachusetts that published Applix TM1, a MOLAP database server, and related presentation tools, including Applix Web and Applix Executive Viewer. Together, Applix TM1, Applix Web and Applix Executive Viewer were the three core components of the *Applix Business Analytics Platform*. Applix did business in over 50 countries with over 3,000 customers worldwide.

On October 25, 2007, Applix was acquired by Cognos. Cognos rebranded all Applix products under its name following the acquisition. On January 31, 2008, Cognos was itself acquired by IBM.

Prior to OLAP industry consolidation in 2007, Applix was the purest OLAP vendor among publicly traded independent BI vendors, and had the greatest growth rate. TM1 is now marketed as IBM Cognos TM1 and the latest version, IBM Cognos TM1 10.1, became publicly available on February 7th, 2012.

Products and technology

IBM Cognos TM1 (formerly Applix TM1) is enterprise planning software used to implement collaborative planning, budgeting and forecasting solutions, as well as analytical and reporting applications. Data in IBM Cognos TM1 is stored and represented as multidimensional cubes, with data being stored at the "leaf" level. Computations on the leaf data are performed in real-time (for example, to aggregate numbers up a dimensional hierarchy). IBM Cognos TM1 also includes a data orchestration environment for accessing external data and systems, as well as capabilities designed for common business planning and budgeting requirements (e.g. workflow, top-down adjustments).

New features added to IBM Cognos TM1 9.5 include *TM1 Contributor*, which combines an OLAP engine with the enterprise planning capabilities of IBM Cognos Planning in a Web-based client. Other features include an "Undo/Redo" capability that lets users store a collection of data value changes and walk back through the actions to undo them; pick lists for cells to reduce the amount of data entry performed; sandboxes for creating personal modeling scenarios, and data entry shortcuts.

Crystal Analysis

Crystal Analysis (a.k.a. **Crystal Analysis Professional**) is an On Line Analytical Processing (OLAP) application for analysing business data originally developed by Seagate Software.

It was first released under the name *Seagate Analysis* as a free application written in Java released in 1999. After disappointing application performance, a decision was made to rewrite using ATL COM in C++. The initial rewrite only supported Microsoft Analysis Services, but support for other vendors soon followed, with Holos cubes in version 8.5, Essbase, IBM DB2 and SAP BW following in later releases. The web client was rewritten using an XSLT abstraction layer for the version 9.0 release, with better standards compliance to support Mozilla based browsers—this work also set the building blocks for support for Safari.

Crystal Analysis relies on Crystal Enterprise for distribution of analytical applications created with it.

Release timeline

- *Seagate Analysis* 1999, by Seagate Software
- *Crystal Analysis Professional* v8.0, 29 May 2001 [1] by Crystal Decisions
- *Crystal Analysis Professional* v8.1, Q4 2001 by Crystal Decisions
- *Crystal Analysis Professional* v8.5 9 July 2002 [2], by Crystal Decisions
- *Crystal Analysis Professional* v9.0 9 April 2003 [3], by Crystal Decisions
- *Crystal Analysis Professional* v10.0 8 January 2004 [4], by Business Objects
- *Crystal Analysis Professional* v11.0 31 January 2005, by Business Objects
- *Crystal Analysis Professional* v11.0 Release 2 30 November 2005 [5], by Business Objects

Future versions will be released under the name, *BusinessObjects OLAP Intelligence*.

CubePort

CubePort

Developer(s)	ExoLogic Corporation (2002-current)
Stable release	v2.23 / 03-31-2010
Operating system	Microsoft Windows
Type	Data transformation
License	Proprietary EULA
Website	[1]

CubePort is a commercial software application that converts from Oracle Essbase to the analogous Microsoft product Microsoft Analysis Services, which is built into Microsoft SQL Server. This application achieves this through various analogy mapping techniques, and is a standard client-server application that runs on a Windows computer but may connect to non-Windows servers. CubePort converts the various OLAP structures and syntaxes in the source through an extraction process, interprets, and recreates in the target. The objective is to simulate exactly the behavior of the original source system to the target system.

The application also includes UI phases such as Authentication, Questions, Extraction, and Verification. Substantial testing normally occurs after the conversion process prior to posting the objects to production.

History

The software was released widely in 2005. CubePort represents the first product of its kind in the Business intelligence platform migration space. The product was design and created to provide an organization with the ability to move their Business Intelligence assets from one platform to another.

Unlike the RDBMS (relational databases) world where there exists the commonplace ability to migrate from one RDBMS product type to another, in the Business Intelligence or OLAP product space, this capability is currently not found in the marketplace.

Usage Motivations

Motivations for migrating from one Business Intelligence platform to another, regardless of whether this is achieved through automated or manual methods, vary from implementation to implementation, and may include one or more of the following motivations:

- Reduction of licensing or recurring maintenance expense
- Increase of detail-level of the cube
- Increase of the user count
- Elimination of cube load and calculation time constraints
- Elimination of pervasive vendor lock-in scenario
- Standardization towards Microsoft BI platform, where appropriate

Objects Converted

These standard objects in a cube are converted by the software with varying levels of robustness:

- Cube Outline
- Cube Data Loads and Dimension Builds
- Cube Security Model
- Cube Substitution Variables
- Cube Calculation Scripts
- Cube Report Scripts

The output objects of a successful run of CubePort are: A relational Star schema and/or relational Snowflake schema, OLAP cube, Etl load packages, MDX (Multidimensional Expressions) files, and others.

Essbase

Essbase

Stable release	11.1.2.3.0 / Apr 2013
Operating system	Microsoft Windows, Linux, AIX, HP-UX , Solaris
Type	Multidimensional database
License	Proprietary
Website	www.oracle.com/technetwork/middleware/essbase [1]

Essbase is a multidimensional database management system (MDBMS) that provides a multidimensional database platform upon which to build analytic applications. Essbase, whose name derives from "**E**xtended **S**pread **S**heet data**BASE**", began as a product of Arbor Software, which merged with Hyperion Software in 1998. Oracle Corporation acquired Hyperion Solutions Corporation in 2007, as of 2009[2] it markets Essbase as "Oracle Essbase". Until late 2005 IBM also marketed the product — as **DB2 OLAP Server**.[3]

The database researcher E. F. Codd coined the term "on-line analytical processing" (OLAP) in a whitepaper that set out twelve rules for analytic systems (an allusion to his earlier famous set of twelve rules defining the relational model). This whitepaper, published by Computerworld, was somewhat explicit in its reference to Essbase features, and when it was later discovered that Codd had been sponsored by Arbor Software, Computerworld withdrew the paper.[4]

In contrast to "on-line transaction processing" (OLTP), OLAP defines a database technology optimized for processing human queries rather than transactions. The results of this orientation were that MDBMS oriented their performance requirements around a different set of benchmarks (Analytic Performance Benchmark, APB-1) than that of RDBMS (Transaction Processing Performance Council (TPC)).

Hyperion renamed many of its products in 2005, giving Essbase an official name of **Hyperion System 9 BI+ Analytic Services**, but the new name was largely ignored by practitioners. The Essbase brand was later returned to the official product name for marketing purposes, but the server software still carried the "Analytic Services" title until it was incorporated into Oracle's Business Intelligence product suite. [5]

In August 2005, *Information Age* magazine named Essbase as one of the 10 most influential technology innovations of the previous 10 years,[6] along with Netscape, the BlackBerry, Google, virtualization, Voice Over IP (VOIP), Linux, XML, the Pentium processor and ADSL. Editor Kenny MacIver said: "Hyperion Essbase was the multi-dimensional database technology that put online analytical processing on the business intelligence map. It has spurred the creation of scores of rival OLAP products – and billions of OLAP cubes".

History and motivation

Although Essbase has been categorisedWikipedia:Manual of Style/Words to watch#Unsupported attributions as a general-purpose multidimensional database, it was originally developed to address the scalability issues associated with spreadsheets such as Lotus 1-2-3 and Microsoft Excel. Indeed, the patent covering Essbase uses spreadsheets as a motivating example to illustrate the need for such a system.[7]

In this context, "multi-dimensional" refers to the representation of financial data in spreadsheet format. A typical spreadsheet may display time intervals along column headings, and account names on row headings. For example:

	Jan	Feb	Mar	Total
Quantity	1000	2000	3000	**6000**
Sales	$100	$200	$300	**$600**
Expenses	$80	$160	$240	**$480**
Profit	$20	$40	$60	**$120**

If a user wants to break down these values by region, for example, this typically involves the duplication of this table on multiple spreadsheets:

	Jan	Feb	Mar	Total
Quantity	240	1890	50	**2180**
Sales	$24	$189	$5	**$218**
Expenses	$20	$150	$3	**$173**
Profit	$4	$39	$2	**$45**

	Jan	Feb	Mar	Total
Quantity	760	110	2950	**3820**
Sales	$76	$11	$295	**$382**
Expenses	$60	$10	$237	**$307**
Profit	$16	$1	$58	**$75**

	Jan	Feb	Mar	Total
Quantity	1000	2000	3000	**6000**
Sales	$100	$200	$300	**$600**
Expenses	$80	$160	$240	**$480**
Profit	$20	$40	$60	**$120**

An alternative representation of this structure would require a three-dimensional spreadsheet grid, giving rise to the idea that "Time", "Account", and "Region" are dimensions. As further dimensions are added to the system, it becomes very difficult to maintain spreadsheets that correctly represent the multi-dimensional values. Multidimensional databases such as Essbase provide a data store for values that exist, at least conceptually, in a multi-dimensional "hypercube".

Sparsity

As the number and size of dimensions increases, developers of multidimensional databases increasingly face technical problems in the physical representation of data. Say the above example was extended to add a "Customer" and "Product" dimension:

Dimension	Number of dimension values
Accounts	4
Time	4
Region	3
Customer	10,000
Product	5,000

If the multidimensional database reserved storage space for every possible value, it would need to store 2,400,000,000 (4 × 4 × 3 × 10,000 × 5,000) cells. If the software maps each cell as a 64-bit floating point value, this equates to a memory requirement of at least 17 gigabytes (exactly 19.2GB). In practice, of course, the number of combinations of "Customer" and "Product" that contain meaningful values will be a tiny subset of the total space. This property of multi-dimensional spaces is referred to as sparsity.

Aggregation

OLAP systems generally provide for multiple levels of detail within each dimension by arranging the members of each dimension into one or more hierarchies. A time dimension, for example, may be represented as a hierarchy starting with "Total Time", and breaking down into multiple years, then quarters, then months. An Accounts dimension may start with "Profit", which breaks down into "Sales" and "Expenses", and so on.

In the example above, if "Product" represents individual product SKUs, analysts may also want to report using aggregations such as "Product Group", "Product Family", "Product Line", etc. Similarly, for "Customer", natural aggregations may arrange customers according to geographic location or industry.

The number of aggregate values implied by a set of input data can become surprisingly large. If the Customer and Product dimensions are each in fact six "generations" deep, then 36 (6 × 6) aggregate values are affected by a single data point. It follows that if all these aggregate values are to be stored, the amount of space required is proportional to the product of the depth of all aggregating dimensions. For large databases, this can cause the effective storage requirements to be many hundred times the size of the data being aggregated.

Block storage (Essbase Analytics)

Since version 7, Essbase has supported two "storage options" which take advantage of sparsity to minimize the amount of physical memory and disk space required to represent large multidimensional spaces. The Essbase patent describes the original method, which aimed to reduce the amount of physical memory required without increasing the time required to look up closely related values. With the introduction of alternative storage options, marketing materials called this the **Block Storage Option** (**Essbase BSO**), later referred to as **Essbase Analytics**.

Put briefly, Essbase requires the developer to tag dimensions as "dense" or "sparse". The system then arranges data to represent the hypercube into "blocks", where each block comprises a multi-dimensional array made up of "dense" dimensions, and space is allocated for every potential cell in that block. Sparsity is exploited because the system only creates blocks when required. In the example above, say the developer has tagged "Accounts" and "Time" as "dense", and "Region", "Customer", and "Product" as "sparse". If there are, say, 12,000 combinations of Region, Customer and Product that contain data, then only 12,000 blocks will be created, each block large enough to store every possible combination of Accounts and Time. The number of cells stored is therefore 192000 (4 × 4 × 12000), requiring under 2 gigabytes of memory (exact 1,536MB), plus the size of the index used to look up the appropriate blocks.

Because the database hides this implementation from front-end tools (i.e., a report that attempts to retrieve data from non-existent cells merely sees "null" values), the full hypercube can be navigated naturally, and it is possible to load values into any cell interactively.

Calculation engine

Users can specify calculations in Essbase BSO as:

- the aggregation of values through dimensional hierarchies;
- stored calculations on dimension members;
- "dynamically calculated" dimension members; or
- procedural "calculation scripts" that act on values stored in the database.

The first method (dimension aggregation) takes place implicitly through addition, or by selectively tagging branches of the hierarchy to be subtracted, multiplied, divided or ignored. Also, the result of this aggregation can be stored in the database, or calculated dynamically on demand—members must be tagged as "Stored" or "Dynamic Calc." to specify which method is to be used.

The second method (stored calculations) uses a formula against each calculated dimension member — when Essbase calculates that member, the result is stored against that member just like a data value.

The third method (dynamic calculation) is specified in exactly the same format as stored calculations, but calculates a result when a user accesses a value addressed by that member; the system does not store such calculated values.

The fourth method (calculation scripts) uses a procedural programming language specific to the Essbase calculation engine. This type of calculation may act upon any data value in the hypercube, and can therefore perform calculations that cannot be expressed as a simple formula.

A calculation script must also be executed to trigger the calculation of aggregated values or stored calculations as described above—a built-in calculation script (called the "default calculation") can be used to execute this type of calculation.

Aggregate storage (Enterprise Analytics)

Although block storage effectively minimizes storage requirements without impacting retrieval time, it has limitations in its treatment of aggregate data in large applications, motivating the introduction of a second storage engine, named **Aggregate Storage Option** (**Essbase ASO**) or more recently, **Enterprise Analytics**. This storage option makes the database behave much more like an OLAP database, such as SQL Server Analysis Services.

Following a data load, Essbase ASO does not store any aggregate values, but instead calculates them on demand. For large databases, where the time required to generate these values may become inconvenient, the database can materialize one or more aggregate "views", made up of one aggregate level from each dimension (for example, the database may calculate all combinations of the fifth generation of Product with the third generation of Customer), and these views are then used to generate other aggregate values where possible. This process can be partially automated, where the administrator specifies the amount of disk space that may be used, and the database generates views according to actual usage.

This approach has a major drawback in that the cube cannot be treated for calculation purposes as a single large hypercube, because aggregate values cannot be directly controlled, so write-back from front-end tools is limited, and complex calculations that cannot be expressed as MDX expressions are not possible.

Calculation engine

Essbase ASO can specify calculations as:

- the aggregation of values through dimensional hierarchies; or
- dynamically calculated dimension members.

The first method (dimension aggregation) basically duplicates the algorithm used by Essbase BSO.

The second method (dynamic calculations) evaluates MDX expressions against dimension members.

User interface

Many users work with Essbase data using as their interface an add-in for Microsoft Excel (previously also Lotus 1-2-3). The add-in adds a menu to the spreadsheet application that can be used to connect to Essbase databases, retrieve data, and navigate the cube's dimensions ("Zoom in", "Pivot", etc.).[8]

With the release of System 9, Hyperion provided a new user interface add-in for Essbase called "Smart View for Microsoft Office". Smart View provides access to Essbase and other System 9 content for Microsoft Powerpoint, Microsoft Word, Microsoft Outlook as well as supplanting the previous add-in for Microsoft Excel.

In 2005, Hyperion began to offer a visualization tool called Tableau under the name "Hyperion Visual Explorer" [9] (2005). Tableau originated at Stanford University as a government-sponsored research project to investigate new ways for users to interact with relational and OLAP databases.

Other user-facing applications with support for Essbase databases include:

- Hyperion Analyzer (aka Hyperion System 9 BI+ Web Analysis)

- Hyperion Reports (aka Hyperion System 9 BI+ Financial Reporting)
- Hyperion Enterprise Reporting
- Hyperion Intelligence (aka Hyperion System 9 BI+ Interactive Reporting)
- Hyperion SQR (aka Hyperion System 9 BI+ Production Reporting)
- Alphablox
- Arcplan dynaSight (aka Arcplan Enterprise)
- Oracle Business Intelligence Suite Enterprise Edition (aka OBIEE, Siebel Analytics)
- Applied OLAP Dodeca [10]
- CXO-Cockpit Reporting Suite [11]

The previous offerings from Hyperion acquired new names as given below:

Hyperion's previous offerings	Hyperion System 9 BI+ offerings
Hyperion Essbase ASO	Enterprise Analytics
Hyperion Essbase BSO	Essbase Analytics
Hyperion Analyzer	Web Analysis
Hyperion Reports	Financial Reporting
Hyperion Intelligence	Interactive Reporting
Hyperion SQR	Production Reporting
Hyperion Metrics Builder	Enterprise Metrics

APIs are available for C, Visual Basic and Java, and embedded scripting support is available for Perl. The standardised XML for Analysis protocol can query Essbase data sources using the MDX language.

In 2007, Oracle Corporation began bundling Hyperion BI tools into Oracle Business Intelligence Enterprise Edition Plus.

Administrative interface

A number of standard interfaces can administer of Essbase applications:

- *ESSCMD*, the original command line interface for administration commands;
- *MaxL*, a "multi-dimensional database access language" which provides both a superset of ESSCMD commands, but with a syntax more akin to SQL, as well as support for MDX queries;
- *Essbase Application Manager*, the original Microsoft Windows GUI administration client, compatible with versions of Essbase before 7.0;
- *Essbase Administration Services*, later renamed *Analytic Administration Services*, and then back to 'Essbase Administration Services' in v. 9.3.1, the currently supported GUI administration client; and
- *Essbase Integration Server* for maintaining the structure and content of Essbase databases based on data models derived from relational or file-based data sources.

Competitors

There are several significant competitors among the OLAP, analytics products to that of Essbase (HOLAP/MOLAP) on the market, among them Microsoft SQL Server Microsoft Analysis Services, (MOLAP, HOLAP, ROLAP), IBM Cognos (ROLAP), IBM/Cognos/Applix TM1 (MOLAP), Oracle OLAP (ROLAP/MOLAP), MicroStrategy (ROLAP), and EXASolution (ROLAP).

Also note that of the above competitors, including Essbase, all use heterogenous relational (Microsoft SQL Server, Oracle, IBM DB/2, TeraData, Access, etc.) or non-relational data sourcing (Excel, text Files, CSV Files, etc.) to feed the cubes (facts and dimensional data), except for Oracle OLAP which may only use Oracle relational sourcing.

Export and/or product migration of Essbase

As of 2009[2] two options can export Essbase cubes into other formats:

1. CubePort, a commercial conversion application, converts Essbase cubes to the Microsoft SQL Server Analysis Services product. This product performs an object-to-object translation that make up an Essbase cube, including: outline, member formulas, calc scripts, data loading (load rules), report scripts to MDX queries, substitution variables, and security model. It can extract from any platform version of Essbase, including Oracle/Hyperion Essbase on Windows, Unix, AIX, HP UX, Solaris, IBM DB/2 OLAP, or AS/400 Showcase Essbase.
2. OlapUnderground Outline Extractor performs a pure, rudimentary, export of the outline, though it does not directly create any new objects. The output is a simple text file that can be pulled indirectly into other OLAP products, among other uses, such as synchronizing outlines. The Outline Extractor [12] is now maintained, supported and distributed free of charge by Applied OLAP, Inc.

Microsoft Analysis Services

Microsoft SQL Server Analysis Services (SSAS)

Developer(s)	Microsoft
Stable release	Analysis Services 2012 / December 21, 2010
Operating system	Microsoft Windows
Type	OLAP, Data Mining
License	Microsoft EULA
Website	[1]

Microsoft SQL Server Analysis Services, SSAS, is an Online Analytical Processing, OLAP, data mining and reporting tool in Microsoft SQL Server. SSAS is used as a tool by organizations to analyze and make sense of information possibly spread out across multiple databases, or in disparate tables. Microsoft has included a number of services in SQL Server related to business intelligence and data warehousing. These services include Integration Services and Analysis Services. Analysis Services includes a group of OLAP and data mining capabilities.

History

In 1996, Microsoft began its foray into the OLAP Server business by acquiring the OLAP software technology from Israel-based Panorama Software. Just over two years later, in 1998, Microsoft released OLAP Services as part of SQL Server 7. OLAP Services supported MOLAP, ROLAP, and HOLAP architectures, and it used OLE DB for OLAP as the client access API and MDX as a query language. It could work in client-server mode or offline mode with local cube files.

In 2000, Microsoft released Analysis Services 2000. It was renamed from "OLAP Services" due to the inclusion of data mining services. Analysis Services 2000 was considered an evolutionary release, since it was built on the same architecture as OLAP Services and was therefore backward compatible with it. Major improvements included more flexibility in dimension design through support of parent child dimensions, changing dimensions, and virtual dimensions. Another feature was a greatly enhanced calculation engine with support for unary operators, custom rollups, and cell calculations. Other features were dimension security, distinct count, connectivity over HTTP, session cubes, grouping levels, and many others.

In 2005, Microsoft released the next generation of OLAP and data mining technology as Analysis Services 2005. It maintained backward compatibility on the API level: although applications written with OLE DB for OLAP and MDX continued to work, the architecture of the product was completely different. The major change came to the model in the form of UDM - Unified Dimensional Model.Wikipedia:Please clarify

Timeline

The key events in the history of Microsoft Analysis Services cover a period starting in 1996.

Microsoft Analysis Services Events

Date	Event
1996-07-01	Microsoft opens new team to build an OLAP product, codenamed Plato (permutation of letters from OLAP)
1996-07-15	Panorama Software delegation meets with Microsoft
1996-10-27	Microsoft announces acquisition of Panorama Software development team
1998-11	OLAP Services 7.0 (codename Sphinx) ships
2000-08	Analysis Services 2000 (codename Shiloh) ships
2001-11	XML for Analysis Software Development Kit 1.0 ships
2003-04	ADOMD.NET and XML for Analysis SDK 1.1 ship
2005-10-28	Analysis Services 2005 (codename Yukon) ships
2008-08-06	Analysis Services 2008 (codename Katmai) ships
2012-03-06	Analysis Services 2012

Storage modes

Microsoft Analysis Services takes a neutral position in the MOLAP vs. ROLAP arguments among OLAP products. It allows all the flavors of MOLAP, ROLAP and HOLAP to be used within the same model.

Partition storage modes

- MOLAP - Multidimensional OLAP - Both fact data and aggregations are processed, stored, and indexed using a special format optimized for multidimensional data.
- ROLAP - Relational OLAP - Both fact data and aggregations remain in the relational data source, eliminating the need for special processing.
- HOLAP - Hybrid OLAP - This mode uses the relational data source to store the fact data, but pre-processes aggregations and indexes, storing these in a special format, optimized for multidimensional data.

Dimension storage modes

- MOLAP - dimension attributes and hierarchies are processed and stored in the special format
- ROLAP - dimension attributes are not processed and remain in the relational data source.

APIs and object models

Microsoft Analysis Services supports different sets of APIs and object models for different operations and in different programming environments.

Querying

- XML for Analysis - The lowest level API. It can be used from any platform and in any language that supports HTTP and XML
- OLE DB for OLAP - Extension of OLEDB. COM based and suitable for C/C++ programs on Windows platform.
- ADOMD - Extension of ADO. COM Automation based and suitable for VB programs on Windows platform.
- ADOMD.NET - Extension of ADO.NET. .NET based and suitable for managed code programs on CLR platforms.
- ADO.NET Entity Framework - Entity Framework and LINQ can be used on top of ADOMD.NET (SSAS Entity Framework Provider is required)

Administration and management

- DSO - For AS 2000. COM Automation based and suitable for VB programs on Windows platform.
- AMO - For AS 2005. .NET based and suitable for managed code programs on CLR platforms.

Query languages

Microsoft Analysis Services supports the following query languages

Data definition language (DDL)

DDL in Analysis Services is XML based and supports commands such as <Create>, <Alter>, <Delete>, and <Process>. For data mining models import and export, it also supports PMML.

Data manipulation language (DML)

- MDX - for querying OLAP cubes
- LINQ - for querying OLAP cubes from .NET using ADO.NET Entity Framework and Language INtegrated Query (SSAS Entity Framework Provider is required)
- SQL - small subset of SQL for querying OLAP cubes and dimensions as if they were tables
- DMX - for querying Data Mining models

....

Mondrian OLAP server

Mondrian OLAP Server

Developer(s)	Pentaho Corporation
Stable release	3.5.0 / November 29, 2012
Operating system	Cross-platform (JVM)
Type	OLAP Server
License	EPL
Website	mondrian.pentaho.org [1]

Mondrian is an open source OLAP (online analytical processing) server, written in Java. It supports the MDX (multidimensional expressions) query language and the XML for Analysis and olap4j [2] interface specifications. It reads from SQL and other data sources and aggregates data in a memory cache.

Mondrian is used for:

- High performance, interactive analysis of large or small volumes of information
- Dimensional exploration of data, for example analyzing sales by product line, by region, by time period
- Parsing the MDX language into Structured Query Language (SQL) to retrieve answers to dimensional queries
- High-speed queries through the use of aggregate tables in the RDBMS
- Advanced calculations using the calculation expressions of the MDX language

Mondrian History

The first public release of Mondrian was on Aug. 9th, 2002.

A release history is here [3]

Mondrian frontends

OLE DB for OLAP

OLE DB for OLAP (Object Linking and Embedding, Database for Online Analytical Processing abbreviated **ODBO**) is a Microsoft published specification and an industry standard for multi-dimensional data processing. ODBO is the standard application programming interface (API) for exchanging metadata and data between an OLAP server and a client on a Windows platform. ODBO extends the ability of OLE DB to access multi-dimensional (OLAP) data stores.[*citation needed*]

Description

ODBO is the most widely supported, multi-dimensional API to date. Platform-specific to Microsoft Windows, ODBO was specifically designed for Online Analytical Processing (OLAP) systems by Microsoft as an extension to Object Linking and Embedding Database (OLE DB). ODBO uses Microsoft's Component Object Model.[*citation needed*]

ODBO permits independent software vendors (ISVs) and corporate developers to create a single set of standard interfaces that allow OLAP clients to access multi-dimensional data, regardless of vendor or data source. ODBO is currently supported by a wide spectrum of server and client tools.[*citation needed*]

When exposing the ODBO interface, the underlying multi-dimensional database must also support the MDX Query Language. XML for Analysis is a newer interface to MDX Data Sources that is often supported in parallel with ODBO.[*citation needed*]

Oracle OLAP

The **Oracle Database OLAP Option** implements On-line Analytical Processing (OLAP) within an Oracle database environment. Oracle Corporation markets the Oracle Database OLAP Option as an extra-cost option to supplement the "Enterprise Edition" of its database. (Oracle offers Essbase for customers without the Oracle Database or who require multiple data-sources to load their cubes.)

As of Oracle Database 11g, the Oracle database optimizer can transparently redirect SQL queries to levels within the OLAP Option cubes. The cubes are managed and can take the place of multi-dimensional materialized views, simplifying Oracle data-warehouse management and speeding up query response.

Logical components

The Oracle Database OLAP Option offers:

- an OLAP analytic engine
- workspaces
- an analytic workspace manager (AWM)[1]
- a worksheet environment
- OLAP DML for DDL and DML
- an interface from SQL
- an analytic workspace Java API
- a Java-based OLAP API

Physical implementation

The Oracle database tablespace `CWMLITE` stores OLAPSYS schema objects and integrates Oracle Database OLAP Option with the Oracle Warehouse Builder (OWB). The CWMLITE name reflects the use of CWM — the Common Warehouse Metamodel, which Oracle Corporation refers to as "Common Warehouse Metadata".

Palo (OLAP database)

Palo

Developer(s)	Jedox AG
Stable release	5.0 SR3 / February 7, 2014
Operating system	Cross-platform, Linux, Windows
Type	OLAP
License	Multi-licensing, GPL v2, LGPL, Proprietary
Website	Jedox.com [1]

Palo is a memory resident multidimensional (online analytical processing (OLAP) or multidimensional online analytical processing (MOLAP)) database server and typically used as a business intelligence tool for controlling and budgeting purposes with spreadsheet software acting as the user interface. Beyond the multidimensional data concept, Palo enables multiple users to share one centralised data storage (single version of the truth).

This type of database is suitable to handle complex data models for business management and statistics. Apart from multidimensional queries, data can also be written back and consolidated real-time. To give rapid access to all data, Palo stores them in the memory during run time. The server is available as open source and proprietary software.

Jedox was founded by Kristian Raue in 2002 and developed by Jedox AG, a company based in Freiburg, Germany. The firm currently employs approximately 100 people.

Features

Palo for Excel is an open source plug-in for Microsoft Excel. There is also an open source plug-in for OpenOffice.org named PalOOCa, with Java and web client also available from the JPalo project.[2] Palo can also be integrated into other systems via its client libraries for Java, PHP, C/C++, or .NET Framework. It is fairly easy to communicate with Palo OLAP Server, since it uses representational state transfer (REST).

Starting in October 2008, Palo supports XML for Analysis and MultiDimensional eXpressions (MDX) APIs for connectivity, and OLE DB for OLAP interface which allows standard Excel pivot tables to serve as a client tool. Starting September 2011, Palo supports SDX [3] dialect of LINQ.

Palo also provides a web-based spreadsheet interface called Palo Web.[4]

Architecture

Palo Suite is a tightly integrated framework consisting of: Palo MOLAP Server, Palo ETL Server, Palo Web (Palo Spreadsheet - Connection, User, ETL, File and Report Manager), Palo for Excel, Palo Supervision Server and the Palo Client Libraries.

The Data in Palo database is stored as a cube in the Palo MOLAP server. The Palo Excel Add-In component is used as a service to communicate between the Excel and the Palo MOLAP Server.

Panorama Software

Panorama Software

Type	Privately held company
Industry	Business intelligence software
Founded	1993
Founder(s)	Rony Ross founded the original co. in 1993; assets were sold to Microsoft in 1996; the current company was founded in 2003 by Janice Anderson and Rony Ross
Headquarters	Toronto, Canada
Area served	Global
Key people	Eynav Azarya, CEO Rony Ross, Executive Chairman and CTO, Oudi Antebi , VP Strategy and Marketing, Kobi Averbuch, VP R&D
Products	Novaview
Website	http://www.panorama.com/

Panorama Software is a Canadian software and consulting company specializing in business intelligence. The company was founded by Rony Ross in Israel in 1993; it relocated its worldwide headquarters to Toronto, Canada in 2003.

Panorama sold its OLAP technology to Microsoft in 1996, which was built into Microsoft OLAP Services and later SQL Server Analysis Services, an integrated component of the Microsoft SQL Server platform.

Panorama supports over 1,600 customers worldwide in industries such as financial services, manufacturing, retail, healthcare, telecommunications and life sciences. Panorama has a wide eco-system of partners in 30 countries, and maintains offices throughout North America, EMEA and Asia.

Products

Necto

The company's main product is a business intelligence suite named **Panorama Necto™**. Deemed a "Business Intelligence 3.0" platform with enhanced user interfaces, increased user adoption, and better self-service for reduced operational costs, Necto presents data in a socially enabled setting. Necto offers the users self-serve data mining and report generation, allowing them to generate their own custom views of the data without having to wait on someone else to run a report for them. It lets users create collaborative "workboards" and visual presentations to provide better context as they put together ad-hoc business teams to address internal issues. The users are able to follow other leaders in the organization and discover those who are attempting to analyze similar data sets. The company contends this focus on social analysis leads, starting with business data and connecting it with the people who are involved in this data.

Necto is a BI application based upon understanding of user behavior, one-click reporting, and collaborative decision making. Panorama positions the product upon three strengths of social business intelligence, insights, and intuitive self-service. The platform supports the social sharing of data, similar to sharing found on consumer oriented social networking sites. Data analysis is treated as "conversations" which can themselves be followed and analyzed. Panorama encourages Necto enterprise users to form cross-departmental teams based on data research behaviors. The solution introduces intelligence to the BI engine through tracking of user behavior and making corresponding adjustments.

Necto is an end-to-end BI suite that includes analytics, custom reporting, intuitive dashboards, and integration with Microsoft Office/SharePoint. The solution is compatible running on top of multiple data sources including spreadsheets, in-memory, OLAP, or relational databases. Integration on Microsoft Azure and optimization with Microsoft SQL Server 2012 platform is also available. Necto™ also integrates with SharePoint and adds a social connection to this integration, combining structured data from Necto's analysis services with unstructured data from SharePoint. It can be scaled up to manage thousands of users and several terabytes of data.

Panorama and Microsoft

Panorama Software is the original developer of the online analytical-processing OLAP technology that Microsoft acquired in 1996 and rebranded as SQL Server Analysis Services, an integrated component of the Microsoft SQL Server platform. Since this acquisition, Panorama has actively offered solutions to support the Microsoft platform as a Microsoft Gold ISV Competency partner. Whether on-premises or as a software-as-a-service, Panorama integrates with Microsoft to meet the demands from the largest of enterprise users.

ProClarity

ProClarity Corporation was a software company specializing in business intelligence and data analysis applications.

The company was founded in 1995 as Knosys Inc. in Boise, Idaho. The company was renamed ProClarity Corporation after its primary commercial software product, "ProClarity", in 2001.

ProClarity's software products integrated tightly with Microsoft Analysis Services.

Among ProClarity's more than 2,000 global clients were AT&T, Ericsson, Hewlett-Packard, Home Depot, Pennzoil QuakerState, Reckitt Benckiser, Roche, Siemens, USDA, Verizon, and Wells Fargo.

On April 3, 2006, Microsoft announced the acquisition of ProClarity.[1] The company was gradually folded into Microsoft's Business Division while a final major version, ProClarity 6.3, was released in 2007 [2] Additional business intelligence components, such as PerformancePoint Services for SharePoint 2010, and business intelligence improvements in existing products, as in Excel 2013, were released by the division in subsequent years.

SAP BI Accelerator

In computing, the **SAP BW Accelerator** is a computer appliance - preinstalled software on predefined hardware - which is used to speed up OLAP queries. The software was initially known as the BI Accelerater.

SAP BW Accelerator includes indexes that are vertically inverted reproductions of all the data included in InfoCubes (i.e., fact and dimension tables as well as master data). Note that there is no relational or other database management systems in BW Accelerator. There is only a file system, and indexes are essentially held as flat files. The second primary component of SAP BW Accelerator is the engine that processes the queries in memory - it uses the SAP TREX search engine. The software is running on an expandable rack of blade servers. The operating system used for BW Accelerator is 64-bit SUSE Linux Enterprise Server (SLES).

Hardware partners

The software is optimized for specific hardware and operating system combinations.

The list of partners which deliver the appliance is:

- IBM BW Accelerator solution [1]
- HP
- Fujitsu Siemens
- Sun BI Accelerator Offering [2]

The product is now going out to the free market; i.e. it is not only the partners that are allowed to offer this product. As always when becoming more open markets, lower prices might therefore be expected.

SAP NetWeaver Business Intelligence

SAP NetWeaver Business Warehouse (**SAP NetWeaver BW**) is business intelligence (BI), analytical, reporting and data warehousing software produced by SAP AG. It was originally named SAP BIW (Business Information Warehouse), then abbreviated to SAP BW, but is now known as "SAP BI" at the end user level. In contrast, "BW" is still used to describe the underlying data warehouse area and accelerator components. It is often used by companies who run their business on SAP's operational systems.

BW is part of the SAP NetWeaver technology. Other components of SAP NetWeaver include SAP Enterprise Portal (EP, called SAP NetWeaver Portal as of Release 7.0), Web Application Server (WAS), SAP Process Integration (PI, or previously XI, i.e. eXchange Infrastructure) and Master Data Management (MDM). It also includes end-user reporting tools such as Report Designer, BEx Query Designer, BEx Web Application Designer and BEx Analyzer.

Structure

SAP's BI products have layers:

- Extract, transform, load (ETL) layer - responsible for extracting data from a specific source, applying transformation rules, and loading it into the Data Warehouse Area.
- Data Warehouse Area - responsible for storing the information in various types of structures (e.g. Data Store Objects, InfoObjects and multidimensional structures called InfoCubes that follows star schema design).
- Reporting - for accessing the information in data warehouse area and presenting it in a user-friendly manner to the analyst or business user.
- Planning and analysis - Provides capabilities for the user to run simulations and perform tasks such as budget calculations.

SAP BW contains pre-defined business content in the form of InfoCubes, Info Objects, authorization roles, and queries. The business content can be modified to meet an organization's specific requirements; however, this requires a longer process of customization of the pre-defined elements.

Security

User management

The following types of general user profiles exist:

- Executives and knowledge workers
- Information consumers

However, roles and authorizations can be customized significantly.

Authentications and Single Sign-On

The following are the most common forms of authentication:

- User ID and Password
- Secure Network Communications (SNC)
- SAP Logon Ticket
- Client Certificates (e.g., x.509)

SAP NetWeaver Single Sign-On Environment

The SAP NetWeaver Portal is the main entry point within SAP NetWeaver. In order to integrate SAP NetWeaver Business Intelligence, the following two conditions must be satisfied: (note that SAP logon tickets are being used in this example) 1) BI trusts SAP logon tickets from EP because the public key of the EP certificate has been imported into BI. 2) EP trusts SAP logon tickets from BI because the public key of the BI certificate has been imported into EP.

Authorizations

Companies have to define who has access to which data. An authorization allows a user to perform a certain activity on a certain object in the BI system. There are two authorizations concepts to consider for BI: standard authorizations[1] and analysis authorizations.[2]

Communication channel security

The communication channel used depends on different cases[3]

- Front end and application server uses RFC
- Application server and application server uses RFC
- SAP J2EE Engine and application server uses RFC
- SAP router and application server uses RFC
- Connection to database uses RFC
- Web browser and application server uses HTTP, HTTPS, and SOAP

Encrypted communications

RFC communications is not encrypted. In order to encrypt RFC communications, the SAP environment must use Secure Network Communications (SNC) or the SAP Cryptographic Library.[4] SAP recommends the usage of x.509 certificates.[5]

Data storage

Data can be protected from being accessed by an authorized end user by assigning analysis authorizations. Data is not protected under BI default settings.

Transactional data is stored in a **Datastore** or an **InfoCube**. A Datastore serves as a storage location for transaction data at an atomic level. The data in a datastore is stored in transparent flat database tables.

An InfoCube is a set of relational tables arranged according to the star schema: A large fact table in the middle surrounded by several dimension tables.5616

History

The 7.0 version of BW was released in June 2006 as part of the SAP NetWeaver 7.0 (also known as 2004s). This release included features such as next-generation reporting and analytical features, data warehousing enhancements, and a memory resident option for improving query performance called "BI Accelerator" (it has since been renamed BW Accelerator). The BW Accelerator comes as an external appliance, i.e. complete hardware with pre-installed software, and requires a separate licence fee. BW Accelerator is licenced per blade server and 16 GB increments of memory.

SAP acquired Business Objects, one of the premier business intelligence software providers, via tender offers executed December 2007-January 2008.[6] SAP has indicated that Business Objects will operate as an independent entity to preserve the principle of application agnosticism, but also promised a tighter integration between SAP BI and Business Objects. A new BI roadmap was recently released by the combined entity.[7]

NEVOD DMB

NEVOD

Company / developer	RELEX Group
License	commercial
Official website	[1]

Data Marts Builder **NEVOD** a product of RELEX Group, created in 1996.

Description

DMB[2] **NEVOD** - object-oriented repository with possibility of search and analysis of structured information (Ad hoc inquiries and semantic net visualization). It is used mainly by security services of commercial organisations and divisions of the Ministry of Internal Affairs of the Russian Federation. For ten consecutive years DMB NEVOD has been presented at the international tradeshow of computer technologies "SofTool", at the RELEX Group exposition.[3]

Technical Characteristics of NEVOD DMB

Parameter	**Value**
Maximum number of accounted object types	65000
Maximum number of objects	1 000 000 000
Maximum number of single-valued attributes for an object	124
Maximum number of many-valued attributes for an object	65000
Maximum number of values in a many-valued attribute	1 000 000 000
Maximum number of users	65000
Possible attribute types	Text (up to 512 Unicode characters) Dictionary value (up to 512 Unicode characters) Date Time Integer Floating-point real number Fixed-point real number Attribute group Object reference Multimedia (up to 2 Gb)
Maximum number of dictionaries	32000
Dictionary views	Linear list Synonym tree Hierarchic dictionary

Types of conditions imposed on attributes and used in queries	Equal Not equal More Less More or equal Less or equal Between According to the hierarchic dictionary Empty Begin with End with Contains Template
Types of conditions imposed on connections and used in queries	Use connection type Mandatory connection Implied connection
Types of logical operations connecting the conditions imposed on attributes	AND, OR, NOT
Maximum number of conditions in a query	32000
Maximum number of queries stored	65000
Maximum number of query results stored	65000
Maximum number of input/output forms stored	65000
Maximum number of connection charts stored	65000
Maximum number of statistic reports stored	65000
Maximum number of XSL reports stored	65000
Maximum number of servers for executing a query	4000
Maximum number of identification rules	65000
Import/export format	XML

Data Transforamtion

Extract, transform, load

In computing, **extract, transform, and load** (**ETL**) refers to a process in database usage and especially in data warehousing that:

- Extracts data from outside sources
- Transforms it to fit operational needs, which can include quality levels
- Loads it into the end target (database, more specifically, operational data store, data mart, or data warehouse)

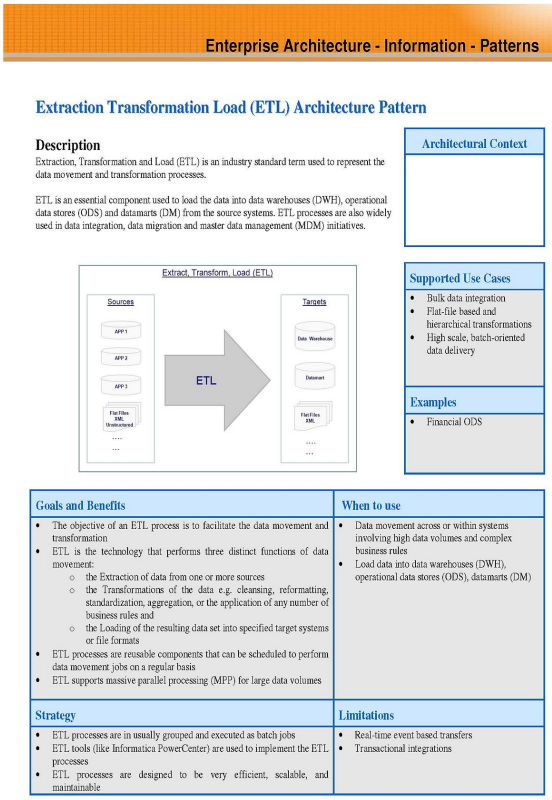
ETL systems are commonly used to integrate data from multiple applications, typically developed and supported by different vendors or hosted on separate computer hardware. The disparate systems containing the original data are frequently managed and operated by different employees. For example a cost accounting system may combine data from payroll, sales and purchasing.

Extract

The first part of an ETL process involves extracting the data from the source systems. In many cases this is the most challenging aspect of ETL, since extracting data correctly sets the stage for how subsequent processes go further.

Most data warehousing projects consolidate data from different source systems. Each separate system may also use a different data organization and/or format. Common data source formats are relational databases and flat files, but may include non-relational database structures such as Information Management System (IMS) or other data structures such as Virtual Storage Access Method (VSAM) or Indexed Sequential Access Method (ISAM), or even fetching from outside sources such as through web spidering or screen-scraping. The streaming of the extracted data source and load on-the-fly to the destination database is another way of performing ETL when no intermediate data storage is required. In general, the goal of the extraction phase is to convert the data into a single format appropriate for transformation processing.

An intrinsic part of the extraction involves the parsing of extracted data, resulting in a check if the data meets an expected pattern or structure. If not, the data may be rejected entirely or in part.



ETL Architecture Pattern

Transform

The transform stage applies a series of rules or functions to the extracted data from the source to derive the data for loading into the end target. Some data sources require very little or even no manipulation of data. In other cases, one or more of the following transformation types may be required to meet the business and technical needs of the target database:

- Selecting only certain columns to load (or selecting null columns not to load). For example, if the source data has three columns (also called attributes), roll_no, age, and salary, then the selection may take only roll_no and salary. Similarly, the selection mechanism may ignore all those records where salary is not present (salary = null).
- Translating coded values (*e.g.*, if the source system stores 1 for male and 2 for female, but the warehouse stores M for male and F for female)
- Encoding free-form values (*e.g.*, mapping "Male" to "M")
- Deriving a new calculated value (*e.g.*, sale_amount = qty * unit_price)
- Sorting
- Joining data from multiple sources (*e.g.*, lookup, merge) and deduplicating the data
- Aggregation (for example, rollup — summarizing multiple rows of data — total sales for each store, and for each region, etc.)
- Generating surrogate-key values
- Transposing or pivoting (turning multiple columns into multiple rows or vice versa)
- Splitting a column into multiple columns (*e.g.*, converting a comma-separated list, specified as a string in one column, into individual values in different columns)
- Disaggregation of repeating columns into a separate detail table (*e.g.*, moving a series of addresses in one record into single addresses in a set of records in a linked *address* table)
- Lookup and validate the relevant data from tables or referential files for slowly changing dimensions.
- Applying any form of simple or complex data validation. If validation fails, it may result in a full, partial or no rejection of the data, and thus none, some or all the data is handed over to the next step, depending on the rule design and exception handling. Many of the above transformations may result in exceptions, for example, when a code translation parses an unknown code in the extracted data.

Load

The load phase loads the data into the end target, usually the data warehouse (DW). Depending on the requirements of the organization, this process varies widely. Some data warehouses may overwrite existing information with cumulative information; frequently, updating extracted data is done on a daily, weekly, or monthly basis. Other data warehouses (or even other parts of the same data warehouse) may add new data in a historical form at regular intervals—for example, hourly. To understand this, consider a data warehouse that is required to maintain sales records of the last year. This data warehouse overwrites any data older than a year with newer data. However, the entry of data for any one year window is made in a historical manner. The timing and scope to replace or append are strategic design choices dependent on the time available and the business needs. More complex systems can maintain a history and audit trail of all changes to the data loaded in the data warehouse.

As the load phase interacts with a database, the constraints defined in the database schema — as well as in triggers activated upon data load — apply (for example, uniqueness, referential integrity, mandatory fields), which also contribute to the overall data quality performance of the ETL process.

- For example, a financial institution might have information on a customer in several departments and each department might have that customer's information listed in a different way. The membership department might list the customer by name, whereas the accounting department might list the customer by number. ETL can bundle all this data and consolidate it into a uniform presentation, such as for storing in a database or data warehouse.

- Another way that companies use ETL is to move information to another application permanently. For instance, the new application might use another database vendor and most likely a very different database schema. ETL can be used to transform the data into a format suitable for the new application to use.
- An example of this would be an Expense and Cost Recovery System (ECRS) such as used by accountancies, consultancies and lawyers. The data usually ends up in the time and billing system, although some businesses may also utilize the raw data for employee productivity reports to Human Resources (personnel dept.) or equipment usage reports to Facilities Management.

Real-life ETL cycle

The typical real-life ETL cycle consists of the following execution steps:

1. Cycle initiation
2. Build reference data
3. Extract (from sources)
4. Validate
5. Transform (clean, apply business rules, check for data integrity, create aggregates or disaggregates)
6. Stage (load into staging tables, if used)
7. Audit reports (for example, on compliance with business rules. Also, in case of failure, helps to diagnose/repair)
8. Publish (to target tables)
9. Archive
10. Clean up

Challenges

ETL processes can involve considerable complexity, and significant operational problems can occur with improperly designed ETL systems.

The range of data values or data quality in an operational system may exceed the expectations of designers at the time validation and transformation rules are specified. Data profiling of a source during data analysis can identify the data conditions that must be managed by transform rules specifications. This leads to an amendment of validation rules explicitly and implicitly implemented in the ETL process.

Data warehouses are typically assembled from a variety of data sources with different formats and purposes. As such, ETL is a key process to bring all the data together in a standard, homogeneous environment.

Design analysts should establish the scalability of an ETL system across the lifetime of its usage. This includes understanding the volumes of data that must be processed within service level agreements. The time available to extract from source systems may change, which may mean the same amount of data may have to be processed in less time. Some ETL systems have to scale to process terabytes of data to update data warehouses with tens of terabytes of data. Increasing volumes of data may require designs that can scale from daily batch to multiple-day micro batch to integration with message queues or real-time change-data capture for continuous transformation and update.

Performance

ETL vendors benchmark their record-systems at multiple TB (terabytes) per hour (or ~1 GB per second) using powerful servers with multiple CPUs, multiple hard drives, multiple gigabit-network connections, and lots of memory. The fastest ETL record is currently held by Syncsort,[1] Vertica and HP at 5.4TB in under an hour, which is more than twice as fast as the earlier record held by Microsoft and Unisys.

In real life, the slowest part of an ETL process usually occurs in the database load phase. Databases may perform slowly because they have to take care of concurrency, integrity maintenance, and indices. Thus, for better performance, it may make sense to employ:

- Direct Path Extract method or bulk unload whenever is possible (instead of querying the database) to reduce the load on source system while getting high speed extract
- Most of the transformation processing outside of the database
- Bulk load operations whenever possible.

Still, even using bulk operations, database access is usually the bottleneck in the ETL process. Some common methods used to increase performance are:

- Partition tables (and indices). Try to keep partitions similar in size (watch for `null` values that can skew the partitioning).
- Do all validation in the ETL layer before the load. Disable integrity checking (`disable constraint ...`) in the target database tables during the load.
- Disable triggers (`disable trigger ...`) in the target database tables during the load. Simulate their effect as a separate step.
- Generate IDs in the ETL layer (not in the database).
- Drop the indices (on a table or partition) before the load - and recreate them after the load (SQL: `drop index ...; create index ...`).
- Use parallel bulk load when possible — works well when the table is partitioned or there are no indices. Note: attempt to do parallel loads into the same table (partition) usually causes locks — if not on the data rows, then on indices.
- If a requirement exists to do insertions, updates, or deletions, find out which rows should be processed in which way in the ETL layer, and then process these three operations in the database separately. You often can do bulk load for inserts, but updates and deletes commonly go through an API (using SQL).

Whether to do certain operations in the database or outside may involve a trade-off. For example, removing duplicates using `distinct` may be slow in the database; thus, it makes sense to do it outside. On the other side, if using `distinct` significantly (x100) decreases the number of rows to be extracted, then it makes sense to remove duplications as early as possible in the database before unloading data.

A common source of problems in ETL is a big number of dependencies among ETL jobs. For example, job "B" cannot start while job "A" is not finished. One can usually achieve better performance by visualizing all processes on a graph, and trying to reduce the graph making maximum use of parallelism, and making "chains" of consecutive processing as short as possible. Again, partitioning of big tables and of their indices can really help.

Another common issue occurs when the data is spread between several databases, and processing is done in those databases sequentially. Sometimes database replication may be involved as a method of copying data between databases - and this can significantly slow down the whole process. The common solution is to reduce the processing graph to only three layers:

- Sources
- Central ETL layer
- Targets

This allows processing to take maximum advantage of parallel processing. For example, if you need to load data into two databases, you can run the loads in parallel (instead of loading into 1st - and then replicating into the 2nd).

Sometimes processing must take place sequentially. For example, dimensional (reference) data is needed before one can get and validate the rows for main "fact" tables.

Parallel processing

A recent[2] development in ETL software is the implementation of parallel processing. This has enabled a number of methods to improve overall performance of ETL processes when dealing with large volumes of data.

ETL applications implement three main types of parallelism:

- **Data**: By splitting a single sequential file into smaller data files to provide parallel access.
- **Pipeline**: Allowing the simultaneous running of several components on the same data stream. For example: looking up a value on record 1 at the same time as adding two fields on record 2.
- **Component**: The simultaneous running of multiple processes on different data streams in the same job, for example, sorting one input file while removing duplicates on another file.

All three types of parallelism usually operate combined in a single job.

An additional difficulty comes with making sure that the data being uploaded is relatively consistent. Because multiple source databases may have different update cycles (some may be updated every few minutes, while others may take days or weeks), an ETL system may be required to hold back certain data until all sources are synchronized. Likewise, where a warehouse may have to be reconciled to the contents in a source system or with the general ledger, establishing synchronization and reconciliation points becomes necessary.

Rerunnability, recoverability

Data warehousing procedures usually subdivide a big ETL process into smaller pieces running sequentially or in parallel. To keep track of data flows, it makes sense to tag each data row with "row_id", and tag each piece of the process with "run_id". In case of a failure, having these IDs help to roll back and rerun the failed piece.

Best practice also calls for *checkpoints*, which are states when certain phases of the process are completed. Once at a checkpoint, it is a good idea to write everything to disk, clean out some temporary files, log the state, and so on.

Virtual ETL

As of 2010[2] data virtualization had begun to advance ETL processing. The application of data virtualization to ETL allowed solving the most common ETL tasks of data migration and application integration for multiple dispersed data sources. So-called Virtual ETL operates with the abstracted representation of the objects or entities gathered from the variety of relational, semi-structured and unstructured data sources. ETL tools can leverage object-oriented modeling and work with entities' representations persistently stored in a centrally located hub-and-spoke architecture. Such a collection that contains representations of the entities or objects gathered from the data sources for ETL processing is called a metadata repository and it can reside in memory[3] or be made persistent. By using a persistent metadata repository, ETL tools can transition from one-time projects to persistent middleware, performing data harmonization and data profiling consistently and in near-real time.[*citation needed*]

Dealing with keys

Keys are some of the most important objects in all relational databases, as they tie everything together. A primary key is a column that identifies a given entity, where a foreign key is a column in another table that refers a primary key. These keys can also be made of several columns, in which case they are composite keys. In many cases the primary key is an auto generated integer that has no meaning for the business entity being represented, but solely exists for the purpose of the relational database - commonly referred to as a surrogate key.

As there is usually more than one data source being loaded into the warehouse, the keys are an important concern to be addressed.
Your customers might be represented in several data sources, and in one their SSN (Social Security Number) might be the primary key, their phone number in another and a surrogate in the third. All of the customers information needs to be consolidated into one dimension table.

A recommended way to deal with the concern is to add a warehouse surrogate key, which is used as a foreign key from the fact table.[4]

Usually updates occur to a dimension's source data, which obviously must be reflected in the data warehouse.
If the primary key of the source data is required for reporting, the dimension already contains that piece of information for each row. If the source data uses a surrogate key, the ware house must keep track of it even though it is never used in queries or reports.

That is done by creating a lookup table that contains the warehouse surrogate key and the originating key.[5] This way the dimension is not polluted with surrogates from various source systems, while the ability to update is preserved.

The lookup table is used in different ways depending on the nature of the source data. There are 5 types to consider,[6] where three selected ones are included here:

Type 1:

- The dimension row is simply updated to match the current state of the source system. The warehouse does not capture history. The lookup table is used to identify the dimension row to update or overwrite.

Type 2:

- A new dimension row is added with the new state of the source system. A new surrogate key is assigned. Source key is no longer unique in the lookup table.

Fully logged:

- A new dimension row is added with the new state of the source system, while the previous dimension row is updated to reflect it is no longer active and record time of deactivation.

Tools

Programmers can set up ETL processes using almost any programming language, but building such processes from scratch can become complex. Increasingly, companies are buying ETL tools to help in the creation of ETL processes.[7]

By using an established ETL framework, one may increase one's chances of ending up with better connectivity and scalability.[*citation needed*] A good ETL tool must be able to communicate with the many different relational databases and read the various file formats used throughout an organization. ETL tools have started to migrate into Enterprise Application Integration, or even Enterprise Service Bus, systems that now cover much more than just the extraction, transformation, and loading of data. Many ETL vendors now have data profiling, data quality, and metadata capabilities. A common use case for ETL tools include converting CSV files to formats readable by relational databases. A typical translation of millions of records is facilitated by ETL tools that enable users to input csv-like data feeds/files and import it into a database with as little code as possible.

ETL Tools are typically used by a broad range of professionals - from students in computer science looking to quickly import large data sets to database architects in charge of company account management, ETL Tools have become a convenient tool that can be relied on to get maximum performance. ETL tools in most cases contain a GUI that helps users conveniently transform data as opposed to writing large programs to parse files and modify data types—which ETL tools facilitate as much as possible.[*citation needed*]

Staging (data)

A **staging area**, or **landing zone**, is an intermediate storage area used for data processing during the extract, transform and load (ETL) process. The data staging area sits between the data source(s) and the data target(s), which are often data warehouses, data marts or other data repositories.[1]

Data staging areas are often transient in nature, with their contents being erased prior to running an ETL process or immediately following successful completion of an ETL process. There are staging area architectures, however, which are designed to hold data for extended periods of time for archival or troubleshooting purposes.

Implementation

Staging areas can be implemented in the form of tables in relational databases, text-based flat files (or XML files) stored in file systems or proprietary formatted binary files stored in file systems.[2] Staging area architectures range in complexity from a set of simple relational tables in a target database to self-contained database instances or file systems.[3] Though the source systems and target systems supported by ETL processes are often relational databases, the staging areas that sit between data sources and targets need not also be relational databases.[4]

Functions

Staging areas can be designed to provide many benefits, but the primary motivations for their use are to increase efficiency of ETL processes, ensure data integrity and support data quality operations. The functions of the staging area include the following:

Consolidation

One of the primary functions performed by a staging area is consolidation of data from multiple source systems. In performing this function the staging area acts as a large "bucket" in which data from multiple source systems can be temporarily placed for further processing. It is common to tag data in the staging area with additional metadata indicating the source of origin and timestamps indicating when the data was placed in the staging area.

Alignment

Aligning data includes standardization of reference data across multiple source systems and validation of relationships between records and data elements from different sources. Data alignment in the staging area is a function closely related to, and acting in support of, master data management capabilities.[5]

Minimizing contention

The staging area and ETL processes it supports are often designed with a goal of minimizing contention within source systems. Copying required data from source systems to the staging area in one shot is often more efficient than retrieving individual records (or small sets of records) on a one-off basis. The former method takes advantage of technical efficiencies, such as data streaming technologies, reduced overhead through minimizing the need to break and re-establish connections to source systems and optimization of concurrency lock management on multi-user source systems. By copying the source data from the source systems and waiting to perform intensive processing and transformation in the staging area, the ETL process exercises a great degree of control over concurrency issues during processing.

Independent scheduling/multiple targets

The staging area can support hosting of data to be processed on independent schedules, and data that is meant to be directed to multiple targets. In some instances data might be pulled into the staging area at different times to be held and processed all at once. This situation might occur when enterprise processing is done across multiple time zones each night, for instance. In other cases data might be brought into the staging area to be processed at different times; or the staging area may be used to push data to multiple target systems. As an example, daily operational data might be pushed to an operational data store (ODS) while the same data may be sent in a monthly aggregated form to a data warehouse.

Change detection

The staging area supports efficient change detection operations against target systems. This functionality is particularly useful when the source systems do not support reliable forms of change detection, such as system-enforced timestamping, change tracking or change data capture (CDC).

Cleansing data

Data cleansing includes identification and removal (or update) of invalid data from the source systems. The ETL process utilizing the staging area can be used to implement business logic to identify and handle "invalid" data. Invalid data is often defined through a combination of business rules and technical limitations. Technical constraints may additionally be placed on staging area structures (such as table constraints in a relational database) to enforce data validity rules.

Aggregate precalculation

Precalculation of aggregates, complex calculations and application of complex business logic may be done in a staging area to support highly responsive service level agreements (SLAs) for summary reporting in target systems.

Data archiving and troubleshooting

Data archiving can be performed in, or supported by, a staging area. In this scenario the staging area can be used to maintain historical records during the load process, or it can be used to push data into a target archive structure. Additionally data may be maintained within the staging area for extended periods of time to support technical troubleshooting of the ETL process.

Vocabulary-based transformation

In metadata, a **vocabulary-based transformation (VBT)** is a transformation aided by the use of a semantic equivalence statements within a controlled vocabulary.

Many organizations today require communication between one or more computers. Although many standards exist to exchange data between computers such as HTML or email, there are still much structured information that needs to be exchanged between computers that is not standardized. The process of mapping one source of data into another is often a slow and labor-intensive process.

VBT is a possible way to avoid much of the time and cost of manual data mapping using traditional Extract, transform, load technologies.

History

The term *vocabulary-based transformation* was first defined by Roy Shulte of the Gartner Group around May 2003 and appeared in annual "hype-cycle" for integration.

Application

VBT allows computer systems integrators to more automatically "look up" the definitions of data elements in a centralized data dictionary and use that definition and the equivalent mappings to transform that data element into a foreign namespace.

The Web Ontology Language (OWL) language also support three semantic equivalence statements.

Surrogate key

A **surrogate key** in a database is a unique identifier for either an *entity* in the modeled world or an *object* in the database. The surrogate key is *not* derived from application data.

Definition

There are at least two definitions of a surrogate:

Surrogate (1) – Hall, Owlett and Codd (1976)

> A surrogate represents an *entity* in the outside world. The surrogate is internally generated by the system but is nevertheless visible to the user or application.

Surrogate (2) – Wieringa and De Jonge (1991)

> A surrogate represents an *object* in the database itself. The surrogate is internally generated by the system and is invisible to the user or application.

The *Surrogate (1)* definition relates to a data model rather than a storage model and is used throughout this article. See Date (1998).

An important distinction between a surrogate and a primary key depends on whether the database is a current database or a temporal database. Since a *current database* stores only *currently* valid data, there is a one-to-one correspondence between a surrogate in the modeled world and the primary key of the database. In this case the surrogate may be used as a primary key, resulting in the term *surrogate key*. In a temporal database, however, there is a many-to-one relationship between primary keys and the surrogate. Since there may be several objects in the database corresponding to a single surrogate, we cannot use the surrogate as a primary key; another attribute is required, in addition to the surrogate, to uniquely identify each object.

Although Hall *et al.* (1976) say nothing about this, othersWikipedia:Citing sources have argued that a surrogate should have the following characteristics:

- the value is unique system-wide, hence never reused
- the value is system generated
- the value is not manipulable by the user or application
- the value contains no semantic meaning
- the value is not visible to the user or application
- the value is not composed of several values from different domains.

Surrogates in practice

In a current database, the surrogate key can be the primary key, generated by the database management system and *not* derived from any application data in the database. The only significance of the surrogate key is to act as the primary key. It is also possible that the surrogate key exists in addition to the database-generated UUID (for example, an HR number for each employee other than the UUID of each employee).

A surrogate key is frequently a sequential number (e.g. a Sybase or SQL Server "identity column", a PostgreSQL or Informix `serial`, an Oracle `SEQUENCE` or a column defined with `AUTO_INCREMENT` in MySQL) but doesn't have to be. Having the key independent of all other columns insulates the database relationships from changes in data values or database design (making the database more agile) and guarantees uniqueness.

In a temporal database, it is necessary to distinguish between the surrogate key and the business key. Every row would have both a business key and a surrogate key. The surrogate key identifies one unique row in the database, the business key identifies one unique entity of the modeled world. One table row represents a slice of time holding all the entities attributes for a defined timespan. Those slices depict the whole lifespan of one business entity. For example, a table *EmployeeContracts* may hold temporal information to keep track of contracted working hours. The business key for one contract will be identical (non-unique) in both rows however the surrogate key for each row is unique.

SurrogateKey	BusinessKey	EmployeeName	WorkingHoursPerWeek	RowValidFrom	RowValidTo
1	BOS0120	John Smith	40	2000-01-01	2000-12-31
56	P0000123	Bob Brown	25	1999-01-01	2011-12-31
234	BOS0120	John Smith	35	2001-01-01	2009-12-31

Some database designers use surrogate keys systematically regardless of the suitability of other candidate keys, while others will use a key already present in the data, if there is one.

A *surrogate key* may also be called a synthetic key, an entity identifier, a system-generated key, a database sequence number, a factless key, a technical key, or an arbitrary unique identifier.[*citation needed*] Some of these terms describe the way of *generating* new surrogate values rather than the *nature* of the surrogate concept.

Approaches to generating surrogates include:

- Universally Unique Identifiers (UUIDs)
- Globally Unique Identifiers (GUIDs)
- Object Identifiers (OIDs)
- Sybase or SQL Server identity column `IDENTITY` OR `IDENTITY(n,n)`
- Oracle `SEQUENCE`
- PostgreSQL or IBM Informix serial
- MySQL `AUTO_INCREMENT`
- AutoNumber data type in Microsoft Access
- `AS IDENTITY GENERATED BY DEFAULT` in IBM DB2
- Identity column (implemented in DDL) in Teradata

Advantages

Immutability

Surrogate keys do not change while the row exists. This has the following advantages:

- Applications cannot lose their reference to a row in the database (since the identifier never changes).
- The primary or natural key data can always be modified, even with databases that do not support cascading updates across related foreign keys.

Requirement changes

Attributes that uniquely identify an entity might change, which might invalidate the suitability of natural keys. Consider the following example:

> An employee's network user name is chosen as a natural key. Upon merging with another company, new employees must be inserted. Some of the new network user names create conflicts because their user names were generated independently (when the companies were separate).

In these cases, generally a new attribute must be added to the natural key (for example, an *original_company* column). With a surrogate key, only the table that defines the surrogate key must be changed. With natural keys, all tables (and possibly other, related software) that use the natural key will have to change.

Some problem domains do not clearly identify a suitable natural key. Surrogate key avoids choosing a natural key that might be incorrect.

Performance

Surrogate keys tend to be a compact data type, such as a four-byte integer. This allows the database to query the single key column faster than it could multiple columns. Furthermore a non-redundant distribution of keys causes the resulting b-tree index to be completely balanced. Surrogate keys are also less expensive to join (fewer columns to compare) than compound keys.

Compatibility

While using several database application development systems, drivers, and object-relational mapping systems, such as Ruby on Rails or Hibernate, it is much easier to use an integer or GUID surrogate keys for every table instead of natural keys in order to support database-system-agnostic operations and object-to-row mapping.

Uniformity

When every table has a uniform surrogate key, some tasks can be easily automated by writing the code in a table-independent way.

Validation

It is possible to design key-values that follow a well-known pattern or structure which can be automatically verified. For instance, the keys that are intended to be used in some column of some table might be designed to "look differently from" those that are intended to be used in another column or table, thereby simplifying the detection of application errors in which the keys have been misplaced. However, this characteristic of the surrogate keys should never be used to drive any of the logic of the applications themselves, as this would violate the principles of Database normalization.

Disadvantages

Disassociation

The values of generated surrogate keys have no relationship to the real-world *meaning* of the data held in a row. When inspecting a row holding a foreign key reference to another table using a surrogate key, the meaning of the surrogate key's row cannot be discerned from the key itself. Every foreign key must be joined to see the related data item. This can also make auditing more difficult,[*citation needed*] as incorrect data is not obvious.

Surrogate keys are unnatural for data that is exported and shared. A particular difficulty is that tables from two otherwise identical schemas (for example, a test schema and a development schema) can hold records that are equivalent in a business sense, but have different keys. This can be mitigated by not exporting surrogate keys, except as transient data (most obviously, in executing applications that have a "live" connection to the database).

Query optimization

Relational databases assume a unique index is applied to a table's primary key. The unique index serves two purposes: (i) to enforce entity integrity, since primary key data must be unique across rows and (ii) to quickly search for rows when queried. Since surrogate keys replace a table's identifying attributes—the natural key—and since the identifying attributes are likely to be those queried, then the query optimizer is forced to perform a full table scan when fulfilling likely queries. The remedy to the full table scan is to apply indexes on the identifying attributes, or sets of them. Where such sets are themselves a candidate key, the index can be a unique index.

These additional indexes, however, will take up disk space and slow down inserts and deletes.

Normalization

The presence of a surrogate key can result in the database administrator forgetting to establish, or accidentally removing, a secondary unique index on the natural key of the table. Without a unique index on the natural key, duplicate rows can appear and once present can be difficult to identify.

Business process modeling

Because surrogate keys are unnatural, flaws can appear when modeling the business requirements. Business requirements, relying on the natural key, then need to be translated to the surrogate key. A strategy is to draw a clear distinction between the logical model (in which surrogate keys do not appear) and the physical implementation of that model, to ensure that the logical model is correct and reasonably well normalised, and to ensure that the physical model is a correct implementation of the logical model.

Inadvertent disclosure

Proprietary information can be leaked if sequential key generators are used. By subtracting a previously generated sequential key from a recently generated sequential key, one could learn the number of rows inserted during that time period. This could expose, for example, the number of transactions or new accounts per period. There are a few ways to overcome this problem:

- Increase the sequential number by a random amount.
- Generate a completely random primary key. However, to prevent duplication which would cause an insert rejection, a randomly generated primary key must either be queried (to check that it is not already in use), or the key must contain enough entropy that one can be confident that collisions will not happen.

Inadvertent assumptions

One might incorrectly infer from sequentially generated surrogate keys that events with a higher primary key value occurred after events with a lower primary key value. The sequential primary key implies nothing of the kind. It is possible for inserts to fail and leave gaps, and for those gaps to be filled at some later time. A sequential key value is not a reliable indicator of chronology. If chronology is important, rely not upon the sequential key but upon a timestamp. A random key would prevent a person from making the assumption that the key has some bearing to real-world chronology only if the person making the assumption is aware that the key is indeed random and has no bearing upon chronology. A randomly generated primary key must be queried before assigned to prevent duplication and cause an insert rejection.[*citation needed*]

Variable data publishing

Variable-data publishing (VDP) (also known as database publishing) is a term referring to the output of a variable composition system. While these systems can produce both electronically viewable and hard-copy (print) output, the "variable-data publishing" term today often distinguishes output destined for electronic viewing, rather than that which is destined for hard-copy print (e.g. variable data printing).

Essentially the same techniques are employed to perform variable-data publishing, as those utilized with variable data printing. The difference is in the interpretation for output. While variable-data printing may be interpreted to produce various print streams or page-description files (e.g. AFP/IPDS, PostScript, PCL), variable-data publishing produces electronically viewable files, most commonly seen in the forms of PDF, HTML, or XML.

Variable-data composition involves the use of data to conditionally:

- exhibit text (static blocks and/or variable content)
- exhibit images
- select fonts
- select colors
- format page layouts & flows

Variable-data may be as simple as an address block or salutation. However, it can be any or all of the document's textual content—including words, sentences, paragraphs, pages, or the entire document. In other words, it can make up as little or as much of the document as the composer desires. Variable data may also be used to exhibit various images, such as logos, products, or membership photos. Further, variable-data can be used to build rule-based design schemes, including fonts, colors, and page formats. The possibilities are vast.

The variable-data tools available today, make it possible to perform variable-data composition at nearly every stage of document production. However, the level of control that can be achieved varies, based upon how far into the document production process a variable-data tool is deployed. For example, if variable-data insertion occurs just prior to output...it's not likely that the text flow or layout can be altered with nearly as much control as would be available at the time of initial document composition.

Many organizations will produce multiple forms of output (aka: multi-channel output), for the same document. This ensures that the published content is available to recipients via any form of access method they might require. When multi-channel output is utilized, integrity between those output channels often becomes important.

Variable-data publishing may be performed on everything from a personal computer to a mainframe system. However, the speed and practical output volumes which can be achieved are directly affected by the computer power utilized.

Origin of the concept

The term variable-data publishing was likely an offshoot of the term "variable-data printing", first introduced to the printing industry by Frank Romano, Professor Emeritus, School of Print Media, at the College of Imaging Arts and Sciences at Rochester Institute of Technology.[*citation needed*] However, the concept of merging static document elements and variable document elements predates the term and has seen various implementations ranging from simple desktop 'mail merge', to complex mainframe applications in the financial and banking industry. In the past, the term VDP has been most closely associated with digital printing machines. However, in the past 3 years the application of this technology has spread to web pages, emails, and mobile messaging.

Semantic warehousing

In data management, **semantic warehousing** is a methodology of digitalized text data using similar functions to Data warehousing (DW), such as ETL(Extract, transform, load), ODS(Operational data store), and MODEL. Key value operation is less useful for the digitalized text. Semantic warehousing is different from DW in that semantic information base from text(semantic) data.

Semantic warehousing is different from search engine in that semantic information base from text data is stored in the database.(DBMS)

Though data is most important word in computing era, it can not explain human knowledge well yet. Data(numeric data) is key element of computing systems for certain organization (especially companies, enterprises), but no performance oriented organization needs something to gather and use knowledge or human feeling. Semantic warehousing will be equally or more important than data warehousing in the future.

Definition

Semantic warehousing is a conceptual and functional term meaning to gather from a source, semantically defining and providing information from digitalized text based knowledge data.

Background

Data warehousing (DW) is popular these days. Gathering data from systems that generate transactions, data warehouses become a base of information. Key of data warehouse is a model (called datamart) and that model is made up of dimensions(key) and measures(value). Users get information from the models by doing certain operations. Online analytical processing (OLAP) is most the important operation for the users to get information from the DW models. Handling dimensions with pivoting, drilling, slice & dice operations users get numeric values like sales amounts, growth rates, etc. Various areas of this world defined and appeared on the world wide web(Internet), eager to present their contents in a semantic way. Briefly speaking semantic warehousing has datawarehousing boby and search head and ontology features.

Data warehousing contributed to companies' business values and lots of solutions and tools are commercially successful. Analysis of internal data delivers a certain level of business values, on the contrary to this Semantic warehousing environment has not yet matured. Capacity of social data is increasing rapidly and various efforts of finding value from that data are made widely known as Big data, etc. Semantic warehousing can be main stream of treat data and intelligence of social world in the future though it is defined with other keywords.

Practices

Some hospital implement semantic warehousing for clinical information (SWCI). Medical information is now knowledge network level. UMLS define semantic knowledge network of medical language. Currently medical information stored in database and not fully used for clinic. Semantic warehousing is next stage of digitalized medical information.

SWCI is a name of conceptual system of clinical information.
Named by Juhan Kim (SNUH, Seoul National University Hospital) and Bohyon Hwang, YongChan Keum on 2008.

Defined architecture on SWCI ;

1. Semantic-oriented cleansing
2. Semantic-oriented meta management
3. Clinical(Medical) knowledge basement
4. Semantic-oriented user intelligence

Connected area

- Semantic web
- Ontology
- Knowledge
- Medical and healthcare : EMR (Electronic Medical Record), EHR (Electronic Health Record)
- Data warehouse
- AI (artificial intelligence)

Scriptella

Scriptella

scriptella	
Stable release	1.1 / 28 December 2012
Operating system	Cross-platform
Type	ETL, Data migration and SQL.
License	Apache Software License
Website	scriptella.javaforge.com [1]

Scriptella is an open source ETL (Extract-Transform-Load) and script execution tool written in Java. Its primary focus is simplicity. It doesn't require the user to learn another complex XML-based language to use it, but allows the use of SQL or another scripting language suitable for the data source to perform required transformations.

Potential users should be aware that Scriptella does not offer any graphical user interface.

Typical use

- Database migration.
- Database creation/update scripts.
- Cross-database ETL operations, import/export.
- Alternative for Ant <sql> task.
- Automated database schema upgrade.

Features

- **Simple XML syntax** for scripts. Add dynamics to your existing SQL scripts by creating a thin wrapper XML file:

```
<!DOCTYPE etl SYSTEM "http://scriptella.javaforge.com/dtd/etl.dtd">
<etl>
    <connection driver="$driver" url="$url" user="$user" password="$password"/>
    <script>
        <include href="PATH_TO_YOUR_SCRIPT.sql"/>
        -- And/or directly insert SQL statements here
    </script>
</etl>
```

- Support for **multiple datasources** (or multiple connections to a single database) in an ETL file.
- Support for many useful **JDBC features**, e.g. parameters in SQL including file blobs and JDBC escaping.
- **Performance.** Performance and low memory usage are one of the primary goals.
- Support for **evaluated expressions and properties** (JEXL syntax)
- Support for **cross-database ETL scripts** by using <dialect> elements

- **Transactional execution**
- **Error handling** via <onerror> elements
- **Conditional scripts/queries execution** (similar to Ant if/unless attributes but more powerful)
- **Easy-to-Use** as a standalone tool or Ant task. No deployment/installation required.
- **Easy-To-Run** ETL files directly from Java code.
- **Built-in adapters for popular databases** for a tight integration. Support for any database with JDBC/ODBC compliant driver.
- Service Provider Interface (SPI) for interoperability with non-JDBC DataSources and integration with scripting languages. Out of the box support for JSR 223 (Scripting for the Java Platform) compatible languages.
- Built-In CSV, TEXT, XML, LDAP, Lucene, Velocity, JEXL and Janino providers. Integration with Java EE, Spring Framework, JMX and JNDI for enterprise ready scripts.

Data Quality

Bit rot

Bit rot, also **bit decay**, **data rot**, or **data decay**, is a colloquial computing phrase for the gradual decay of storage media.[*citation needed*]

The *Jargon File,* a compendium of hacker's lore, defines "bit rot" as a jocular explanation for the software rot, the degradation of a software program over time even if "nothing has changed"; an explanations is that bits are subject to decay as if they were radioactive.

Decay of storage media

Bit rot is often defined as the event in which the small electric charge of a bit in memory disperses, possibly altering program code or stored data. The hypothesis that semiconductor RAM may occasionally be altered by cosmic rays is also known as soft error.

Bit rot can also be used to describe the phenomenon of storage media gradually decaying over the duration of many years. The cause of bit rot varies depending on the medium:

- *Solid state media* – such as EPROMs, flash memory and other solid-state drives – stores data using electrical charges, which can slowly leak away due to imperfect insulation. The chip itself is not affected by this, so re-programming it once per decade or so will prevent bit rot. The biggest problem can be finding a clean copy of the chip from which to make the copy; frequently, by the time the user discovers the bit rot, there are no un-damaged chips to use as a master.
- *Magnetic media* – such as floppy disks and magnetic tapes – may experience bit rot as bits lose their magnetic orientation. Periodic refreshing by rewriting the data can alleviate this problem. Also, in warm and humid conditions these media are prone to literal rotting.
- *Optical media* – such as CD-R, DVD-R and BD-R – may experience bit rot from the breakdown of the material onto which the data is stored. This can be mitigated by storing discs in a dark, cool location with low humidity. "Archival quality" discs are also available, but do not necessarily provide a permanent solution to the onset of bit rot or other types of data corruption beyond a certain amount of time. Some media (such as M-DISC) are designed to improve longevity over DVD-R and BD-R.
- *Paper media* – such as punched cards and punched tape – may also experience literal rotting. Mylar punched tape is available for use in this situation.

Component and system failures

Most disk, disk controller and higher level systems are subject to a small degree of unrecoverable failure. With ever-growing disk capacities, file sizes, and increases in the amount of data stored on a disk, the likelihood of the occurrence of bit rot and other forms of uncorrected and undetected data corruption increases.

Higher level software systems may be employed to mitigate the risk of such underlying failures by increasing redundancy and implementing integrity checking and self-repairing algorithms. The ZFS file system was designed to address many of these issues. The Btrfs file system also includes data protection and recovery mechanisms, and so does ReFS.

References

Cleansing and Conforming Data

This process of **Cleansing and Conforming Data** change data on its way from source system(s) to the data warehouse and can also be used to identify and record errors about data. The latter information can be used to fix how the source system(s) work(s).

Good quality source data has to do with “Data Quality Culture” and must be initiated at the top of the organization. It is not just a matter of implementing strong validation checks on input screens, because almost no matter how strong these checks are, they can often still be circumvented by the users.

There is a nine-step guide for organizations that wish to improve data quality:

- Declare a high level commitment to a data quality culture
- Drive process reengineering at the executive level
- Spend money to improve the data entry environment
- Spend money to improve application integration
- Spend money to change how processes work
- Promote end-to-end team awareness
- Promote interdepartmental cooperation
- Publicly celebrate data quality excellence
- Continuously measure and improve data quality

Data Cleansing System

The essential job of this system is to find a suitable balance between fixing dirty data and maintaining the data as close as possible to the original data from the source production system. This is a challenge for the Extract, transform, load architect.

The system should offer an architecture that can cleanse data, record quality events and measure/control quality of data in the data warehouse.

A good start is to perform a thorough data profiling analysis that will help define to the required complexity of the data cleansing system and also give an idea of the current data quality in the source system(s).

Quality Screens

Part of the data cleansing system is a set of diagnostic filters known as quality screens. They each implement a test in the data flow that, if it fails records an error in the Error Event Schema. Quality screens are divided into three categories:

- Column screens. Testing the individual column, e.g. for unexpected values like NULL values; non-numeric values that should be numeric; out of range values; etc.
- Structure screens. These are used to test for the integrity of different relationships between columns (typically foreign/primary keys) in the same or different tables. They are also used for testing that a group of columns is valid according to some structural definition it should adhere.
- Business rule screens. The most complex of the three tests. They test to see if data, maybe across multiple tables, follow specific business rules. An example could be, that if a customer is marked as a certain type of customer, the business rules that define this kind of customer should be adhered.

When a quality screen records an error, it can either stop the dataflow process, send the faulty data somewhere else than the target system or tag the data. The latter option is considered the best solution because the first option requires, that someone has to manually deal with the issue each time it occurs and the second implies that data are missing from the target system (integrity) and it is often unclear, what should happen to these data.

Criticism of existing tools and processes

The main reasons cited are:

- **Project costs**: costs typically in the hundreds of thousands of dollars
- **Time**: lack of enough time to deal with large-scale data-cleansing software
- **Security**: concerns over sharing information, giving an application access across systems, and effects on legacy systems

Error Event Schema

This schema is the place, where all error events thrown by quality screens, are recorded. It consists of an Error Event Fact table with foreign keys to three dimension tables that represent date (when), batch job (where) and screen (who produced error). It also holds information about exactly when the error occurred and the severity of the error. In addition there is an Error Event Detail Fact table with a foreign key to the main table that contains detailed information about in which table, record and field the error occurred and the error condition.

Data auditing

Data auditing is the process of conducting a data audit to assess how company's data is fit for given purpose. This involves profiling the data and assessing the impact of poor quality data on the organization's performance and profits.

Data cleansing

Data cleansing, **data cleaning** or **data scrubbing** is the process of detecting and correcting (or removing) corrupt or inaccurate records from a record set, table, or database. Used mainly in databases, the term refers to identifying incomplete, incorrect, inaccurate, irrelevant, etc. parts of the data and then replacing, modifying, or deleting this dirty data.

After cleansing, a data set will be consistent with other similar data sets in the system. The inconsistencies detected or removed may have been originally caused by user entry errors, by corruption in transmission or storage, or by different data dictionary definitions of similar entities in different stores.

Data cleansing differs from data validation in that validation almost invariably means data is rejected from the system at entry and is performed at entry time, rather than on batches of data.

The actual process of data cleansing may involve removing typographical errors or validating and correcting values against a known list of entities. The validation may be strict (such as rejecting any address that does not have a valid postal code) or fuzzy (such as correcting records that partially match existing, known records).

Some data cleansing solutions will clean data by cross checking with a validated data set. Also data enhancement, where data is made more complete by adding related information, is a common data cleansing practice. For example, appending addresses with phone numbers related to that address.

Data cleansing may also involve activities like, harmonization of data, and standardization of data. For example, harmonization of short codes (St, rd etc.) to actual words (street, road). Standardization of data is a means of changing a reference data set to a new standard, ex, use of standard codes.

Motivation

Administratively, incorrect or inconsistent data can lead to false conclusions and misdirected investments on both public and private scales. For instance, the government may want to analyze population census figures to decide which regions require further spending and investment on infrastructure and services. In this case, it will be important to have access to reliable data to avoid erroneous fiscal decisions.

In the business world, incorrect data can be costly. Many companies use customer information databases that record data like contact information, addresses, and preferences. For instance, if the addresses are inconsistent, the company will suffer the cost of resending mail or even losing customers.

There are packages available so you can cleanse/wash address data while you enter it into your system. This is normally done via an API and will prompt staff as they type the address.

Data quality

High-quality data needs to pass a set of quality criteria. Those include:

- **Validity**: The degree to which the measures conform to defined business rules or constraints (see also Validity (statistics). When modern database technology is used to design data-capture systems, validity is fairly easy to ensure: invalid data arises mainly in legacy contexts (where constraints were not implemented in software) or where inappropriate data-capture technology was used (e.g., spreadsheets, where it is very hard to limit what a user chooses to enter into a cell).Data constraints fall into the following categories:
  - *Data-Type Constraints* – e.g., values in a particular column must be of a particular datatype, e.g., Boolean, numeric (integer or real), date, etc.
  - *Range Constraints:* typically, numbers or dates should fall within a certain range. That is, they have minimum and/or maximum permissible values.
  - *Mandatory Constraints:* Certain columns cannot be empty.
  - *Unique Constraints:* A field, or a combination of fields, must be unique across a dataset. For example, no two persons can have the same social security number.
  - *Set-Membership constraints*: The values for a column come from a set of discrete values or codes. For example, a person's gender may be Female, Male or Unknown (not recorded).
  - *Foreign-key constraints*: This is the more general case of set membership. The set of values in a column is defined in a column of another table that contains unique values. For example, in a US taxpayer database, the "state" column is required to belong to one of the US's defined states or territories: the set of permissible states/territories is recorded in a separate States table. The term foreign key is borrowed from relational database terminology: follow the hyperlink for more details.
  - Regular expression patterns: Occasionally, text fields will have to be validated this way. For example, phone numbers may be required to have the pattern (999) 999-9999.
- **Decleansing** is detecting errors and syntactically removing them for better programming.
  - Cross-field validation: Certain conditions that utilize multiple fields must hold. For example, in laboratory medicine, the sum of the components of the differential white blood cell count must be equal to 100 (since they are all percentages). In a hospital database, a patient's date of discharge from hospital cannot be earlier than the date of admission.
- **Accuracy**: The degree of conformity of a measure to a standard or a true value - see also Accuracy and precision. Accuracy is very hard to achieve through data-cleansing in the general case, because it requires accessing an external source of data that contains the true value: such "gold standard" data is often unavailable. Accuracy has been achieved in some cleansing contexts, notably customer contact data, by using external databases that match up zip codes to geographical locations (city and state), and also help verify that street addresses within these zip codes actually exist.
- **Completeness**: The degree to which all required measures are known (see also Completeness). Incompleteness is almost impossible to fix with data cleansing methodology: one cannot infer facts that were not captured when the data in question was initially recorded. (In some contexts, e.g., interview data, it may be possible to fix incompleteness by going back to the original source of data, i,e., re-interviewing the subject, but even this does not guarantee success because of problems of recall - e.g., in an interview to gather data on food consumption, no one is likely to remember exactly what one ate six months ago. In the case of systems that insist certain columns should not be empty, one may work around the problem by designating a value that indicates "unknown" or "missing", but supplying of default values does not imply that the data has been made complete.
- **Consistency**: The degree to which a set of measures are equivalent in across systems (see also Consistency). Inconsistency occurs when two data items in the data set contradict each other: e.g., a customer is recorded in two different systems as having two different current addresses, and only one of them can be correct. Fixing inconsistency is not always possible: it requires a variety of strategies - e.g., deciding which data were recorded

more recently, which data source is likely to be most reliable (the latter knowledge may be specific to a given organization), or simply trying to find the truth by testing both data items (e.g., calling up the customer).

- **Uniformity**: The degree to which a set data measures are specified using the same units of measure in all systems (see also Unit of measure). In datasets pooled from different locales, weight may be recorded either in pounds or kilos, and must be converted to a single measure using an arithmetic transformation.

The term **Integrity** encompasses accuracy, consistency and some aspects of validation (see also Data integrity) but is rarely used by itself in data-cleansing contexts because it is insufficiently specific. (For example, "referential integrity" is a term used to refer to the enforcement of foreign-key constraints above.)

The process of data cleansing

- **Data auditing**: The data is audited with the use of statistical and database methods to detect anomalies and contradictions: this eventually gives an indication of the characteristics of the anomalies and their locations. Several commercial software packages will let you specify constraints of various kinds (using a grammar that conforms to that of a standard programming language, e.g., JavaScript or Visual Basic) and then generate code that checks the data for violation of these constraints. This process is referred to below in the bullets "workflow specification" and "workflow execution." For users who lack access to high-end cleansing software, Microcomputer database packages such as Microsoft Access or FileMaker Pro will also let you perform such checks, on a constraint-by-constraint basis, interactively with little or no programming required in many cases.
- **Workflow specification**: The detection and removal of anomalies is performed by a sequence of operations on the data known as the workflow. It is specified after the process of auditing the data and is crucial in achieving the end product of high-quality data. In order to achieve a proper workflow, the causes of the anomalies and errors in the data have to be closely considered.
- **Workflow execution**: In this stage, the workflow is executed after its specification is complete and its correctness is verified. The implementation of the workflow should be efficient, even on large sets of data, which inevitably poses a trade-off because the execution of a data-cleansing operation can be computationally expensive.
- **Post-processing and controlling**: After executing the cleansing workflow, the results are inspected to verify correctness. Data that could not be corrected during execution of the workflow is manually corrected, if possible. The result is a new cycle in the data-cleansing process where the data is audited again to allow the specification of an additional workflow to further cleanse the data by automatic processing.

Decleanse

- **Parsing**: for the detection of syntax errors. A parser decides whether a string of data is acceptable within the allowed data specification. This is similar to the way a parser works with grammars and languages.
- **Data transformation**: Data transformation allows the mapping of the data from its given format into the format expected by the appropriate application. This includes value conversions or translation functions, as well as normalizing numeric values to conform to minimum and maximum values.
- **Duplicate elimination**: Duplicate detection requires an algorithm for determining whether data contains duplicate representations of the same entity. Usually, data is sorted by a key that would bring duplicate entries closer together for faster identification.
- **Statistical methods**: By analyzing the data using the values of mean, standard deviation, range, or clustering algorithms, it is possible for an expert to find values that are unexpected and thus erroneous. Although the correction of such data is difficult since the true value is not known, it can be resolved by setting the values to an average or other statistical value. Statistical methods can also be used to handle missing values which can be replaced by one or more plausible values, which are usually obtained by extensive data augmentation algorithms.

Challenges and problems

- **Error correction and loss of information**: The most challenging problem within data cleansing remains the correction of values to remove duplicates and invalid entries. In many cases, the available information on such anomalies is limited and insufficient to determine the necessary transformations or corrections, leaving the deletion of such entries as a primary solution. The deletion of data, though, leads to loss of information; this loss can be particularly costly if there is a large amount of deleted data.
- **Maintenance of cleansed data**: Data cleansing is an expensive and time-consuming process. So after having performed data cleansing and achieving a data collection free of errors, one would want to avoid the re-cleansing of data in its entirety after some values in data collection change. The process should only be repeated on values that have changed; this means that a cleansing lineage would need to be kept, which would require efficient data collection and management techniques.
- **Data cleansing in virtually integrated environments**: In virtually integrated sources like IBM's DiscoveryLink, the cleansing of data has to be performed every time the data is accessed, which considerably decreases the response time and efficiency.
- **Data-cleansing framework**: In many cases, it will not be possible to derive a complete data-cleansing graph to guide the process in advance. This makes data cleansing an iterative process involving significant exploration and interaction, which may require a framework in the form of a collection of methods for error detection and elimination in addition to data auditing. This can be integrated with other data-processing stages like integration and maintenance.

Major players and technologies

- IBM - InfoSphere Information Server is a tool that provides data cleansing and data monitoring services.
- SAS - Integration with DataFlux suite of data integration, cleansing, data governance, and data quality services.
- Oracle – Data quality solutions work with both customer and product data.
- Experian – QAS Clean service provides CASS certification (Coding Accuracy Support System) for address verification services.
- D&B – Offers data management transition and data quality programs
- Equifax – Offers database management, data integration, and analytics solutions

Data corruption

Data corruption refers to errors in computer data that occur during writing, reading, storage, transmission, or processing, which introduce unintended changes to the original data. Computer, transmission and storage systems use a number of measures to provide end-to-end data integrity, or lack of errors.

In general, when data corruption occurs, a file containing that data will produce unexpected results when accessed by the system or the related application; results could range from a minor loss of data to a system crash. For example, if a Microsoft Word file is corrupted, when a person tries to open that file with MS Word, they may get an error message, thus the file would not be opened or the file might open with some of the data corrupted. The image to the right is a corrupted jpg file in which most of the information has been lost.

Photo data corruption; in this case, a result of a failed data recovery from a hard disk drive

Some programs can give a suggestion to repair the file automatically (after the error), and some programs cannot repair it. It depends on the level of corruption, and the built-in functionality of the application to handle the error. There are various causes of the corruption.

Overview

There are two types of data corruption associated with computer systems:

Undetected

> Also known as *silent data corruption;* such problems are the most dangerous errors as there is no indication that the data is incorrect.

Detected

> Detected errors may be permanent with the loss of data or maybe temporary where some part of the system is able to detect and correct the error, in this latter case there is no data corruption.

Data corruption can occur at any level in a system, from the host to the storage medium. Modern systems attempt to detect corruption at many layers and then recover or correct the corruption; this is almost always successful but very rarely the information arriving in the systems memory is corrupted and can cause unpredictable results.

Data corruption during transmission has a variety of causes. Interruption of data transmission causes information loss. Environmental conditions can interfere with data transmission, especially when dealing with wireless transmission methods. Heavy clouds can block satellite transmissions. Wireless networks are susceptible to interference from devices such as microwave ovens.

Hardware and software failure are the two main causes for data loss. Background radiation, head crashes, and aging or wear of the storage device fall into the former category, while software failure typically occurs due to bugs in the

code. Cosmic rays cause most soft errors in DRAM.

Silent data corruption

The worst type of errors are those that go unnoticed, and are not even detected by the disk firmware or the host operating system. This is known as *silent corruption*.

There are many error sources beyond the disk storage subsystem itself. For instance, cables might be slightly loose, the power supply might be unreliable, external vibrations such as a loud sound, the network might introduce undetected corruption, cosmic radiation and many other causes of soft memory errors, etc. In 39,000 storage systems that were analyzed, firmware bugs accounted for 5–10% of storage failures. All in all, the error rates as observed by a CERN study on silent corruption are far higher than one in every 10^{16} bits. Webshop Amazon.com confirms these high data corruption rates.

The main problem is that hard disk capacities have increased substantially, but their error rates remain unchanged. The data corruption rate has always been roughly constant in time, meaning that modern disks are not much safer than old disks. In old disks the probability of data corruption was very small because they stored tiny amounts of data. In modern disks the probability is much larger because they store much more data, whilst not being safer. That way, silent data corruption has not been a serious concern while storage devices remained relatively small and slow. Hence, the users of small disks very rarely faced silent corruption, so the data corruption was not considered a problem that required a solution. But in modern times and with the advent of larger drives and very fast RAID setups, users are capable of transferring 10^{16} bits in a reasonably short time, thus easily reaching the data corruption thresholds.

As an example, ZFS creator Jeff Bonwick stated that the fast database at Greenplum – a database software company specializing in large-scale data warehousing and analytics – faces silent corruption every 15 minutes. As another example, a real-life study performed by NetApp on more than 1.5 million HDDs over 41 months found more than 400,000 silent data corruptions, out of which more than 30,000 were not detected by the hardware RAID controller. Another study, performed by CERN over six months and involving about 97 petabytes of data, found about 1.2×10^{-9} of involved data (or about 116 gigabytes) becoming permanently corrupted.

Countermeasures

When data corruption behaves as a Poisson process, where each bit of data has an independently low probability of being changed, data corruption can generally be detected by the use of checksums, and can often be corrected by the use of error correcting codes.

If an uncorrectable data corruption is detected, procedures such as automatic retransmission or restoration from backups can be applied. Certain levels of RAID disk arrays have the ability to store and evaluate parity bits for data across a set of hard disks and can reconstruct corrupted data upon the failure of a single or multiple disks, depending on the level of RAID implemented.

Many errors are detected and corrected by the hard disk drives using the ECC/CRC codes which are stored on disk for each sector. If the disk drive detects multiple read errors on a sector it may make a copy of the failing sector on another part of the disk- remapping the failed sector of the disk to a spare sector without the involvement of the operating system (though this may be delayed until the next write to the sector).

This "silent correction" can lead to other problems if disk storage is not managed well, as the disk drive will continue to remap sectors until it runs out of spares, at which time the temporary correctable errors can turn into permanent ones as the disk drive deteriorates. S.M.A.R.T. provides a standardized way of monitoring the health of a disk drive, and there are tools available for most operating systems to automatically check the disk drive for impending failures by watching for deteriorating SMART parameters.

Some filesystems (including Btrfs and ZFS) provide internal data and metadata checksumming, what is used for detecting silent data corruption; if a corruption is detected that way and internal RAID mechanisms provided by those filesystems are also used, such filesystems can additionally reconstruct corrupted data in a transparent way. This approach allows improved data integrity protection covering the entire data paths, which is usually known as *end-to-end data protection*.

"Data scrubbing" is another method to reduce the likelihood of data corruption, as disk errors are caught and recovered from, before multiple errors accumulate and overwhelm the number of parity bits. Instead of parity being checked on each read, the parity is checked during a regular scan of the disk, often done as a low priority background process. Note that the "data scrubbing" operation activates a parity check. If a user simply runs a normal program that reads data from the disk, then the parity would not be checked unless parity-check-on-read was both supported and enabled on the disk subsystem.

If appropriate mechanisms are employed to detect and remedy data corruption, data integrity can be maintained. This is particularly important in commercial applications (e.g. banking), where an undetected error could either corrupt a database index or change data to drastically affect an account balance, and in the use of encrypted or compressed data, where a small error can make an extensive dataset unusable.

Data integrity

Data integrity refers to maintaining and assuring the accuracy and consistency of data over its entire life-cycle, and is a critical aspect to the design, implementation and usage of any system which stores, processes or retrieves data. The term **data integrity** is broad in scope and may have widely different meanings depending on the specific context - even under the same general umbrella of computing. This article provides only a broad overview of some of the different types and concerns of data integrity.

Data integrity is the opposite of data corruption, which is a form of data loss. The overall intent of any data integrity technique is the same: ensure data is recorded exactly as intended (such as a database correctly rejecting mutually exclusive possibilities,) and upon later retrieval, ensure the data is the same as it was when it was originally recorded. In short, data integrity aims to prevent unintentional changes to information. Data integrity is not to be confused with data security, the discipline of protecting data from unauthorized parties.

Any unintended changes to data as the result of a storage, retrieval or processing operation, including malicious intent, unexpected hardware failure, and human error, is failure of data integrity. If the changes are the result of unauthorized access, it may also be a failure of data security. Depending on the data involved this could manifest itself as benign as a single pixel in an image appearing a different color than was originally recorded, to the loss of vacation pictures or a business-critical database, to even catastrophic loss of human life in a Life-critical system.

Physical vs. logical integrity

Data integrity can be roughly divided into two overlapping categories:

Physical integrity - deals with challenges associated with correctly storing and fetching the data itself. Challenges with physical integrity may include electromechanical faults, design flaws, material fatigue, corrosion, power outages, natural disasters, acts of war and terrorism, and other special environmental hazards such as ionizing radiation, extreme temperatures, pressures and g-forces. Ensuring physical integrity includes methods such as redundant hardware, an uninterruptible power supply, certain types of RAID arrays, radiation hardened chips, ECC memory, use of a clustered file system, using file systems that employ block level checksums such as ZFS, storage

arrays that compute parity calculations such as Exclusive or or use a Cryptographic hash function and even having a watchdog timer on critical subsystems.

Physical integrity often makes extensive use of error detecting algorithms known as error-correcting codes. Human induced data integrity errors are often detected through the use of simpler check digits and algorithms used to detect them such as the Damm algorithm or Luhn algorithm. These are used to maintain data integrity after manual transcription from one computer system to another by a human intermediary. Examples include credit card and bank routing numbers. Computer induced transcription errors can be detected through hash functions.

In production systems these techniques are used in combination to ensure various degrees of data integrity. For example a computer file system may configured on a fault tolerant RAID array, but might not provide block level checksums to detect and prevent silent data corruption. A database management system might be ACID compliant, but the raid controller or hard drive's internal write-cache might not be.

Logical integrity - concerned with the correctness or rationality of a piece of data, given a particular context. This includes topics such as referential integrity and entity integrity in a relational database or correctly ignoring impossible sensor data in robotic systems. These concerns involve making certain the data "makes sense" given its environment. Challenges include software bugs, design flaws, human error. Common methods of ensuring logical integrity include things such as a Check constraint, foreign key constraint, program assertion (computing) and other runtime sanity checks.

Both physical and logical integrity often share many common challenges such as human error, design flaws and both must appropriately deal with concurrent requests to record and retrieve data, the later of which is its own subject entirely. See mutex and Copy-on-write.

Databases

Data integrity contains guidelines for data retention, specifying or guaranteeing the length of time of data can be retained in a particular database. It specifies what can be done with data values when its validity or usefulness expires. In order to achieve data integrity, these rules are consistently and routinely applied to all data entering the system, and any relaxation of enforcement could cause errors in the data. Implementing checks on the data as close as possible to the source of input (such as human data entry), causes less erroneous data to enter the system. Strict enforcement of data integrity rules causes the error rates to be lower, resulting in time saved troubleshooting and tracing erroneous data and the errors it causes algorithms.

Data integrity also includes rules defining the relations a piece of data can have, to other pieces of data, such as a *Customer* record being allowed to link to purchased *Products*, but not to unrelated data such as *Corporate Assets*. Data integrity often includes checks and correction for invalid data, based on a fixed schema or a predefined set of rules. An example being textual data entered where a date-time value is required. Rules for data derivation are also applicable, specifying how a data value is derived based on algorithm, contributors and conditions. It also specifies the conditions on how the data value could be re-derived.

Types of integrity constraints

Data integrity is normally enforced in a database system by a series of integrity constraints or rules. Three types of integrity constraints are an inherent part of the relational data model: entity integrity, referential integrity and domain integrity:

- *Entity integrity* concerns the concept of a primary key. Entity integrity is an integrity rule which states that every table must have a primary key and that the column or columns chosen to be the primary key should be unique and not null.
- *Referential integrity* concerns the concept of a foreign key. The referential integrity rule states that any foreign-key value can only be in one of two states. The usual state of affairs is that the foreign key value refers to

a primary key value of some table in the database. Occasionally, and this will depend on the rules of the data owner, a foreign-key value can be null. In this case we are explicitly saying that either there is no relationship between the objects represented in the database or that this relationship is unknown.

- *Domain integrity* specifies that all columns in relational database must be declared upon a defined domain. The primary unit of data in the relational data model is the data item. Such data items are said to be non-decomposable or atomic. A domain is a set of values of the same type. Domains are therefore pools of values from which actual values appearing in the columns of a table are drawn.

If a database supports these features it is the responsibility of the database to insure data integrity as well as the consistency model for the data storage and retrieval. If a database does not support these features it is the responsibility of the applications to ensure data integrity while the database supports the consistency model for the data storage and retrieval.

Having a single, well-controlled, and well-defined data-integrity system increases

- stability (one centralized system performs all data integrity operations)
- performance (all data integrity operations are performed in the same tier as the consistency model)
- re-usability (all applications benefit from a single centralized data integrity system)
- maintainability (one centralized system for all data integrity administration).

As of 2012[1], since all modern databases support these features (see Comparison of relational database management systems), it has become the *de-facto* responsibility of the database to ensure data integrity. Out-dated and legacy systems that use file systems (text, spreadsheets, ISAM, flat files, etc.) for their consistency model lack any[*citation needed*] kind of data-integrity model. This requires organizations to invest a large amount of time, money, and personnel in building data-integrity systems on a per-application basis that effectively just duplicate the existing data integrity systems found in modern databases. Many companies, and indeed many database systems themselves, offer products and services to migrate out-dated and legacy systems to modern databases to provide these data-integrity features. This offers organizations substantial savings in time, money, and resources because they do not have to develop per-application data-integrity systems that must be re-factored each time business requirements change.

Examples

An example of a data-integrity mechanism is the parent-and-child relationship of related records. If a parent record owns one or more related child records all of the referential integrity processes are handled by the database itself, which automatically insures the accuracy and integrity of the data so that no child record can exist without a parent (also called being orphaned) and that no parent loses their child records. It also ensures that no parent record can be deleted while the parent record owns any child records. All of this is handled at the database level and does not require coding integrity checks into each applications.

File systems

Various research results show that neither widespread filesystems (including UFS, Ext, XFS, JFS and NTFS) nor hardware RAID solutions provide sufficient protection against data integrity problems.

Some filesystems (including Btrfs and ZFS) provide internal data and metadata checksumming, what is used for detecting silent data corruption and improving data integrity. If a corruption is detected that way and internal RAID mechanisms provided by those filesystems are also used, such filesystems can additionally reconstruct corrupted data in a transparent way. This approach allows improved data integrity protection covering the entire data paths, which is usually known as end-to-end data protection.

Data storage

Apart from data in databases, standards exist to address the integrity of data on storage devices.

Data profiling

Data profiling is the process of examining the data available in an existing data source (e.g. a database or a file) and collecting statistics and information about that data. The purpose of these statistics may be to:

1. Find out whether existing data can easily be used for other purposes
2. Improve the ability to search the data by tagging it with keywords, descriptions, or assigning it to a category
3. Give metrics on data quality including whether the data conforms to particular standards or patterns
4. Assess the risk involved in integrating data for new applications, including the challenges of joins
5. Assess whether metadata accurately describes the actual values in the source database
6. Understanding data challenges early in any data intensive project, so that late project surprises are avoided. Finding data problems late in the project can lead to delays and cost overruns.
7. Have an enterprise view of all data, for uses such as master data management where key data is needed, or data governance for improving data quality.

Data Profiling in Relation to Data Warehouse/Business Intelligence Development

Introduction

Data profiling is an analysis of the candidate data sources for a data warehouse to clarify the structure, content, relationships and derivation rules of the data.[1] Profiling helps not only to understand anomalies and to assess data quality, but also to discover, register, and assess enterprise metadata.[2] Thus the purpose of data profiling is both to validate metadata when it is available and to discover metadata when it is not.[3] The result of the analysis is used both strategically, to determine suitability of the candidate source systems and give the basis for an early go/no-go decision, and tactically, to identify problems for later solution design, and to level sponsors' expectations.

How to do Data Profiling

Data profiling utilizes different kinds of descriptive statistics such as minimum, maximum, mean, mode, percentile, standard deviation, frequency, and variation as well as other aggregates such as count and sum. Additional metadata information obtained during data profiling could be data type, length, discrete values, uniqueness, occurrence of null values, typical string patterns, and abstract type recognition.[4][5] The metadata can then be used to discover problems such as illegal values, misspelling, missing values, varying value representation, and duplicates. Different

analyses are performed for different structural levels. E.g. single columns could be profiled individually to get an understanding of frequency distribution of different values, type, and use of each column. Embedded value dependencies can be exposed in cross-columns analysis. Finally, overlapping value sets possibly representing foreign key relationships between entities can be explored in an inter-table analysis. Normally purpose-built tools are used for data profiling to ease the process.[6][7] The computation complexity increases when going from single column, to single table, to cross-table structural profiling. Therefore, performance is an evaluation criterion for profiling tools.

When to Conduct Data Profiling

According to Kimball, data profiling is performed several times and with varying intensity throughout the data warehouse developing process. A light profiling assessment should be undertaken as soon as candidate source systems have been identified right after the acquisition of the business requirements for the DW/BI. The purpose is to clarify at an early stage if the right data is available at the right detail level and that anomalies can be handled subsequently. If this is not the case the project might have to be canceled. More detailed profiling is done prior to the dimensional modeling process in order to see what it will require to convert data into the dimensional model, and extends into the ETL system design process to establish what data to extract and which filters to apply. An additional time to conduct data profiling is during the data warehouse development process after data has been loaded into staging, the data marts, etc. Doing so at these points in time helps assure that data cleaning and transformations have been done correctly according to requirements.

Benefits of Data Profiling

The benefits of data profiling is to improve data quality, shorten the implementation cycle of major projects, and improve understanding of data for the users. Discovering business knowledge embedded in data itself is one of the significant benefits derived from data profiling. Data profiling is one of the most effective technologies for improving data accuracy in corporate databases. Although data profiling is effective, then do remember to find a suitable balance and do not slip into “analysis paralysis”.

Data quality

Data are of high quality "if they are fit for their intended uses in operations, decision making and planning" (J. M. Juran). Alternatively, the data are deemed of high quality if they correctly represent the real-world construct to which they refer. Furthermore, apart from these definitions, as data volume increases, the question of *internal consistency* within data becomes paramount, regardless of fitness for use for any external purpose, e.g. a person's age and birth date may conflict within different parts of a database. The first views can often be in disagreement, even about the same set of data used for the same purpose. This article discusses the concept as it related to business data processing, although of course other data have various quality issues as well.

Definitions

This list is taken from the online book "Data Quality: High-impact Strategies". See also the Glossary of data quality terms [1]

- Degree of excellence exhibited by the data in relation to the portrayal of the actual scenario.
- The state of completeness, validity, consistency, timeliness and accuracy that makes data appropriate for a specific use.[2]
- The totality of features and characteristics of data that bears on their ability to satisfy a given purpose; the sum of the degrees of excellence for factors related to data.[3]
- The processes and technologies involved in ensuring the conformance of data values to business requirements and acceptance criteria.[4]
- Complete, standards based, consistent, accurate and time stamped.[5]

History

Before the rise of the inexpensive server, massive mainframe computers were used to maintain name and address data so that the mail could be properly routed to its destination. The mainframes used business rules to correct common misspellings and typographical errors in name and address data, as well as to track customers who had moved, died, gone to prison, married, divorced, or experienced other life-changing events. Government agencies began to make postal data available to a few service companies to cross-reference customer data with the National Change of Address registry (NCOA). This technology saved large companies millions of dollars compared to manually correcting customer data. Large companies saved on postage, as bills and direct marketing materials made their way to the intended customer more accurately. Initially sold as a service, data quality moved inside the walls of corporations, as low-cost and powerful server technology became available.

Companies with an emphasis on marketing often focus their quality efforts on name and address information, but data quality is recognized as an important property of all types of data. Principles of data quality can be applied to supply chain data, transactional data, and nearly every other category of data found in the enterprise. For example, making supply chain data conform to a certain standard has value to an organization by: 1) avoiding overstocking of similar but slightly different stock; 2) improving the understanding of vendor purchases to negotiate volume discounts; and 3) avoiding logistics costs in stocking and shipping parts across a large organization.

While name and address data has a clear standard as defined by local postal authorities, other types of data have few recognized standards. There is a movement in the industry today to standardize certain non-address data. The non-profit group GS1 is among the groups spearheading this movement.

For companies with significant research efforts, data quality can include developing protocols for research methods, reducing measurement error, bounds checking of the data, cross tabulation, modeling and outlier detection, verifying data integrity, etc.

Overview

There are a number of theoretical frameworks for understanding data quality. A systems-theoretical approach influenced by American pragmatism expands the definition of data quality to include information quality, and emphasizes the inclusiveness of the fundamental dimensions of accuracy and precision on the basis of the theory of science (Ivanov, 1972). One framework, dubbed "Zero Defect Data" (Hansen, 1991) adapts the principles of statistical process control to data quality. Another framework seeks to integrate the product perspective (conformance to specifications) and the service perspective (meeting consumers' expectations) (Kahn et al. 2002). Another framework is based in semiotics to evaluate the quality of the form, meaning and use of the data (Price and Shanks, 2004). One highly theoretical approach analyzes the ontological nature of information systems to define data quality rigorously (Wand and Wang, 1996).

A considerable amount of data quality research involves investigating and describing various categories of desirable attributes (or dimensions) of data. These lists commonly include accuracy, correctness, currency, completeness and relevance. Nearly 200 such terms have been identified and there is little agreement in their nature (are these concepts, goals or criteria?), their definitions or measures (Wang et al., 1993). Software engineers may recognise this as a similar problem to "ilities".

MIT has a Total Data Quality Management program, led by Professor Richard Wang, which produces a large number of publications and hosts a significant international conference in this field (International Conference on Information Quality, ICIQ). This program grew out of the work done by Hansen on the "Zero Defect Data" framework (Hansen, 1991).

In practice, data quality is a concern for professionals involved with a wide range of information systems, ranging from data warehousing and business intelligence to customer relationship management and supply chain management. One industry study estimated the total cost to the US economy of data quality problems at over US$600 billion per annum (Eckerson, 2002). Incorrect data – which includes invalid and outdated information – can originate from different data sources – through data entry, or data migration and conversion projects.[6]

In 2002, the USPS and PricewaterhouseCoopers released a report stating that 23.6 percent of all U.S. mail sent is incorrectly addressed.[7]

One reason contact data becomes stale very quickly in the average database – more than 45 million Americans change their address every year.[8]

In fact, the problem is such a concern that companies are beginning to set up a data governance team whose sole role in the corporation is to be responsible for data quality. In someWikipedia:Avoid weasel words organizations, this data governance function has been established as part of a larger Regulatory Compliance function - a recognition of the importance of Data/Information Quality to organizations.

Problems with data quality don't only arise from *incorrect* data. *Inconsistent* data is a problem as well. Eliminating data shadow systems and centralizing data in a warehouse is one of the initiatives a company can take to ensure data consistency.

Enterprises, scientists, and researchers are starting to participate within data curation communities to improve the quality of their common data.[9]

The market is going some way to providing data quality assurance. A number of vendors make tools for analysing and repairing poor quality data *in situ*, service providers can clean the data on a contract basis and consultants can advise on fixing processes or systems to avoid data quality problems in the first place. Most data quality tools offer a series of tools for improving data, which may include some or all of the following:

1. Data profiling - initially assessing the data to understand its quality challenges
2. Data standardization - a business rules engine that ensures that data conforms to quality rules
3. Geocoding - for name and address data. Corrects data to US and Worldwide postal standards

4. Matching or Linking - a way to compare data so that similar, but slightly different records can be aligned. Matching may use "fuzzy logic" to find duplicates in the data. It often recognizes that 'Bob' and 'Robert' may be the same individual. It might be able to manage 'householding', or finding links between husband and wife at the same address, for example. Finally, it often can build a 'best of breed' record, taking the best components from multiple data sources and building a single super-record.
5. Monitoring - keeping track of data quality over time and reporting variations in the quality of data. Software can also auto-correct the variations based on pre-defined business rules.
6. Batch and Real time - Once the data is initially cleansed (batch), companies often want to build the processes into enterprise applications to keep it clean.

There are several well-known authors and self-styled experts, with Larry English perhaps the most popular guru. In addition, the International Association for Information and Data Quality (IAIDQ) [10] was established in 2004 to provide a focal point for professionals and researchers in this field.

ISO 8000 is the international standard for data quality.

Data quality control

Data quality control is the process of controlling the usage of data with known quality measurement—for an application or a process. This process is usually done after a Data Quality Assurance (QA) process, which consists of discovery of data inconsistency and correction.

Data QA process provides following information to Data Quality Control (QC):

- Severity of inconsistency
- Incompleteness
- Accuracy
- Precision
- Missing / Unknown

The Data QC process uses the information from the QA process, then it decides to use the data for analysis or in an application or business process. For example, if a Data QC process finds the data contains too much error or inconsistency, it rejects the data to be processed. The usage of incorrect data could crucially impact output. For example, providing invalid measurements from several sensors to the automatic pilot feature on an aircraft could cause it to crash. Thus, establishing data QC process provides the protection of usage of data control and establishes safe information usage.

optimum use of data quality

Data Quality is a niche area which is the backbone for the integrity of the data management by covering gaps of data issues. This is the key piece that aids to data governance and monitors data to find exceptions undiscovered by current data management operations. Some data quality checks may translate as future business requirements. Below are the possible sections of data flows that need perennial DQ checks.

Data quality excludes activities done in business logic to avoid duplication of the check (redundancy) and better ROI (return of investment).

Data if sourced from database that has valid not null columns should not under go DQ check for completeness and precision. (redundancy). So it's done infrequently to discover database design issues or Source inconsistencies. (this should be avoided as a regular check). Results are used for DB structure changes

Data if validated against a set of well-defined valid values are atomically performed to discover new valid values or discrepant valid values through the validity DQ check. Results are used for Reference data updates in the master data management.

Data if validated from third party before providing to the internal transformations should be checked for its accuracy (DQ).

Data, either semi static or a golden copy, that's maintained internally (reference data or master data (Master data management: MDM)) is validated for its consistency check to segregate discrepant or/and new data for the MDM process.

Time stamp, that proves the data position (time and location), comparisons are done to verify the SLA of the data from one team to another team and validated against a known maximum constant time difference for its timeliness DQ checks. SLA should be defined and used as source for this DQ check.

Complex logic which is segregated into multiple processes and can be rolled up into a logical result with minimum/maximum values or interrelationships can be validated for reasonableness DQ check. This check may discover outliers of the data and its drift from BAU (business as usual) and eventually provide possible exceptions. And then they may be identified as data issues. This check may be simple generic rules engulfed by large chunk of data or it can be complicated logic pertaining to the core business of the company. This DQ check requires high degree of business knowledge. And discovery of reasonableness issues may aid for policy/strategy changes by either business or data governance or both.

Conformity checks and integrity checks need not covered in all business needs, it's strictly under the database architecture's discretion.

Data Quality Assurance

Data quality assurance is the process of profiling the data to discover inconsistencies, and other anomalies in the data and performing data cleansing activities (e.g. removing outliers, missing data interpolation) to improve the data quality .

These activities can be undertaken as part of data warehousing or as part of the database administration of an existing piece of applications software.

Criticism of existing tools and processes

The main reasons cited are:

- **Project costs**: costs typically in the hundreds of thousands of dollars
- **Time**: lack of enough time to deal with large-scale data-cleansing software
- **Security**: concerns over sharing information, giving an application access across systems, and effects on legacy systems

Data quality assessment

Data quality assessment is the process of exposing technical and business data issues in order to plan data cleansing and data enrichment strategies. Technical quality issues are generally easy to discover and correct, such as:

- Inconsistent standards in structure, format/ values
- Missing data, default values
- Spelling errors, data in wrong fields

Business quality issues are more subjective and are associated with business processes such as generating accurate reports, ensuring that data driven processes are working correctly.

Business data quality measures like accuracy and correctness are subjective and need Subject Matter Expert (SME) involvement to assess data quality.

Data quality assurance

Data are of high quality "if they are fit for their intended uses in operations, decision making and planning" (J. M. Juran). Alternatively, the data are deemed of high quality if they correctly represent the real-world construct to which they refer. Furthermore, apart from these definitions, as data volume increases, the question of *internal consistency* within data becomes paramount, regardless of fitness for use for any external purpose, e.g. a person's age and birth date may conflict within different parts of a database. The first views can often be in disagreement, even about the same set of data used for the same purpose. This article discusses the concept as it related to business data processing, although of course other data have various quality issues as well.

Definitions

This list is taken from the online book "Data Quality: High-impact Strategies". See also the Glossary of data quality terms [1]

- Degree of excellence exhibited by the data in relation to the portrayal of the actual scenario.
- The state of completeness, validity, consistency, timeliness and accuracy that makes data appropriate for a specific use.[2]
- The totality of features and characteristics of data that bears on their ability to satisfy a given purpose; the sum of the degrees of excellence for factors related to data.[3]
- The processes and technologies involved in ensuring the conformance of data values to business requirements and acceptance criteria.[4]
- Complete, standards based, consistent, accurate and time stamped.[5]

History

Before the rise of the inexpensive server, massive mainframe computers were used to maintain name and address data so that the mail could be properly routed to its destination. The mainframes used business rules to correct common misspellings and typographical errors in name and address data, as well as to track customers who had moved, died, gone to prison, married, divorced, or experienced other life-changing events. Government agencies began to make postal data available to a few service companies to cross-reference customer data with the National Change of Address registry (NCOA). This technology saved large companies millions of dollars compared to manually correcting customer data. Large companies saved on postage, as bills and direct marketing materials made their way to the intended customer more accurately. Initially sold as a service, data quality moved inside the walls of corporations, as low-cost and powerful server technology became available.

Companies with an emphasis on marketing often focus their quality efforts on name and address information, but data quality is recognized as an important property of all types of data. Principles of data quality can be applied to supply chain data, transactional data, and nearly every other category of data found in the enterprise. For example, making supply chain data conform to a certain standard has value to an organization by: 1) avoiding overstocking of similar but slightly different stock; 2) improving the understanding of vendor purchases to negotiate volume discounts; and 3) avoiding logistics costs in stocking and shipping parts across a large organization.

While name and address data has a clear standard as defined by local postal authorities, other types of data have few recognized standards. There is a movement in the industry today to standardize certain non-address data. The non-profit group GS1 is among the groups spearheading this movement.

For companies with significant research efforts, data quality can include developing protocols for research methods, reducing measurement error, bounds checking of the data, cross tabulation, modeling and outlier detection, verifying data integrity, etc.

Overview

There are a number of theoretical frameworks for understanding data quality. A systems-theoretical approach influenced by American pragmatism expands the definition of data quality to include information quality, and emphasizes the inclusiveness of the fundamental dimensions of accuracy and precision on the basis of the theory of science (Ivanov, 1972). One framework, dubbed "Zero Defect Data" (Hansen, 1991) adapts the principles of statistical process control to data quality. Another framework seeks to integrate the product perspective (conformance to specifications) and the service perspective (meeting consumers' expectations) (Kahn et al. 2002). Another framework is based in semiotics to evaluate the quality of the form, meaning and use of the data (Price and Shanks, 2004). One highly theoretical approach analyzes the ontological nature of information systems to define data quality rigorously (Wand and Wang, 1996).

A considerable amount of data quality research involves investigating and describing various categories of desirable attributes (or dimensions) of data. These lists commonly include accuracy, correctness, currency, completeness and relevance. Nearly 200 such terms have been identified and there is little agreement in their nature (are these concepts, goals or criteria?), their definitions or measures (Wang et al., 1993). Software engineers may recognise this as a similar problem to "ilities".

MIT has a Total Data Quality Management program, led by Professor Richard Wang, which produces a large number of publications and hosts a significant international conference in this field (International Conference on Information Quality, ICIQ). This program grew out of the work done by Hansen on the "Zero Defect Data" framework (Hansen, 1991).

In practice, data quality is a concern for professionals involved with a wide range of information systems, ranging from data warehousing and business intelligence to customer relationship management and supply chain management. One industry study estimated the total cost to the US economy of data quality problems at over

US$600 billion per annum (Eckerson, 2002). Incorrect data – which includes invalid and outdated information – can originate from different data sources – through data entry, or data migration and conversion projects.[6]

In 2002, the USPS and PricewaterhouseCoopers released a report stating that 23.6 percent of all U.S. mail sent is incorrectly addressed.[7]

One reason contact data becomes stale very quickly in the average database – more than 45 million Americans change their address every year.[8]

In fact, the problem is such a concern that companies are beginning to set up a data governance team whose sole role in the corporation is to be responsible for data quality. In someWikipedia:Avoid weasel words organizations, this data governance function has been established as part of a larger Regulatory Compliance function - a recognition of the importance of Data/Information Quality to organizations.

Problems with data quality don't only arise from *incorrect* data. *Inconsistent* data is a problem as well. Eliminating data shadow systems and centralizing data in a warehouse is one of the initiatives a company can take to ensure data consistency.

Data Quality Firewall

A **data quality firewall** is the use of software to protect a computer system from the entry of erroneous, duplicated or poor quality data. Gartner estimates that poor quality data causes failure in up to 50% of customer relationship management systems.[*citation needed*] Older technology required the tight integration of data quality software, whereas this can now be accomplished by loosely coupling technology in a service-oriented architecture.

Features and functionality

A data quality firewall guarantees database accuracy and consistency. This application ensures that only valid and high quality data enter the system, which means that it obliquely protects the database from damage; this is extremely important since database integrity and security are absolutely essential. A data quality firewall provides real time feedback information about the quality of the data submitted to the system.

The main goal of a data quality process consists in capturing erroneous and invalid data, processing them and eliminating duplicates and, lastly, exporting valid data to the user without failing to store a back-up copy into the database. A data quality firewall acts similarly to a network security firewall. It enables packets to pass through specified ports by filtering out data that present quality issues and allowing the remaining, valid data to be stored in the database. In other words, the firewall sits between the data source and the database and works throughout the extraction, processing and loading of data.

It is necessary that data streams be subject to accurate validity checks before they can be considered as being correct or trustworthy. Such checks are of a temporal, formal, logic and forecasting kind.

Data truncation

In databases and computer networking **data truncation** occurs when data or a data stream (such as a file) is stored in a location too short to hold its entire length. Data truncation may occur automatically, such as when a long string is written to a smaller buffer, or deliberately, when only a portion of the data is wanted.

Depending on what type of data validation a program or operating system has, the data may be truncated silently (i.e., without informing the user), or the user may be given an error message.

Data validation

In computer science, **data validation** is the process of ensuring that a program operates on clean, correct and useful data. It uses routines, often called "validation rules" or "check routines", that check for correctness, meaningfulness, and security of data that are input to the system. The rules may be implemented through the automated facilities of a data dictionary, or by the inclusion of explicit application program validation logic.

For business applications, data validation can be defined through declarative data integrity rules, or procedure-based business rules.[1] Data that does not conform to these rules will negatively affect business process execution. Therefore, data validation should start with business process definition and set of business rules within this process. Rules can be collected through the requirements capture exercise.[2]

The simplest data validation verifies that the characters provided come from a valid set. For example, telephone numbers should include the digits and possibly the characters +, −, (, and) (plus, minus, and parentheses). A more sophisticated data validation routine would check to see the user had entered a valid country code, i.e., that the number of digits entered matched the convention for the country or area specified.

Incorrect data validation can lead to data corruption or a security vulnerability. Data validation checks that data are valid, sensible, reasonable, and secure before they are processed.

A validation process involves two distinct steps: (a) Validation Check and (b) Post-Check action. The check step uses one or more computational rules (see section below) to determine if the data is valid. The Post-validation action sends feedback to help enforce validation.

Validation methods

Allowed character checks Checks that ascertain that only expected characters are present in a field. For example a numeric field may only allow the digits 0-9, the decimal point and perhaps a minus sign or commas. A text field such as a personal name might disallow characters such as < and >, as they could be evidence of a markup-based security attack. An e-mail address might require at least one @ sign and various other structural details. Regular expressions are effective ways of implementing such checks. (See also data type checks below)

Batch totals Checks for missing records. Numerical fields may be added together for all records in a batch. The batch total is entered and the computer checks that the total is correct, e.g., add the 'Total Cost' field of a number of transactions together.

Cardinality check Checks that record has a valid number of related records. For example if Contact record classified as a Customer it must have at least one associated Order (Cardinality > 0). If order does not exist for a "customer" record then it must be either changed to "seed" or the order must be created. This type of rule can be complicated by additional conditions. For example if contact record in Payroll database is marked as "former employee", then this record must not have any associated salary payments after the date on which employee left organization (Cardinality = 0).

Check digits Used for numerical data. An extra digit is added to a number which is calculated from the digits. The computer checks this calculation when data are entered. For example the last digit of an ISBN for a book is a check digit calculated modulus 10.[3]

Consistency checks Checks fields to ensure data in these fields corresponds, e.g., If Title = "Mr.", then Gender = "M".

Control totals This is a total done on one or more numeric fields which appears in every record. This is a meaningful total, e.g., add the total payment for a number of Customers.

Cross-system consistency checks Compares data in different systems to ensure it is consistent, e.g., The address for the customer with the same id is the same in both systems. The data may be represented differently in different systems and may need to be transformed to a common format to be compared, e.g., one system may store customer name in a single Name field as 'Doe, John Q', while another in three different fields: First_Name (John), Last_Name (Doe) and Middle_Name (Quality); to compare the two, the validation engine would have to transform data from the second system to match the data from the first, for example, using SQL: Last_Name || ', ' || First_Name || substr(Middle_Name, 1, 1) would convert the data from the second system to look like the data from the first 'Doe, John Q'

Data type checks Checks the data type of the input and give an error message if the input data does not match with the chosen data type, e.g., In an input box accepting numeric data, if the letter 'O' was typed instead of the number zero, an error message would appear.

File existence check Checks that a file with a specified name exists. This check is essential for programs that use file handling.

Format or picture check Checks that the data is in a specified format (template), e.g., dates have to be in the format DD/MM/YYYY. Regular expressions should be considered for this type of validation.

Hash totals This is just a batch total done on one or more numeric fields which appears in every record. This is a meaningless total, e.g., add the Telephone Numbers together for a number of Customers.

Limit check Unlike range checks, data are checked for one limit only, upper OR lower, e.g., data should not be greater than 2 (<=2).

Logic check Checks that an input does not yield a logical error, e.g., an input value should not be 0 when it will divide some other number somewhere in a program.

Presence check Checks that important data is actually present and have not been missed out, e.g., customers may be required to have their telephone numbers listed.

Range check Checks that the data lie within a specified range of values, e.g., the month of a person's date of birth should lie between 1 and 12.

Referential integrity In modern Relational database values in two tables can be linked through foreign key and primary key. If values in the primary key field are not constrained by database internal mechanism,[4] then they should be validated. Validation of the foreign key field checks that referencing table must always refer to a valid row in the referenced table.[5]

Spelling and grammar check Looks for spelling and grammatical errors.

Uniqueness check Checks that each value is unique. This can be applied to several fields (i.e. Address, First Name, Last Name).

Table Look Up Check A table look up check takes the entered data item and compares it to a valid list of entries that are stored in a database table.

Post-validation actions

Enforcement Action

Enforcement action typically rejects the data entry request and requires the input actor to make a change that brings the data into compliance. This is most suitable for interactive use, where a real person is sitting on the computer and making entry. It also works well for batch upload, where a file input may be rejected and a set of messages sent back to the input source for why the data is rejected. Another form of enforcement action involves automatically changing the data and saving a conformant version instead of the original version. This is most suitable for cosmetic change. For example, converting an [all-caps] entry to a [Pascal case] entry does not need user input. An inappropriate use of automatic enforcement would be in situations where the enforcement leads to loss of business information. For example, saving a truncated comment if the length is longer than expected. This is not typically a good thing since it may result in loss of significant data.

Advisory Action

Advisory actions typically allow data to be entered unchanged but sends a message to the source actor indicating those validation issues that were encountered. This is most suitable for non-interactive system, for systems where the change is not business critical, for cleansing steps of existing data and for verification steps of an entry process.

Verification Action

Verification actions are special cases of advisory actions. In this case, the source actor is asked to verify that this data is what they would really want to enter, in the light of a suggestion to the contrary. Here, the check step suggests an alternative (e.g.: a check of your mailing address returns a different way of formatting that address or suggests a different address altogether). You would want in this case, to give the user the option of accepting the recommendation or keeping their version. This is not a strict validation process, by design and is useful for capturing addresses to a new location or to a location that is not yet supported by the validation database.

Data verification

Data **Verification** is a process where in different types of data are checked for accuracy and inconsistencies after data migration is done.[1]

It helps to determine whether data was accurately translated when data is transferred from one source to another, is complete, and supports processes in the new system. During verification, there may be a need for a parallel run of both systems to identify areas of disparity and forestall erroneous data loss.

A type of Data Verification is double entry and proofreading data. Proofreading data involves someone checking the data entered against the original document. This is also time consuming and costly.

Database integrity

Database integrity ensures that data entered into the database is accurate, valid, and consistent. Any applicable integrity constraints and data validation rules must be satisfied before permitting a change to the database.

Three basic types of database integrity constraints are:

- Entity integrity, not allowing multiple rows to have the same identity within a table.
- Domain integrity, restricting data to predefined data types, e.g.: dates.
- Referential integrity, requiring the existence of a related row in another table, e.g. a customer for a given customer ID.

Database preservation

Database preservation usually involves converting the information stored in a database to a form likely to be accessible in the long term as technology changes, without losing the initial characteristics (Context, Content, Structure, Appearance and Behaviour) of the data.

Database preservation projects

In the past different research groups have contributed to the solutions of the problems of database preservation. Research projects carried out in the past in this regard include:

- Software independent archival of relational databases (SIARD)[1]
- Repository of Authentic Digital Objects (RODA)[2]
- Digital Preservation Testbed[3]
- Lots of Copies Keep Stuff Safe (LOCKSS)[4]

Declarative Referential Integrity

Declarative Referential Integrity (DRI) is one of the techniques in the SQL database programming language to ensure data integrity.

Meaning in SQL

A table (called the child table) can refer to a column (or a group of columns) in another table (the parent table) by using a foreign key. The referenced column(s) in the parent table must be under a unique constraint, such as a primary key. Also, self-references are possible (not fully implemented in MS SQL Server though). On inserting a new row into the child table, the relational database management system (RDBMS) checks if the entered key value exists in the parent table. If not, no insert is possible. It is also possible to specify DRI actions on UPDATE and DELETE, such as CASCADE (forwards a change/delete in the parent table to the child tables), NO ACTION (if the specific row is referenced, changing the key is not allowed) or SET NULL / SET DEFAULT (a changed/deleted key in the parent table results in setting the child values to NULL or to the DEFAULT value if one is specified).

Product specific meaning

In Microsoft SQL Server the term DRI also applies to the assigning of permissions to users on a database object. Giving DRI permission to a database user allows them to add foreign key constraints on a table.

Digital continuity

Digital continuity is the ability to maintain the digital information of a creator in such a way that the information will continue to be available, as needed, despite changes in digital storage technology. It focuses on making sure that information is complete, available and therefore usable. Activities involved with managing digital continuity include information management, information risk assessment and managing technical environments, including file format conversion. Digital continuity management is particularly important to organisations that have a duty to maintain accountability, and to act transparently and legally, such as government and infrastructure companies. Digital continuity is also an important issue for organisations responsible for maintaining repositories of information in digital form over time, such as archives and libraries.

Focus of digital continuity

The focus of digital continuity differs from that of digital preservation and business continuity. While there is some overlap among these areas, they should be treated as related but separate issues. Business continuity focuses on making sure that critical business functions will be available to customers, suppliers, regulators, and other entities that must have access to those functions. Digital preservation focuses on long term strategies and requirements for storing digital information in an effort to stabilize the collection of digital records. Digital continuity is concerned with the ability to make digitally preserved information continuously usable. What constitutes usable will be different depending on each organization's needs. For the purposes of digital continuity, The National Archives believes digital information is usable when one can:

- find it when needed
- open it as needed
- work with it in the way needed
- understand what it is and what it is about
- trust that it is what it says it is.

Digital continuity projects

The National Archives in the United Kingdom began a digital continuity project for public use in 2007. The project is based on a four-stage process for managing digital information effectively in organisations:

- Step 1: Plan for action: All employees in the organization need to be aware of the digital continuity project and have an understanding of what digital continuity means for the information they create. This step also includes assessing existing work practices in order to ensure that people working within the system have the potential to deliver continuity.

- Step 2: Define your digital continuity requirements: Ensure that an effective records management system is in place so that it is understood what information needs to be kept and how it will be used over time, regardless of change.
- Step 3: Assess and manage risks to digital continuity: This step involves a digital continuity risk assessment which highlights areas of concern. This may include identifying file formats in current use which are susceptible to obsolescence. Identifying risks will help mitigate potential problems.
- Step 4: Maintain digital continuity: This step ensures that your organization will be able to continue to use the digital information it produces in the future through changes in technology. This involves embedding the concept of digital continuity into existing business processes.

At Archives New Zealand, the digital continuity project is entitled the *Digital Continuity Action Plan*. The Archives New Zealand project is focused on ensuring digital information is available in the future, that the information remains authentic and reliable, and that the public has continuous access through a proactive approach to maintaining digital information.

The Digital Preservation Coalition (DPC), which concerns itself with digital preservation issues including digital continuity, has published reports advocating the assessment of digital preservation needs in the UK, and has been consulted in the creation of the *Digital Continuity Action Plan* at Archives New Zealand. The National Archives is also a member of the DPC.

Other digital continuity projects are underway at the Welsh Assembly Government in conjunction with the University of Wales, Newport., and the National Library of Australia.

Digital preservation

In library and archival science, **digital preservation** is a formal endeavor to ensure that digital information of continuing value remains accessible and usable. It involves planning, resource allocation, and application of preservation methods and technologies,[1] and it combines policies, strategies and actions to ensure access to reformatted and "born-digital" content, regardless of the challenges of media failure and technological change. The goal of digital preservation is the accurate rendering of authenticated content over time.[2]

Challenges of digital preservation

Society's heritage has been presented on many different materials, including stone, vellum, bamboo, silk, and paper. Now a large quantity of information exists in digital forms, including emails, blogs, social networking websites, national elections websites, web photo albums, and sites which change their content over time. With digital media it is easier to create content and keep it up-to-date, but at the same time there are many challenges in the preservation of this content, both technical and economic.

Unlike traditional analog objects such as books or photographs where the user has unmediated access to the content, a digital object always needs a software environment to render it. These environments keep evolving and changing at a rapid pace, threatening the continuity of access to the content. Physical storage media, data formats, hardware, and software all become obsolete over time, posing significant threats to the survival of the content. This process can be referred to as digital obsolescence.

In the case of born-digital content (e.g., institutional archives, Web sites, electronic audio and video content, born-digital photography and art, research data sets, observational data), the enormous and growing quantity of content presents significant scaling issues to digital preservation efforts. Rapidly changing technologies can hinder

digital preservationists work and techniques due to outdated and antiquated machines or technology. This has become a common problem and one that is a constant worry for a digital archivist—how to prepare for the future.

Digital content can also present challenges to preservation because of its complex and dynamic nature, e.g., interactive Web pages, virtual reality and gaming environments, learning objects, social media sites. In many cases of emergent technological advances there are substantial difficulties in maintaining the authenticity, fixity, and integrity of objects over time deriving from the fundamental issue of experience with that particular digital storage medium and while particular technologies may prove to be more robust in terms of storage capacity, there are issues in securing a framework of measures to ensure that the object remains fixed while in stewardship.

For the preservation of software as digital content, a specific challenge is the typically non-availability of the source code as commercial software is normally distributed only in compiled binary form. Without the source code an adaption (Porting) on modern computing hardware or operating system is most often impossible, therefore the original hardware and software context needs to be emulated. Another potential challenge for software preservation can be the copyright who prohibits often the bypassing of copy protection mechanisms (Digital Millennium Copyright Act) incase software has become a orphaned work (Abandonware). An exemption from the United States Digital Millennium Copyright Act to permit to bypass copy protection was approved in 2003 for a period of 3 years to the Internet Archive who created an archive of "vintage software", as a way to preserve them. The exemption was renewed in 2006, and as of 27 October 2009[3], has been indefinitely extended pending further rulemakings "for the purpose of preservation or archival reproduction of published digital works by a library or archive."

Another challenge surrounding preservation of digital content resides in the issue of scale. The amount of digital information being created along with the "proliferation of format types" makes creating trusted digital repositories with adequate and sustainable resources a challenge. The Web is only one example of what might be considered the "data deluge". For example, the Library of Congress currently amassed 170 billion tweets between 2006 and 2010 totaling 133.2 terabytes[4] and each Tweet is composed of 23 fields of metadata.[5]

The economic challenges of digital preservation are also great. Preservation programs require significant up front investment to create, along with ongoing costs for data ingest, data management, data storage, and staffing. One of the key strategic challenges to such programs is the fact that, while they require significant current and ongoing funding, their benefits accrue largely to future generations.

Intellectual foundations of digital preservation

"*Preserving Digital Information* (1996)"

The challenges of long-term preservation of digital information have been recognized by the archival community for years. In December 1994, the Research Libraries Group (RLG) and Commission on Preservation and Access (CPA) formed a Task Force on Archiving of Digital Information with the main purpose of investigating what needed to be done to ensure long-term preservation and continued access to the digital records. The final report published by the Task Force (Garrett, J. and Waters, D., ed. (1996). “Preserving digital information: Report of the task force on archiving of digital information.”) became a fundamental document in the field of digital preservation that helped set out key concepts, requirements, and challenges.

The Task Force proposed development of a national system of digital archives that would take responsibility for long-term storage and access to digital information; introduced the concept of trusted digital repositories and defined their roles and responsibilities; identified five features of digital information integrity (content, fixity, reference, provenance, and context) that were subsequently incorporated into a definition of Preservation Description Information in the Open Archival Information System Reference Model; and defined migration as a crucial function of digital archives. The concepts and recommendations outlined in the report laid a foundation for subsequent research and digital preservation initiatives.

OAIS

To standardize digital preservation practice and provide a set of recommendations for preservation program implementation, the Reference Model for an Open Archival Information System (OAIS) was developed. OAIS is concerned with all technical aspects of a digital object's life cycle: ingest, archival storage, data management, administration, access and preservation planning. The model also addresses metadata issues and recommends that five types of metadata be attached to a digital object: reference (identification) information, provenance (including preservation history), context, fixity (authenticity indicators), and representation (formatting, file structure, and what "imparts meaning to an object's bitstream").[6]

Trusted Digital Repository Model

In March 2000, the Research Libraries Group (RLG) and Online Computer Library Center (OCLC) began a collaboration to establish attributes of a digital repository for research organizations, building on and incorporating the emerging international standard of the Reference Model for an Open Archival Information System (OAIS). In 2002, they published "Trusted Digital Repositories: Attributes and Responsibilities." In that document a "Trusted Digital Repository" (TDR) is defined as "one whose mission is to provide reliable, long-term access to managed digital resources to its designated community, now and in the future." The TDR must include the following seven attributes: compliance with the reference model for an Open Archival Information System (OAIS), administrative responsibility, organizational viability, financial sustainability, technological and procedural suitability, system security, procedural accountability. The Trusted Digital Repository Model outlines relationships among these attributes. The report also recommended the collaborative development of digital repository certifications, models for cooperative networks, and sharing of research and information on digital preservation with regard to intellectual property rights.[7]

In 2004 Henry M. Gladney proposed another approach to digital object preservation that called for the creation of "Trustworthy Digital Objects" (TDOs). TDOs are digital objects that can speak to their own authenticity since they incorporate a record maintaining their use and change history, which allows the future users to verify that the contents of the object are valid.

InterPARES

International Research on Permanent Authentic Records in Electronic Systems (InterPARES) is a collaborative research initiative led by the University of British Columbia that is focused on addressing issues of long-term preservation of authentic digital records. The research is being conducted by focus groups from various institutions in North America, Europe, Asia, and Australia, with an objective of developing theories and methodologies that provide the basis for strategies, standards, policies, and procedures necessary to ensure the trustworthiness, reliability, and accuracy of digital records over time.

The project began in 1999 with the first phase, InterPARES 1, which ran to 2001 and focused on establishing requirements for authenticity of inactive records generated and maintained in large databases and document management systems created by government agencies. InterPARES 2 (2002 – 2007) concentrated on issues of reliability, accuracy and authenticity of records throughout their whole life cycle, and examined records produced in dynamic environments in the course of artistic, scientific and online government activities. The third five-year phase (InterPARES 3) was initiated in 2007. Its goal is to utilize theoretical and methodological knowledge generated by InterPARES and other preservation research projects for developing guidelines, action plans, and training programs on long-term preservation of authentic records for small and medium-sized archival organizations.

Strategies

In 2006, the Online Computer Library Center developed a four-point strategy for the long-term preservation of digital objects that consisted of:

- Assessing the risks for loss of content posed by technology variables such as commonly used proprietary file formats and software applications.
- Evaluating the digital content objects to determine what type and degree of format conversion or other preservation actions should be applied.
- Determining the appropriate metadata needed for each object type and how it is associated with the objects.
- Providing access to the content.[8]

There are several additional strategies that individuals and organizations may use to actively combat the loss of digital information.

Refreshing

Refreshing is the transfer of data between two types of the same storage medium so there are no bitrot changes or alteration of data. For example, transferring census data from an old preservation CD to a new one. This strategy may need to be combined with migration when the software or hardware required to read the data is no longer available or is unable to understand the format of the data. Refreshing will likely always be necessary due to the deterioration of physical media.

Migration

Migration is the transferring of data to newer system environments (Garrett et al., 1996). This may include conversion of resources from one file format to another (e.g., conversion of Microsoft Word to PDF or OpenDocument) or from one operating system to another (e.g., Windows to GNU/Linux) so the resource remains fully accessible and functional. Two significant problems face migration as a plausible method of digital preservation in the long terms. Due to the fact that digital objects are subject to a state of near continuous change, migration may cause problems in relation to authenticity and migration has proven to be time-consuming and expensive for "large collections of heterogeneous objects, which would need constant monitoring and intervention.

Replication

Creating duplicate copies of data on one or more systems is called *replication*. Data that exists as a single copy in only one location is highly vulnerable to software or hardware failure, intentional or accidental alteration, and environmental catastrophes like fire, flooding, etc. Digital data is more likely to survive if it is replicated in several locations. Replicated data may introduce difficulties in refreshing, migration, versioning, and access control since the data is located in multiple places.

Emulation

Emulation is the replicating of functionality of an obsolete system. According to van der Hoeven, "Emulation does not focus on the digital object, but on the hard- and software environment in which the object is rendered. It aims at (re)creating the environment in which the digital object was originally created.".[9] Examples are having the ability to replicate or imitate another operating system. Examples include emulating an Atari 2600 on a Windows system or emulating WordPerfect 1.0 on a Macintosh. Emulators may be built for applications, operating systems, or hardware platforms. Emulation has been a popular strategy for retaining the functionality of old video game systems, such as with the MAME project. The feasibility of emulation as a catch-all solution has been debated in the academic community. (Granger, 2000)

Raymond A. Lorie has suggested a Universal Virtual Computer (UVC) could be used to run any software in the future on a yet unknown platform. The UVC strategy uses a combination of emulation and migration. The UVC strategy has not yet been widely adopted by the digital preservation community.

Jeff Rothenberg, a major proponent of Emulation for digital preservation in libraries, working in partnership with Koninklijke Bibliotheek and National Archief of the Netherlands, developed a software program called Dioscuri, a modular emulator that succeeds in running MS-DOS, WordPerfect 5.1, DOS games, and more.

Another example of emulation as a form of digital preservation can be seen in the example of Emory University and the Salman Rushdie's papers. Rushdie donated an outdated computer to the Emory University library, which was so old that the library was unable to extract papers from the harddrive. In order to procure the papers, the library emulated the old software system and was able to take the papers off his old computer.[10]

Encapsulation

This method maintains that preserved objects should be self-describing, virtually "linking content with all of the information required for it to be deciphered and understood". The files associated with the digital object would have details of how to interpret that object by using "logical structures called "containers" or "wrappers" to provide a relationship between all information components[11] that could be used in future development of emulators, viewers or converters through machine readable specifications.[12] The method of encapsulation is usually applied to collections that will go unused for long periods of time

Persistent Archives Concept

Developed by the San Diego Supercomputing Center and funded by the National Archives and Records Administration, this method requires the development of comprehensive and extensive infrastructure that enables "the preservation of the organisation of collection as well as the objects that make up that collection, maintained in a platform independent form". A persistent archive includes both the data constituting the digital object and the context that the defines the provenance, authenticity, and structure of the digital entities.[13] This allows for the replacement of hardware or software components with minimal effect on the preservation system. This method can be based on virtual data grids and resembles OAIS Information Model (specifically the Archival Information Package).

Metadata attachment

Metadata is data on a digital file that includes information on creation, access rights, restrictions, preservation history, and rights management.[14] Metadata attached to digital files may be affected by file format obsolescence. ASCII is considered to be the most durable format for metadata [15] because it is widespread, backwards compatible when used with Unicode, and utilizes human-readable characters, not numeric codes. It retains information, but not the structure information it is presented in. For higher functionality, SGML or XML should be used. Both markup languages are stored in ASCII format, but contain tags that denote structure and format.

Digital sustainability

Digital sustainability encompasses a range of issues and concerns that contribute to the longevity of digital information.[16] Unlike traditional, temporary strategies, and more permanent solutions, digital sustainability implies a more active and continuous process. Digital sustainability concentrates less on the solution and technology and more on building an infrastructure and approach that is flexible with an emphasis on interoperability, continued maintenance and continuous development.[17] Digital sustainability incorporates activities in the present that will facilitate access and availability in the future.[18][19]

Preservation repository assessment and certification

A few of the major frameworks for digital preservation repository assessment and certification are described below. A more detailed list is maintained by the U.S. Center for Research Libraries.

Specific tools and methodologies

TRAC

In 2007, CRL/OCLC published Trustworthy Repositories Audit & Certification: Criteria & Checklist (TRAC), a document allowing digital repositories to assess their capability to reliably store, migrate, and provide access to digital content. TRAC is based upon existing standards and best practices for trustworthy digital repositories and incorporates a set of 84 audit and certification criteria arranged in three sections: Organizational Infrastructure; Digital Object Management; and Technologies, Technical Infrastructure, and Security.

TRAC "provides tools for the audit, assessment, and potential certification of digital repositories, establishes the documentation requirements required for audit, delineates a process for certification, and establishes appropriate methodologies for determining the soundness and sustainability of digital repositories".

DRAMBORA

Digital Repository Audit Method Based On Risk Assessment (DRAMBORA), introduced by the Digital Curation Centre (DCC) and Digital Preservation Europe (DPE) in 2007, offers a methodology and a toolkit for digital repository self-assessment.

The DRAMBORA process is arranged in six stages and concentrates on evaluation of likelihood and potential impact of risks on the repository. The auditor is required to describe and document the repository's role, objectives, policies, activities and assets, in order to identify and assess the risks associated with these activities and assets and define appropriate measures to manage them.

European Framework for Audit and Certification of Digital Repositories

The European Framework for Audit and Certification of Digital Repositories [20] was defined in a memorandum of understanding signed in July 2010 between Consultative Committee for Space Data Systems (CCSDS), Data Seal of Approval (DSA) Board and German Institute for Standardization (DIN) "Trustworthy Archives – Certification" Working Group.

The framework is intended to help organizations in obtaining appropriate certification as a trusted digital repository and establishes three increasingly demanding levels of assessment:

1. Basic Certification: self-assessment using 16 criteria of the Data Seal of Approval (DSA).
2. Extended Certification: Basic Certification and additional externally reviewed self-audit against ISO 16363 or DIN 31644 requirements.
3. Formal Certification: validation of the self-certification with a third-party official audit based on ISO 16363 or DIN 31644.

nestor Catalogue of Criteria

A German initiative, *nestor* [21] (the Network of Expertise in Long-Term Storage of Digital Resources) sponsored by the German Ministry of Education and Research, developed a catalogue of criteria for trusted digital repositories in 2004. In 2008 the second version of the document was published. The catalogue, aiming primarily at German cultural heritage and higher education institutions, establishes guidelines for planning, implementing, and self-evaluation of trustworthy long-term digital repositories.

The *nestor* catalogue of criteria conforms to the OAIS reference model terminology and consists of three sections covering topics related to Organizational Framework, Object Management, and Infrastructure and Security.

PLANETS Project

In 2002 the *Preservation and Long-term Access through Networked Services* (PLANETS) project, part of the EU Framework Programmes for Research and Technological Development 6, addressed core digital preservation challenges. The primary goal for *Planets* was to build practical services and tools to help ensure long-term access to digital cultural and scientific assets. The outputs of the project are now sustained by the follow-on organisation, the Open Planets Foundation.

PLATTER

Planning Tool for Trusted Electronic Repositories (PLATTER) is a tool released by DigitalPreservationEurope (DPE) to help digital repositories in identifying their self-defined goals and priorities in order to gain trust from the stakeholders.

PLATTER is intended to be used as a complementary tool to DRAMBORA, NESTOR, and TRAC. It is based on ten core principles for trusted repositories and defines nine Strategic Objective Plans, covering such areas as acquisition, preservation and dissemination of content, finance, staffing, succession planning, technical infrastructure, data and metadata specifications, and disaster planning. The tool enables repositories to develop and maintain documentation required for an audit.[:49]

Audit and Certification of Trustworthy Digital Repositories (ISO 16363)

Audit and Certification of Trustworthy Digital Repositories (ISO 16363:2012), developed by the Consultative Committee for Space Data Systems (CCSDS), was approved as a full international standard in March 2012. Extending the OAIS Reference Model and based largely on the TRAC checklist, the standard is designed for all types of digital repositories. It provides a detailed specification of criteria against which the trustworthiness of a digital repository should be evaluated.

The CCSDS Repository Audit and Certification Working Group has also developed and submitted for approval a second standard, Requirements for Bodies Providing Audit and Certification of Candidate Trustworthy Digital Repositories (ISO 16919), that defines the external auditing process and requirements for organizations responsible for assessment and certification of digital repositories.

Digital preservation best practices

Although preservation strategies vary for different types of materials and between institutions, adhering to nationally and internationally recognized standards and practices is a crucial part of digital preservation activities. Best or recommended practices define strategies and procedures that may help organizations to implement existing standards or provide guidance in areas where no formal standards have been developed.

Best practices in digital preservation continue to evolve and may encompass processes that are performed on content prior to or at the point of ingest into a digital repository as well as processes performed on preserved files post-ingest over time. Best practices may also apply to the process of digitizing analog material and may include the creation of specialized metadata (such as technical, administrative and rights metadata) in addition to standard descriptive metadata. The preservation of born-digital content may include format transformations to facilitate long-term preservation or to provide better access.

Audio preservation

Various best practices and guidelines for digital audio preservation have been developed, including:

- *Capturing Analog Sound for Digital Preservation: Report of a Roundtable Discussion of Best Practices for Transferring Analog Discs and Tapes* (2006), which defined procedures for reformatting sound from analog to digital and provided recommendations for best practices for digital preservation
- *Digital Audio Best Practices* (2006) prepared by the Collaborative Digitization Program Digital Audio Working Group, which covers best practices and provides guidance both on digitizing existing analog content and on creating new digital audio resources
- *Sound Directions: Best Practices for Audio Preservation* (2007) published by the Sound Directions Project, which describes the audio preservation workflows and recommended best practices and has been used as the basis for other projects and initiatives
- Documents developed by the International Association of Sound and Audiovisual Archives (IASA), the European Broadcasting Union (EBU), the Library of Congress, and the Digital Library Federation (DLF).

The Audio Engineering Society (AES) also issues a variety of standards and guidelines relating to the creation of archival audio content and technical metadata.

Moving Image Preservation

The term “moving images” includes analog film and video and their born-digital forms: digital video, digital motion picture materials, and digital cinema. As analog videotape and film become obsolete, digitization has become a key preservation strategy, although many archives do continue to perform photochemical preservation of film stock.

"Digital preservation" has a double meaning for audiovisual collections: analog originals are preserved through digital reformatting, with the resulting digital files preserved; and born-digital content is collected, most often in proprietary formats that pose problems for future digital preservation.

There is currently no broadly accepted standard target digital preservation format for analog moving images.

The following resources offer information on analog to digital reformatting and preserving born-digital audiovisual content.

- The Library of Congress tracks the sustainability of digital formats, including moving images.[22]
- *The Digital Dilemma 2: Perspectives from Independent Filmmakers, Documentarians and Nonprofit Audiovisual Archives (2012)*. The section on nonprofit archives reviews common practices on digital reformatting, metadata, and storage. There are four case studies.
- Federal Agencies Digitization Guidelines Initiative (FADGI). Started in 2007, this is a collaborative effort by federal agencies to define common guidelines, methods, and practices for digitizing historical content. As part of this, two working groups are studying issues specific to two major areas, Still Image and Audio Visual.
- PrestoCenter publishes general audiovisual information and advice at a European level. Its online library has research and white papers on digital preservation costs and formats.[23]
- The Association of Moving Image Archivists (AMIA) sponsors conferences, symposia, and events on all aspects of moving image preservation, including digital. The *AMIA Tech Review* [24] contains articles reflecting current thoughts and practices from the archivists’ perspectives. *Video Preservation for the Millennia (2012)*, published in the *AMIA Tech Review*, details the various strategies and ideas behind the current state of video preservation.

Email preservation

Email poses special challenges for preservation: email client software varies widely; there is no common structure for email messages; email often communicates sensitive information; individual email accounts may contain business and personal messages intermingled; and email may include attached documents in a variety of file formats. Email messages can also carry viruses or have spam content. While email transmission is standardized, there is no formal standard for the long-term preservation of email messages.

Approaches to preserving email may vary according to the purpose for which it is being preserved. For businesses and government entities, email preservation may be driven by the need to meet retention and supervision requirements for regulatory compliance and to allow for legal discovery. (Additional information about email archiving approaches for business and institutional purposes may be found under the separate article, Email archiving.) For research libraries and archives, the preservation of email that is part of born-digital or hybrid archival collections has as its goal ensuring its long-term availability as part of the historical and cultural record.

Several projects developing tools and methodologies for email preservation have been conducted based on various preservation strategies: normalizing email into XML format, migrating email to a new version of the software and emulating email environments: Memories Using Email [25] (MUSE), Collaborative Electronic Records Project [26] (CERP), E-Mail Collection And Preservation [27] (EMCAP), PeDALS Email Extractor Software [28] (PeDALS), XML Electronic Normalizing of Archives tool [29] (XENA).

Some best practices and guidelines for email preservation can be found in the following resources:

- *Curating E-Mails: A Life-cycle Approach to the Management and Preservation of E-mail Messages* (2006) by Maureen Pennock.
- *Technology Watch Report 11-01: Preserving Email* (2011) by Christopher J Prom.
- *Best Practices: Email Archiving* by Jo Maitland.

Video game preservation

In 2007 the *Keeping Emulation Environments Portable* (KEEP) project, part of the EU Framework Programmes for Research and Technological Development 7, developed tools and methodologies to keep digital software objects available in their original context. Digital software objects as video games might get lost because of digital obsolescence and non-availability of required legacy hardware or operating system software; such software is referred to as abandonware. Because the source code is often not available any longer, emulation is the only preservation opportunity. KEEP provided an emulation framework to help the creation of such emulators. KEEP was developed by Vincent Joguin, first launched in February 2009 and was coordinated by Elisabeth Freyre of the French National Library.

Personal Archiving

There are many things consumers and artists can do themselves to help care for their collections at home.

- "Resource Center: Caring For Your Treasures" by American Institute for Conservation of Historic and Artistic Works details simple strategies for artists and consumers to care for and preserve their work themselves.

The Library of Congress also hosts a list for the self-preserver which includes direction toward programs and guidelines from other institutions that will help the user preserve social media, email, and formatting general guidelines (such as caring for CDs).[30] Some of the programs listed include:

- HTTrack Website Copier [31]: A site which allows the user to download a World Wide Web site from the Internet to a local directory, building recursively all directories, getting HTML, images, and other files from the server to their computer.
- Muse [25]: Muse (short for Memories Using Email) is a program that helps users revive memories, using their long-term email archives, run by Stanford University.

Education for digital preservation

Digital Preservation Outreach and Education (DPOE)

The Digital Preservation Outreach and Education (DPOE), as part of the Library of Congress, serves to foster preservation of digital content through a collaborative network of instructors and collection management professionals working in cultural heritage institutions. Composed of Library of Congress staff, the National Trainer Network, the DPOE Steering Committee, and a community of Digital Preservation Education Advocates, as of 2013 the DPOE has 24 working trainers across the six regions of the United States.

In 2010 the DPOE conducted an assessment, reaching out to archivists, librarians, and other information professionals around the country. A working group of DPOE instructors then developed a curriculum [32] based on the assessment results and other similar digital preservation curricula designed by other training programs, such as LYRASIS, Educopia Institute, MetaArchive Cooperative, University of North Carolina, DigCCurr (Digital Curation Curriculum) and Cornell University-ICPSR Digital Preservation Management Workshops. The resulting core principles are also modeled on the principles outlined in "A Framework of Guidance for Building Good Digital Collections" by the National Information Standards Organization (NISO).[33]

Examples of digital preservation initiatives

- The Library of Congress operates the National Digital Stewardship Alliance [34]
- The British Library is responsible for several programmes in the area of **digital preservation** and is a founding member of the Digital Preservation Coalition [35]. Their digital preservation strategy [36] is publicly available. The National Archives of the United Kingdom have also pioneered various initiatives in the field of **digital preservation**.

Digitization at the British Library of a Dunhuang manuscript for the International Dunhuang Project

A number of open source products have been developed to assist with digital preservation, including DSpace, Fedora, EPrints and Research-Output Repository Platform. The commercial sector also offers digital preservation software tools, such as Ex Libris Ltd.'s *Rosetta*, Tessella Ltd.'s *Safety Deposit Box* and cloud based *Preservica*, CONTENTdm, Digital Commons, Equella, intraLibrary, Open Repository and Vital.

Large-scale digital preservation initiatives (LSDIs)

Many research libraries and archives have begun or are about to begin Large-Scale digital preservation initiatives (LSDIs). The main players in LSDIs are cultural institutions, commercial companies such as Google and Microsoft, and non-profit groups including the Open Content Alliance (OCA), the Million Book Project (MBP), and HathiTrust. The primary motivation of these groups is to expand access to scholarly resources.

LSDIs: library perspective

Approximately 30 cultural entities, including the 12-member Committee on Institutional Cooperation (CIC), have signed digitization agreements with either Google or Microsoft. Several of these cultural entities are participating in the Open Content Alliance (OCA) and the Million Book Project (MBP). Some libraries are involved in only one initiative and others have diversified their digitization strategies through participation in multiple initiatives. The three main reasons for library participation in LSDIs are: Access, Preservation and Research and Development. It is hoped that digital preservation will ensure that library materials remain accessible for future generations. Libraries have a perpetual responsibility for their materials and a commitment to archive their digital materials. Libraries plan

to use digitized copies as backups for works in case they go out of print, deteriorate, or are lost and damaged.

Editing this page here to potentially reorganize it.

Digital preservation is the set of processes, activities and management of digital information over time to ensure its long term accessibility. The goal of digital preservation is to preserve materials resulting from digital reformatting, and particularly information that is born-digital with no analog counterpart. Because of the relatively short lifecycle of digital information, preservation is an ongoing process.

In the language of digital imaging and electronic resources, preservation is no longer just the product of a program but an ongoing process. In this regard the way digital information is stored is important in ensuring its longevity. The long-term storage of digital information is assisted by the inclusion of preservation metadata.

Digital preservation is defined as: long-term, error-free storage of digital information, with means for retrieval and interpretation, for the entire time span the information is required for. Long-term is defined as "long enough to be concerned with the impacts of changing technologies, including support for new media and data formats, or with a changing user community. Long Term may extend indefinitely".[1] "Retrieval" means obtaining needed digital files from the long-term, error-free digital storage, without possibility of corrupting the continued error-free storage of the digital files. "Interpretation" means that the retrieved digital files, files that, for example, are of texts, charts, images or sounds, are decoded and transformed into usable representations. This is often interpreted as "rendering", i.e. making it available for a human to access. However, in many cases it will mean able to be processed by computational means.

Digital Format Preservation Concerns

Society's heritage has been presented on many different materials, including stone, vellum, bamboo, silk, and paper. Now a large quantity of information exists in digital forms, including emails, blogs, social networking websites, national elections websites, web photo albums, and sites which change their content over time. According an article by Brewster Kahle, in 1996 founder of Internet Archive, "Preserving the Internet", Scientific American, the average life of a URL was, in 1997, 44 days.[2]

The unique characteristic of digital forms makes it easy to create content and keep it up-to-date, but at the same time brings many difficulties in the preservation of this content. Margaret Hedstrom points out that "...digital preservation raises challenges of a fundamentally different nature which are added to the problems of preserving traditional format materials."[3]

Physical deterioration

The media on which digital contents are stored are more vulnerable to deterioration and catastrophic loss than some analog media such as paper. While acid paper is prone to deterioration, becoming brittle and yellowing with age, the deterioration may not become apparent for some decades and progresses slowly. It remains possible to retrieve information without loss once deterioration is noticed. Digital data recording media may deteriorate more rapidly and once the deterioration starts, in most cases there may already be data loss. This characteristic of digital forms leaves a very short time frame for preservation decisions and actions.

Digital obsolescence

Another challenge is the issue of long-term access to data. Digital technology is developing quickly and retrieval and playback technologies can become obsolete in a matter of years. When faster, more capable and less expensive storage and processing devices are developed, older versions may be quickly replaced. When a software or decoding technology is abandoned, or a hardware device is no longer in production, records created with such technologies are at great risk of loss, simply because they are no longer accessible. This process is known as digital obsolescence.

This challenge is exacerbated by a lack of established standards, protocols and proven methods for preserving digital information.[4] We used to save copies of data on tapes, but media standards for tapes have changed considerably over the last five to ten years, and there is no guarantee that tapes will be readable in the future.[5] Recovering these materials may require special tools Hedstrom further explained that almost all digital library researches have been focused on "...architectures and systems for information organization and retrieval, presentation and visualization, and administration of intellectual property rights" and that "...digital preservation remains largely experimental and replete with the risks associated with untested methods".

Strategies

In 2006, the Online Computer Library Center developed a four-point strategy for the long-term preservation of digital objects that consisted of:

- Assessing the risks for loss of content posed by technology variables such as commonly used proprietary file formats and software applications.
- Evaluating the digital content objects to determine what type and degree of format conversion or other preservation actions should be applied.
- Determining the appropriate metadata needed for each object type and how it is associated with the objects.
- Providing access to the content.[6]

There are several additional strategies that individuals and organizations may use to actively combat the loss of digital information.

Refreshing

Refreshing is the transfer of data between two types of the same storage medium so there are no bitrate changes or alteration of data.[7] For example, transferring census data from an old preservation CD to a new one. This strategy may need to be combined with migration when the software or hardware required to read the data is no longer available or is unable to understand the format of the data. Refreshing will likely always be necessary due to the deterioration of physical media.

Migration

Migration is the transferring of data to newer system environments (Garrett et al., 1996). This may include conversion of resources from one file format to another (e.g., conversion of Microsoft Word to PDF or OpenDocument), from one operating system to another (e.g., Windows to Linux) or from one programming language to another (e.g., C to Java) so the resource remains fully accessible and functional. Resources that are migrated run the risk of losing some type of functionality since newer formats may be incapable of capturing all the functionality of the original format, or the converter itself may be unable to interpret all the nuances of the original format. The latter is often a concern with proprietary data formats.

The US National Archives Electronic Records Archives and Lockheed Martin are jointly developing a migration system that will preserve any type of document, created on any application or platform, and delivered to the archives on any type of digital media. In the system, files are translated into flexible formats, such as XML; they will therefore be accessible by technologies in the future. Lockheed Martin argues that it would be impossible to develop an emulation system for the National Archives ERA because the volume of records and cost would be prohibitive.

Replication

Creating duplicate copies of data on one or more systems is called *replication*. Data that exists as a single copy in only one location is highly vulnerable to software or hardware failure, intentional or accidental alteration, and environmental catastrophes like fire, flooding, etc. Digital data is more likely to survive if it is replicated in several locations. Replicated data may introduce difficulties in refreshing, migration, versioning, and access control since the data is located in multiple places.

Emulation

Emulation is the replicating of functionality of an obsolete system. Examples include emulating an Atari 2600 on a Windows system or emulating WordPerfect 1.0 on a Macintosh. Emulators may be built for applications, operating systems, or hardware platforms. Emulation has been a popular strategy for retaining the functionality of old video game systems, such as with the MAME project. The feasibility of emulation as a catch-all solution has been debated in the academic community. (Granger, 2000)

Raymond A. Lorie has suggested a Universal Virtual Computer (UVC) could be used to run any software in the future on a yet unknown platform. The UVC strategy uses a combination of emulation and migration. The UVC strategy has not yet been widely adopted by the digital preservation community.

Jeff Rothenberg, a major proponent of Emulation for digital preservation in libraries, working in partnership with Koninklijke Bibliotheek and National Archief of the Netherlands, has recently helped launch Dioscuri, a modular emulator that succeeds in running MS-DOS, WordPerfect 5.1, DOS games, and more.

Metadata attachment

Metadata is data on a digital file that includes information on creation, access rights, restrictions, preservation history, and rights management.[8] Metadata attached to digital files may be affected by file format obsolescence. ASCII is considered to be the most durable format for metadata [9] because it is widespread, backwards compatible when used with Unicode, and utilizes human-readable characters, not numeric codes. It retains information, but not the structure information it is presented in. For higher functionality, SGML or XML should be used. Both markup languages are stored in ASCII format, but contain tags that denote structure and format.

Trustworthy digital objects

Digital objects that can speak to their own authenticity are called *trustworthy digital objects* (TDOs). TDOs were proposed by Henry M. Gladney to enable digital objects to maintain a record of their change history so future users can know with certainty that the contents of the object are authentic. Other preservation strategies like replication and migration are necessary for the long-term preservation of TDOs.

Digital sustainability

Digital sustainability encompasses a range of issues and concerns that contribute to the longevity of digital information.[10] Unlike traditional, temporary strategies and more permanent solutions, digital sustainability implies a more active and continuous process. Digital sustainability concentrates less on the solution and technology and more on building an infrastructure and approach that is flexible with an emphasis on interoperability, continued maintenance and continuous development.[11] Digital sustainability incorporates activities in the present that will facilitate access and availability in the future.

Digital preservation standards

To standardize digital preservation practice and provide a set of recommendations for preservation program implementation, the Reference Model for an Open Archival Information System (OAIS) was developed. The reference model (ISO 14721:2003) includes the following responsibilities that an OAIS archive must abide by:

- Negotiate for and accept appropriate information from information Producers.
- Obtain sufficient control of the information provided to the level needed to ensure Long-Term Preservation.
- Determine, either by itself or in conjunction with other parties, which communities should become the Designated Community and, therefore, should be able to understand the information provided.
- Ensure that the information to be preserved is Independently Understandable to the Designated Community. In other words, the community should be able to understand the information without needing the assistance of the experts who produced the information.
- Follow documented policies and procedures which ensure that the information is preserved against all reasonable contingencies, and which enable the information to be disseminated as authenticated copies of the original, or as traceable to the original.
- Make the preserved information available to the Designated Community.[12]

OAIS is concerned with all technical aspects of a digital object's life cycle: ingest into and storage in a preservation infrastructure, data management, accessibility, and distribution. The model also addresses metadata issues and recommends that five types of metadata be attached to a digital object: reference (identification) information, provenance (including preservation history), context, fixity (authenticity indicators), and representation (formatting, file structure, and what "imparts meaning to an object's bitstream").[13]

Prior to Gladney's proposal of TDOs was the Research Library Group's (RLG) development of "attributes and responsibilities" that denote the practices of a "Trusted Digital Repository" (TDR) The seven attributes of a TDR are: "compliance with the Reference Model for an Open Archival Information System (OAIS), Administrative responsibility, Organizational viability, Financial sustainability, Technological and procedural suitability, System security, Procedural accountability." Among RLG's attributes and responsibilities were recommendations calling for the collaborative development of digital repository certifications, models for cooperative networks, and sharing of research and information on digital preservation with regards to intellectual property rights.[14]

Digital sound preservation standards

In January 2004, the Council on Library and Information Resources (CLIR) hosted a roundtable meeting of audio experts discussing best practices, which culminated in a report delivered March 2006. This report investigated procedures for reformatting sound from analog to digital, summarizing discussions and recommendations for best practices for digital preservation. Participants made a series of 15 recommendations for improving the practice of analog audio transfer for archiving:

- Develop core competencies in audio preservation engineering. Participants noted with concern that the number of experts qualified to transfer older recordings is shrinking and emphasized the need to find a way to ensure that the technical knowledge of these experts can be passed on.
- Develop arrangements among smaller institutions that allow for cooperative buying of esoteric materials and supplies.
- Pursue a research agenda for magnetic-tape problems that focuses on a less destructive solution for hydrolysis than baking, relubrication of acetate tapes, and curing of cupping.
- Develop guidelines for the use of automated transfer of analog audio to digital preservation copies.
- Develop a web-based clearinghouse for sharing information on how archives can develop digital preservation transfer programs.
- Carry out further research into nondestructive playback of broken audio discs.

- Develop a flowchart for identifying the composition of various types of audio discs and tapes.
- Develop a reference chart of problematic media issues.
- Collate relevant audio engineering standards from organizations.
- Research safe and effective methods for cleaning analog tapes and discs.
- Develop a list of music experts who could be consulted for advice on transfer of specific types of musical content (e.g., determining the proper key so that correct playback speed can be established).
- Research the life expectancy of various audio formats.
- Establish regional digital audio repositories.
- Cooperate to develop a common vocabulary within the field of audio preservation.
- Investigate the transfer of technology from such fields as chemistry and materials science to various problems in audio preservation.[15]

Updated technical guidelines on the creation and preservation of digital audio have been prepared by the International Association of Sound and Audiovisual Archives (IASA).[16]

Examples of digital preservation initiatives

- The Library of Congress operates the National Digital Information Infrastructure and Preservation Program [17]
- The British Library is responsible for several programmes in the area of **digital preservation**. The National Archives of the United Kingdom have also pioneered various initiatives in the field of **digital preservation**.
- The Safety Deposit Box [18] software from Tessella is being widely adopted by National Archives and has been selected by the National Archives in the UK, Netherlands, Switzerland, Finland, Estonia, Malaysia and Austria as well as FamilySearch and the Wellcome Collection. It was recently awarded the Queen's Awards for Enterprise in the UK.
- **Ex Libris Rosetta** is commercial software helping memory institutions to collect, manage, archive and preserve their digital collections, ensuring its data integrity and access over time. The system enables managing digital entities end to end—from submission to dissemination. A rule-based workflow engine and open architecture allow institutions using the system to develop unique plug-in tools and applications to enhance the system's ingest, management, preservation and delivery processes.
- The MetaArchive Cooperative is a library-run, collaborative approach to digital preservation that embeds digital preservation infrastructure and knowledge in each of its constituent member institutions. Comprised mainly of University libraries, the Cooperative functions as a network wherein each preserved file is replicated seven times, is stored in geographically distinct locations across four countries, and is carefully managed from ingest (as a SIP) to dissemination (as a DIP).

Large-scale digital preservation initiatives (LSDIs)

Many research libraries and archives have begun or are about to begin Large-Scale digital preservation initiatives (LSDI's). The main players in LSDIs are cultural institutions, commercial companies such as Google and Microsoft, and non-profit groups including the Open Content Alliance (OCA), the Million Book Project (MBP), and HathiTrust. The primary motivation of these groups is to expand access to scholarly resources.

LSDIs: library perspective

Approximately 30 cultural entities, including the 12-member Committee on Institutional Cooperation (CIC), have signed digitization agreements with either Google or Microsoft. Several of these cultural entities are participating in the Open Content Alliance (OCA) and the Million Book Project (MBP). Some libraries are involved in only one initiative and others have diversified their digitization strategies through participation in multiple initiatives. The three main reasons for library participation in LSDIs are: Access, Preservation and Research and Development. It is hoped that digital preservation will ensure that library materials remain accessible for future generations. Libraries

have a perpetual responsibility for their materials and a commitment to archive their digital materials. Libraries plan to use digitized copies as backups for works in case they go out of print, deteriorate, or are lost and damaged.

Dirty data

Dirty data is inaccurate, incomplete or erroneous data, especially in a computer system or database.

In reference to databases, this is data that contain errors. Unclean data can contain such mistakes as spelling or punctuation errors, incorrect data associated with a field, incomplete or outdated data, or even data that has been duplicated in the database.

References

Entity integrity

In the relational data model, **entity integrity** is one of the three inherent integrity rules. Entity integrity is an integrity rule which states that every table must have a primary key and that the column or columns chosen to be the primary key should be unique and not null.[1]

Within relational databases using SQL, entity integrity is enforced by adding a primary key clause to a schema definition. The system enforces Entity Integrity by not allowing operation (INSERT, UPDATE) to produce an invalid primary key. Any operation that is likely to create a duplicate primary key or one containing nulls is rejected. The Entity Integrity ensures that the data that you store remains in the proper format as well as comprehensible.

Information quality

Information quality (IQ) is a term to describe the quality of the content of information systems. It is often pragmatically defined as: "The fitness for use of the information provided."

Conceptual problems

Although this pragmatic definition is usable for most everyday purposes, specialists often use more complex models for information quality. Most information system practitioners use the term synonymously with data quality. However, as many academics make a distinction between data and information,[1] some will insist on a distinction between data quality and information quality. This distinction would be akin to the distinction between syntax and semantics where for example, the semantic value of "one" could be expressed in different syntaxes like 00001; 1.0000; 01.0; or 1. Thus a data difference may not necessarily represent poor information quality.

Information quality assurance is the process to guarantee confidence that particular information meets some context specific quality requirements. It has been suggested, however, that higher the quality the greater will be the confidence in meeting more general, less specific contexts.[2]

Dimensions and metrics of Information Quality

"Information quality" is a measure of the value which the information provides to the user of that information. "Quality" is often perceived as subjective and the quality of information can then vary among users and among uses of the information. Nevertheless, a high degree of quality increases its objectivity or at least the intersubjectivity. Accuracy can be seen as just one element of IQ but, depending upon how it is defined, can also be seen as encompassing many other dimensions of quality.

If not, it is perceived that often there is a trade-off between accuracy and other dimensions, aspects or elements of the information determining its suitability for any given tasks. Wang and Strong propose a list of dimensions or elements used in assessing Information Quality is:[3]

- Intrinsic IQ: Accuracy, Objectivity, Believability, Reputation
- Contextual IQ: Relevancy, Value-Added, Timeliness, Completeness, Amount of information
- Representational IQ: Interpretability, Format, Coherence, Compatibility
- Accessibility IQ: Accessibility, Access security

Other authors propose similar but different lists of dimensions for analysis, and emphasize measurement and reporting as information quality metrics. Larry English prefers the term "characteristics" to dimensions.[4]

While information as a distinct term has various ambiguous definitions, there's one which is more general, such as "description of events". While the occurrences being described cannot be subjectively evaluated for quality, since they're very much autonomous events in space and time, their description can—since it possesses a garnishment attribute, unavoidably attached by the medium which carried the information, from the initial moment of the occurrences being described.

In an attempt to deal with this natural phenomenon, qualified professionals primarily representing the researchers' guild, have at one point or another identified particular metrics for information quality. They could also be described as 'quality traits' of information, since they're not so easily quantified, but rather subjectively identified on an individual basis.

Proposed quality metrics

- **Authority/Verifiability**

Authority refers to the expertise or recognized official status of a source. Consider the reputation of the author and publisher. When working with legal or government information, consider whether the source is the official provider of the information. Verifiability refers to the ability of a reader to verify the validity of the information irresepective of how authoritative the source is. To verify the facts is part of the duty of care of the journalistic deontology, as well as, where possible, to provide the sources of information so that they can be verified

- **Scope of coverage**

Scope of coverage refers to the extent to which a source explores a topic. Consider time periods, geography or jurisdiction and coverage of related or narrower topics.

- **Composition and Organization**

Composition and Organization has to do with the ability of the information source to present it's particular message in a coherent, logically sequential manner.

- **Objectivity**

Objectivity is the bias or opinion expressed when a writer interprets or analyze facts. Consider the use of persuasive language, the source's presentation of other viewpoints, its reason for providing the information and advertising.

- **Integrity**

1. Adherence to moral and ethical principles; soundness of moral character
2. The state of being whole, entire, or undiminished

- **Comprehensiveness**

1. Of large scope; covering or involving much; inclusive: a comprehensive study.
2. Comprehending mentally; having an extensive mental grasp.
3. Insurance. covering or providing broad protection against loss.

- **Validity**

Validity of some information has to do with the degree of obvious truthfulness which the information carries

- **Uniqueness**

As much as 'uniqueness' of a given piece of information is intuitive in meaning, it also significantly implies not only the originating point of the information but also the manner in which it is presented and thus the perception which it conjures. The essence of any piece of information we process consists to a large extent of those two elements.

- **Timeliness**

Timeliness refers to information that is current at the time of publication. Consider publication, creation and revision dates. Beware of Web site scripting that automatically reflects the current day's date on a page.

- **Reproducibility** (utilized primarily when referring to instructive information)

Means that documented methods are capable of being used on the same data set to achieve a consistent result.

Education

University of Arkansas at Little Rock offers graduate degrees in the field of Information Quality.[5] University level Information Quality courses around the world are listed in [6]

Professional Associations

International Association for Information and Data Quality (IAIDQ)[7]

IAIDQ is a not-for-profit, vendor neutral, professional association formed in 2004, dedicated to building the information and data quality profession.

Information Quality conferences

A number of major conferences relevant to information quality are held annually:

Data Governance and Information Quality Conference[8]

Commercial conferences held each year in the USA

Data Quality Asia Pacific[9]

Commercial conference held annually or Sydney or Melbourne, Australia

Enterprise Data and Business Intelligence Conference Europe[10]

Commercial conferences held annually in London, England.

Information and Data Quality Conference[11]

Not for profit conference run annually by IAIDQ in the USA

International Conference on Information Quality[12]

Academic Conference launched through MITIQ held annually at a University

Master Data Management & Data Governance Conferences[13]

Six major conferences are run annually by the MDM Institute in venues such as London, San Francisco, Sydney, Toronto, Madrid, Frankfurt, Shanghai and New York City.

Link rot

Link rot (or **linkrot**), also known as **link death** or **link breaking**, is an informal term for the process by which hyperlinks (either on individual websites or the Internet in general) point to web pages, servers or other resources that have become permanently unavailable. The phrase also describes the effects of failing to update out-of-date web pages that clutter search engine results. A link that does not work any more is called a **broken link**, **dead link**, or **dangling link**.

Causes

A link may become broken for several reasons. The simplest and most common reason is that the web page it links to doesn't exist anymore. The most common result of a dead link is a 404 error, which indicates that the web server responded, but the specific page could not be found.

Some news sites contribute to the problem of link rot by keeping only recent news articles freely accessible, then removing them or moving them to a paid subscription area. This causes a heavy loss of supporting links in sites discussing newsworthy events and using news sites as references.[*citation needed*]

Another type of dead link occurs when the server that hosts the target page stops working or relocates to a new domain name. In this case the browser may return a DNS error, or it may display a site unrelated to the content sought. The latter can occur when a domain name is allowed to lapse and is subsequently reregistered by another party. Domain names acquired in this manner are attractive to those who wish to take advantage of the stream of unsuspecting surfers that will inflate hit counters and PageRanking.

A link might also be broken because of some form of blocking such as content filters or firewalls. Dead links commonplace on the Internet can also occur on the authoring side, when website content is assembled, copied, or deployed without properly verifying the targets, or simply not kept up to dateWikipedia:Please clarify. Dead links can also occur when a website without Clean URLs is "re-organized".

Prevalence

The 404 "Not Found" response is familiar to even the occasional web user. A number of studies have examined the prevalence of link rot on the web, in academic literature, and in digital libraries. In a 2003 experiment, Fetterly et al. discovered that about one link out of every 200 disappeared each week from the internet. McCown et al. (2005) discovered that half of the URLs cited in D-Lib Magazine articles were no longer accessible 10 years after publication, and other studies have shown link rot in academic literature to be even worse (Spinellis, 2003, Lawrence et al., 2001). Nelson and Allen (2002) examined link rot in digital libraries and found that about 3% of the objects were no longer accessible after one year.

Discovering

Detecting link rot for a given URL is difficult using automated methods. If a URL is accessed and returns an HTTP 200 (OK) response, it may be considered accessible, but the contents of the page may have changed and may no longer be relevant. Some web servers also return a soft 404, a page returned with a 200 (OK) response (instead of a 404 that indicates the URL is no longer accessible). Bar-Yossef et al. (2004) developed a heuristic for automatically discovering soft 404s.

Combating

Due to the unprofessional image that dead links bring to both sites linking and linked to, there are multiple solutions that are available to tackle them: some working to prevent them in the first place, and others trying to resolve them when they have occurred. There are several tools that have been developed to help combat link rot.

Server side

- Avoiding unmanaged hyperlink collections
- Avoiding links to pages deep in a website ("deep linking")
- Using redirection mechanisms (e.g. "301: Moved Permanently") to automatically refer browsers and crawlers to the new location of a URL
- Content management systems may offer builtin solutions to the management of links, e.g. links are updated when content is changed or moved on the site.
- WordPress guards against link rot by replacing non-canonical URLs with their canonical versions.
- IBM's Peridot attempts to automatically fix broken links.
- Permalinking stops broken links by guaranteeing that the content will not move for the foreseeable future. Another form of permalinking is linking to a permalink that then redirects to the actual content, ensuring that even though the real content may be moved etc., links pointing to the resources stay intact.

User side

- The Linkgraph widget gets the URL of the correct page based upon the old broken URL by using historical location information.
- The Google 404 Widget employs Google technology to 'guess' the correct URL, and also provides the user a Google search box to find the correct page.
- When a user receives a 404 response, the Google Toolbar attempts to assist the user in finding the missing page.
- Deadurl.com gathers and ranks alternate urls for a broken link using Google Cache, the Internet Archive, and user submissions. Typing deadurl.com/ left of a broken link in the browser's address bar and pressing enter loads a ranked list of alternate urls, or (depending on user preference) immediately forwards to the best one.

Web archiving

To combat link rot, web archivists are actively engaged in collecting the Web or particular portions of the Web and ensuring the collection is preserved in an archive, such as an archive site, for future researchers, historians, and the public. The largest web archiving organization is the Internet Archive[*citation needed*], whose goal is to maintain an archive of the entire Web, taking periodic snapshots of pages that can then be accessed for free via the Wayback Machine and without registration many years later simply by typing in the URL, or automatically by using browser extensions.WP:NOTRS National libraries, national archives and various consortia of organizations are also involved in archiving culturally important Web content.

Individuals may also use a number of tools that allow them to archive web resources that may go missing in the future:

- WebCite, a tool specifically for scholarly authors, journal editors and publishers to permanently archive "on-demand" and retrieve cited Internet references (Eysenbach and Trudel, 2005).
- Archive-It, a subscription service that allows institutions to build, manage and search their own web archive
- Some social bookmarking websites such as peeep.us, or evernote.com allow users to make online clones of any web page on the internet, creating a copy at an independent url which remains online even if the original page goes down.
- Google keeps a text-based cache (temporary copy) of the pages it has crawled, which can be used to read the information of recently removed pages. However, unlike in archiving services, cached pages are not stored

permanently.
- The WayBack Machine, at the Internet Archive, is a free website that archives old web pages. It does not archive websites whose owners have stated they do not want their website archived.
- archive.is [1], a personal WayBack Machine, which saves text and screenshot of a webpage and keeps it online even if the original page is rot. In most aspects it is a WebCite analog, but also saves images and can save pages from Web 2.0 sites (like Twitter).

Authors citing URLs

A number of studies have shown how widespread link rot is in academic literature (see below). Authors of scholarly publications have also developed best practices for combating link rot in their work:

- Avoiding URL citations that point to resources on a researcher's personal home page (McCown et al., 2005)
- Using Persistent Uniform Resource Locators (PURLs) and digital object identifiers (DOIs) whenever possible
- Using web archiving services (e.g. WebCite) to permanently archive and retrieve cited Internet references (Eysenbach and Trudel, 2005).

One-for-one checking

In systems auditing, **one-for-one checking** is a control process that is frequently used to ensure that specific elements between two or more sources of data are consistent. The control process can also reduce the chances of human error by typos and miskeyed information.

An operations manager might use one-for-one checking of cheques and receivables in order to verify that cash collected is properly reflected by the receivable accounts with regard to the collected cash (i.e., each cheque is associated with an invoice).

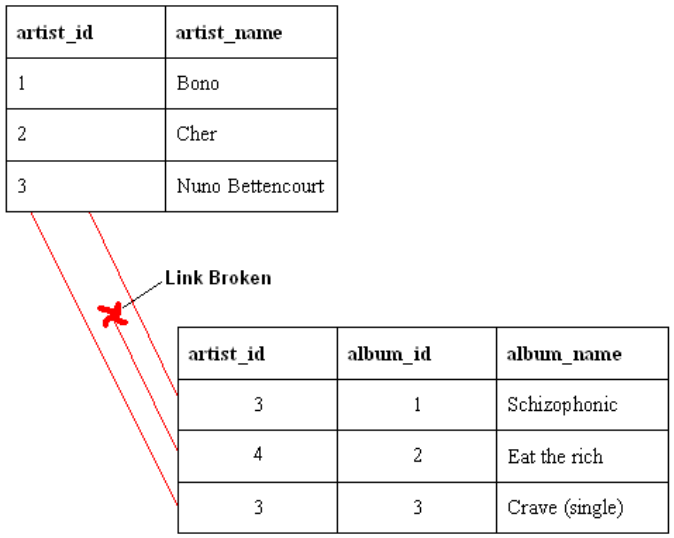
Referential integrity

Referential integrity is a property of data which, when satisfied, requires every value of one attribute (column) of a relation (table) to exist as a value of another attribute in a different (or the same) relation (table).



An example of a database that has not enforced **referential integrity**. In this example, there is a foreign key (`artist_id`) value in the album table that references a non-existent artist — in other words there is a foreign key value with no corresponding primary key value in the referenced table. What happened here was that there was an artist called "Aerosmith", with an `artist_id` of `4`, which was deleted from the artist table. However, the album "Eat the Rich" referred to this artist. With referential integrity enforced, this would not have been possible.

For referential integrity to hold in a relational database, any field in a table that is declared a foreign key can contain either a null value, or only values from a parent table's primary key or a candidate key.[1] In other words, when a foreign key value is used it must reference a valid, existing primary key in the parent table. For instance, deleting a record that contains a value referred to by a foreign key in another table would break referential integrity. Some relational database management systems (RDBMS) can enforce referential integrity, normally either by deleting the foreign key rows as well to maintain integrity, or by returning an error and not performing the delete. Which method is used may be determined by a referential integrity constraint defined in a data dictionary.

"Referential" the adjective describes the action that a foreign key performs, 'referring' to a link field in another table. In simple terms, 'referential integrity' is a guarantee that the target it 'refers' to will be found. A lack of referential integrity in a database can lead relational databases to return incomplete data, usually with no indication of an error. A common problem occurs with relational database tables linked with an 'inner join' which requires non-NULL values in both tables, a requirement that can only be met through careful design and referential integrity.

Formalization

An **inclusion dependency** over two (possibly identical) predicates R and S from a schema is written $R[A_1, ..., A_n] \subseteq S[B_1, ..., B_n]$, where the A_i, B_i are distinct attributes (column names) of R and S. It implies that the tuples of values appearing in columns $A_1, ..., A_n$ for facts of R must also appear as a tuple of values in columns $B_1, ..., B_n$ for some fact of S.

Logical implication between inclusion dependencies can be axiomatized by inference rules [2] and can be decided by a PSPACE algorithm. The problem can be shown to be PSPACE-complete by reduction from the acceptance problem for a linear bounded automaton.[3] However, logical implication between dependencies that can be inclusion dependencies or functional dependencies is undecidable by reduction from the word problem for monoids.[4]

Soft error

In electronics and computing, a **soft error** is a type of error where a signal or datum is wrong. Errors may be caused by a defect, usually understood either to be a mistake in design or construction, or a broken component. A soft error is also a signal or datum which is wrong, but is not assumed to imply such a mistake or breakage. After observing a soft error, there is no implication that the system is any less reliable than before. In the spacecraft industry this kind of error is called a single-event upset.

In a computer's memory system, a soft error changes an instruction in a program or a data value. Soft errors typically can be remedied by cold booting the computer. A soft error will not damage a system's hardware; the only damage is to the data that is being processed.

There are two types of soft errors:

Chip-level soft error

> These errors occur when the radioactive atoms in the chip's material decay and release alpha particles into the chip.
>
> Because an alpha particle contains a positive charge and kinetic energy, the particle can hit a memory cell and cause the cell to change state to a different value. The atomic reaction is so tiny that it does not damage the actual structure of the chip.

System-level soft error

> These errors occur when the data being processed is hit with a noise phenomenon, typically when the data is on a data bus. The computer tries to interpret the noise as a data bit, which can cause errors in addressing or processing program code. The bad data bit can even be saved in memory and cause problems at a later time.

If detected, a soft error may be corrected by rewriting correct data in place of erroneous data. Highly reliable systems use error correction to correct soft errors on the fly. However, in many systems, it may be impossible to determine the correct data, or even to discover that an error is present at all. In addition, before the correction can occur, the system may have crashed, in which case the recovery procedure must include a reboot.

Soft errors involve changes to data — the electrons in a storage circuit, for example — but not changes to the physical circuit itself, the atoms. If the data is rewritten, the circuit will work perfectly again.

Soft errors can occur on transmission lines, in digital logic, analog circuits, magnetic storage, and elsewhere, but are most commonly known in semiconductor storage.

Critical charge

Whether or not a circuit experiences a soft error depends on the energy of the incoming particle, the geometry of the impact, the location of the strike, and the design of the logic circuit. Logic circuits with higher capacitance and higher logic voltages are less likely to suffer an error. This combination of capacitance and voltage is described by the **critical charge** parameter, $\mathbf{Q_{crit}}$, the minimum electron charge disturbance needed to change the logic level. A higher Q_{crit} means fewer soft errors. Unfortunately, a higher Q_{crit} also means a slower logic gate and a higher power dissipation. Reduction in chip feature size and supply voltage, desirable for many reasons, decreases Q_{crit}. Thus, the importance of soft errors increases as chip technology advances.

In a logic circuit, Q_{crit} is defined as the minimum amount of induced charge required at a circuit node to cause a voltage pulse to propagate from that node to the output and be of sufficient duration and magnitude to be reliably latched. Since a logic circuit contains many nodes that may be struck, and each node may be of unique capacitance and distance from output, Q_{crit} is typically characterized on a per-node basis.

Causes of soft errors

Alpha particles from package decay

Soft errors became widely known with the introduction of dynamic RAM in the 1970s. In these early devices, chip packaging materials contained small amounts of radioactive contaminants. Very low decay rates are needed to avoid excess soft errors, and chip companies have occasionally suffered problems with contamination ever since. It is extremely hard to maintain the material purity needed. Controlling alpha particle emission rates for critical packaging materials to less than a level of 0.001 counts per hour per cm^2 (cph/cm^2) is required for reliable performance of most circuits. For comparison, the count rate of a typical shoe's sole is between 0.1 and 10 cph/cm^2.

Package radioactive decay usually causes a soft error by alpha particle emission. The positively charged alpha particle travels through the semiconductor and disturbs the distribution of electrons there. If the disturbance is large enough, a digital signal can change from a 0 to a 1 or vice versa. In combinational logic, this effect is transient, perhaps lasting a fraction of a nanosecond, and this has led to the challenge of soft errors in combinational logic mostly going unnoticed. In sequential logic such as latches and RAM, even this transient upset can become stored for an indefinite time, to be read out later. Thus, designers are usually much more aware of the problem in storage circuits.

A 2011 'Black Hat' paper discusses the real-life security implications of such bit-flips in the internet's DNS system. The paper found up to 3,434 incorrect requests a day due to bit-flip changes for various common domains. Many of these bit-flips would probably be attributable to hardware problems, but some could be attributed to alpha particles.

Isaac Asimov received a letter congratulating him on an accidental prediction of alpha-particle RAM errors in a 1950s novel.[1]

Cosmic rays creating energetic neutrons and protons

Once the electronics industry had determined how to control package contaminants, it became clear that other causes were also at work. James F. Ziegler led a program of work at IBM which culminated in the publication of a number of papers (Ziegler and Lanford, 1979) demonstrating that cosmic rays also could cause soft errors. Indeed, in modern devices, cosmic rays may be the predominant cause. Although the primary particle of the cosmic ray does not generally reach the Earth's surface, it creates a shower of energetic secondary particles. At the Earth's surface approximately 95% of the particles capable of causing soft errors are energetic neutrons with the remainder

composed of protons and pions. IBM estimated in 1996 that one error per month per 256 MiB of ram was expected for a desktop computer. This flux of energetic neutrons is typically referred to as "cosmic rays" in the soft error literature. Neutrons are uncharged and cannot disturb a circuit on their own, but undergo neutron capture by the nucleus of an atom in a chip. This process may result in the production of charged secondaries, such as alpha particles and oxygen nuclei, which can then cause soft errors.

Cosmic ray flux depends on altitude. For the common reference location of 40.7° N, 74° W at sea level (New York City, NY, USA) the flux is approximately 14 neutrons/cm^2/hour. Burying a system in a cave reduces the rate of cosmic-ray induced soft errors to a negligible level. In the lower levels of the atmosphere, the flux increases by a factor of about 2.2 for every 1000 m (1.3 for every 1000 ft) increase in altitude above sea level. Computers operated on top of mountains experience an order of magnitude higher rate of soft errors compared to sea level. The rate of upsets in aircraft may be more than 300 times the sea level upset rate. This is in contrast to package decay induced soft errors, which do not change with location. As chip density increases, Intel expects the errors caused by cosmic rays to increase and be a limiting factor in design.[]

The average rate of cosmic-ray soft errors is *inversely* proportional to sunspot activity. That is, the average number of cosmic-ray soft errors decreases during the active portion of the sunspot cycle and increases during the quiet portion. This counterintuitive result occurs for two reasons. The sun does not generally produce cosmic ray particles with energy above 1 GeV that are capable of penetrating to the Earth's upper atmosphere and creating particle showers, so the changes in the solar flux do not directly influence the number of errors. Further, the increase in the solar flux during an active sun period does have the effect of reshaping the Earth's magnetic field providing some additional shielding against higher energy cosmic rays, resulting in a decrease in the number of particles creating showers. The effect is fairly small in any case resulting in a ±7% modulation of the energetic neutron flux in New York City. Other locations are similarly affected.

Energetic neutrons produced by cosmic rays may lose most of their kinetic energy and reach thermal equilibrium with their surroundings as they are scattered by materials. The resulting neutrons are simply referred to as thermal neutrons and have an average kinetic energy of about 25 millielectron-volts at 25°C. Thermal neutrons are also produced by environmental radiation sources such as the decay of naturally occurring uranium or thorium. The thermal neutron flux from sources other than cosmic-ray showers may still be noticeable in an underground location and an important contributor to soft errors for some circuits.

Thermal neutrons

Neutrons that have lost kinetic energy until they are in thermal equilibrium with their surroundings are an important cause of soft errors for some circuits. At low energies many neutron capture reactions become much more probable and result in fission of certain materials creating charged secondaries as fission byproducts. For some circuits the capture of a thermal neutron by the nucleus of the ^{10}B isotope of boron is particularly important. This nuclear reaction is an efficient producer of an alpha particle, ^{7}Li nucleus and gamma ray. Either of the charged particles (alpha or ^{7}Li) may cause a soft error if produced in very close proximity, approximately 5 μm, to a critical circuit node. The capture cross section for ^{11}B is 6 orders of magnitude smaller and does not contribute to soft errors.

Boron has been used in BPSG, the insulator in the interconnection layers of integrated circuits, particularly in the lowest one. The inclusion of boron lowers the melt temperature of the glass providing better reflow and planarization characteristics. In this application the glass is formulated with a boron content of 4% to 5% by weight. Naturally occurring boron is 20% ^{10}B with the remainder the ^{11}B isotope. Soft errors are caused by the high level of ^{10}B in this critical lower layer of some older integrated circuit processes. Boron-11, used at low concentrations as a p-type dopant, does not contribute to soft errors. Integrated circuit manufacturers eliminated borated dielectrics by the 150 nm process node, largely due to this problem.

In critical designs, depleted boron — consisting almost entirely of boron-11 — is used, to avoid this effect and therefore to reduce the soft error rate. Boron-11 is a by-product of the nuclear industry.

For applications in medical electronic devices this soft error mechanism may be extremely important. Neutrons are produced during high energy cancer radiation therapy using photon beam energies above 10 MeV. These neutrons are moderated as they are scattered from the equipment and walls in the treatment room resulting in a thermal neutron flux that is about 40×10^6 higher than the normal environmental neutron flux. This high thermal neutron flux will generally result in a very high rate of soft errors and consequent circuit upset. [2]

Other causes

Soft errors can also be caused by random noise or signal integrity problems, such as inductive or capacitive crosstalk. However, in general, these sources represent a small contribution to the overall soft error rate when compared to radiation effects.

Designing around soft errors

Soft error mitigation

A designer can attempt to minimize the rate of soft errors by judicious device design, choosing the right semiconductor, package and substrate materials, and the right device geometry. Often, however, this is limited by the need to reduce device size and voltage, to increase operating speed and to reduce power dissipation. The susceptibility of devices to upsets is described in the industry using the JEDEC JESD-89 standard.

One technique that can be used to reduce the soft error rate in digital circuits is called radiation hardening. This involves increasing the capacitance at selected circuit nodes in order to increase its effective Q_{crit} value. This reduces the range of particle energies to which the logic value of the node can be upset. Radiation hardening is often accomplished by increasing the size of transistors who share a drain/source region at the node. Since the area and power overhead of radiation hardening can be restrictive to design, the technique is often applied selectively to nodes which are predicted to have the highest probability of resulting in soft errors if struck. Tools and models that can predict which nodes are most vulnerable are the subject of past and current research in the area of soft errors.

Detecting soft errors

There has been work addressing soft errors in processor and memory resources using both hardware and software techniques. Several research efforts addressed soft errors by proposing error detection and recovery via hardware-based redundant multi-threading. These approaches used special hardware to replicate an application execution to identify errors in the output, which increased hardware design complexity and cost including high performance overhead.

Correcting soft errors

Designers can choose to accept that soft errors will occur, and design systems with appropriate error detection and correction to recover gracefully. Typically, a semiconductor memory design might use forward error correction, incorporating redundant data into each word to create an error correcting code. Alternatively, roll-back error correction can be used, detecting the soft error with an error-detecting code such as parity, and rewriting correct data from another source. This technique is often used for write-through cache memories.

Soft errors in logic circuits are sometimes detected and corrected using the techniques of fault tolerant design. These often include the use of redundant circuitry or computation of data, and typically come at the cost of circuit area, decreased performance, and/or higher power consumption. The concept of triple modular redundancy (TMR) can be employed to ensure very high soft-error reliability in logic circuits. In this technique, three identical copies of a circuit compute on the same data in parallel and outputs are fed into majority voting logic, returning the value that occurred in at least two of three cases. In this way, the failure of one circuit due to soft error is discarded assuming the other two circuits operated correctly. In practice, however, few designers can afford the greater than 200% circuit

area and power overhead required, so it is usually only selectively applied. Another common concept to correct soft errors in logic circuits is temporal (or time) redundancy, in which one circuit operates on the same data multiple times and compares subsequent evaluations for consistency. This approach, however, often incurs performance overhead, area overhead (if copies of latches are used to store data), and power overhead, though is considerably more area-efficient than modular redundancy.

Traditionally, DRAM has had the most attention in the quest to reduce, or work-around soft errors, due to the fact that DRAM has comprised the majority-share of susceptible device surface area in desktop, and server computer systems (ref. the prevalence of ECC RAM in server computers). Hard figures for DRAM susceptibility are hard to come by, and vary considerably across designs, fabrication processes, and manufacturers. 1980s technology 256 kilobit DRAMS could have clusters of five or six bits flip from a single alpha particle. Modern DRAMs have much smaller feature sizes, so the deposition of a similar amount of charge could easily cause many more bits to flip.

The design of error detection and correction circuits is helped by the fact that soft errors usually are localised to a very small area of a chip. Usually, only one cell of a memory is affected, although high energy events can cause a multi-cell upset. Conventional memory layout usually places one bit of many different correction words adjacent on a chip. So, even a *multi-cell upset* leads to only a number of separate *single-bit upsets* in multiple correction words, rather than a *multi-bit upset* in a single correction word. So, an error correcting code needs only to cope with a single bit in error in each correction word in order to cope with all likely soft errors. The term 'multi-cell' is used for upsets affecting multiple cells of a memory, whatever correction words those cells happen to fall in. 'Multi-bit' is used when multiple bits in a single correction word are in error.

Soft errors in combinational logic

The three natural masking effects in combinational logic that determine whether a single event upset (SEU) will propagate to become a soft error are electrical masking, logical masking, and temporal (or timing-window) masking. An SEU is *logically masked* if its propagation is blocked from reaching an output latch because off-path gate inputs prevent a logical transition of that gate's output. An SEU is *electrically masked* if the signal is attenuated by the electrical properties of gates on its propagation path such that the resulting pulse is of insufficient magnitude to be reliably latched. An SEU is *temporally masked* if the erroneous pulse reaches an output latch, but it does not occur close enough to when the latch is actually triggered to hold.

If all three masking effects fail to occur, the propagated pulse becomes latched and the output of the logic circuit will be an erroneous value. In the context of circuit operation, this erroneous output value may be considered a soft error event. However, from a microarchitectural-level standpoint, the affected result may not change the output of the currently-executing program. For instance, the erroneous data could be overwritten before use, masked in subsequent logic operations, or simply never be used. If erroneous data does not affect the output of a program, it is considered to be an example of *microarchitectural masking*.

Soft error rate

Soft error rate (SER) is the rate at which a device or system encounters or is predicted to encounter soft errors. It is typically expressed as either number of failures-in-time (FIT), or mean time between failures (MTBF). The unit adopted for quantifying failures in time is called FIT, equivalent to 1 error per billion hours of device operation. MTBF is usually given in years of device operation. To put it into perspective, a one-year MTBF equals to approximately 114,077 FIT (approximately $\frac{1{,}000{,}000{,}000}{24 \times 365.25}$).

While many electronic systems have an MTBF that exceeds the expected lifetime of the circuit, the SER may still be unacceptable to the manufacturer or customer. For instance, many failures per million circuits due to soft errors can be expected in the field if the system does not have adequate soft error protection. The failure of even a few products in the field, particularly if catastrophic, can tarnish the reputation of the product and company that designed it. Also,

in safety- or cost-critical applications where the cost of system failure far outweighs the cost of the system itself, a 1% chance of soft error failure per lifetime may be too high to be acceptable to the customer. Therefore, it is advantageous to design for low SER when manufacturing a system in high-volume or requiring extremely high reliability.

Two pass verification

Two-pass verification, also called **double data entry**, is a data entry quality control method that was originally employed when data records were entered onto sequential 80-column Hollerith cards with a keypunch. In the first pass through a set of records, the data keystrokes were entered onto each card as the data entry operator typed them. On the second pass through the batch, an operator at a separate machine, called a *verifier*, entered the same data. The verifier compared the second operator's keystrokes with the contents of the original card. If there were no differences, a verification notch was punched on the right edge of the card.

The later IBM 129 keypunch also could operate as a verifier. In that mode, it read a completed card (record) and loaded the 80 keystrokes into a buffer. A data entry operator reentered the record and the keypunch compared the new keystrokes with those loaded into the buffer. If a discrepancy occurred the operator was given a chance to reenter that keystroke and ultimately overwrite the entry in the buffer. If all keystrokes matched the original card, it was passed through and received a verification punch. If corrections were required, then the operator was prompted to discard the original card and insert a fresh card on which corrected keystrokes were typed. The corrected record (card) was passed through and received a corrected verification punch.

Modern use

While this method of quality control clearly is not proof against systematic errors or operator misread entries from a source document, it is very useful in catching and correcting random miskeyed strokes which occur even with experienced data entry operators. However, it proved to be a fatally tragic flaw in the Therac 25 incident. This method has survived the keypunch and is available in some currently available data entry programs (e.g. PSPP/SPSS Data Entry). At least one study suggests that single-pass data entry with range checks and skip rules approaches the reliability of two-pass data entry;[1] however, it is desirable to implement both systems in a data entry application.

Validation rule

A **Validation rule** is a criterion used in the process of data validation, carried out after the data has been encoded onto an input medium and involves a data vet or validation program. This is distinct from formal verification, where the operation of a program is determined to be that which was intended, and that meets the purpose.

The method is to check that data falls the appropriate parameters defined by the systems analyst. A judgement as to whether data is valid is made possible by the validation program, but it cannot ensure complete accuracy. This can only be achieved through the use of all the clerical and computer controls built into the system at the design stage. The difference between data validity and accuracy can be illustrated with a trivial example. A company has established a Personnel file and each record contains a field for the Job Grade. The permitted values are A, B, C, or D. An entry in a record may be valid and accepted by the system if it is one of these characters, but it may not be the correct grade for the individual worker concerned. Whether a grade is correct can only be established by clerical checks or by reference to other files. During systems design, therefore, data definitions are established which place limits on what constitutes valid data. Using these data definitions, a range of software validation checks can be carried out.

Criteria

An example of a validation check is the procedure used to verify an ISBN.[1]

- Size. The number of characters in a data item value is checked; for example, an ISBN must consist of 10 characters only (in the previous version—the standard for 1997 and later has been changed to 13 characters.)
- Format checks. Data must conform to a specified format. Thus, the first 9 characters must be the digits 0 through 9' the 10th must be either those digits or an *X*
- Consistency. Codes in the data items which are related in some way can thus be checked for the consistency of their relationship. The first number of the ISBN designates the language of publication. for example, books published in French-speaking countries carry the digit "2". This must match the address of the publisher, as given elsewhere in the record. .
- Range. Does not apply to ISBN, but typically data must lie within maximum and minimum preset values. For example, customer account numbers may be restricted within the values 10000 to 20000, if this is the arbitrary range of the numbers used for the system.
- Check digit. An extra digit calculated on, for example, an account number, can be used as a self-checking device. When the number is input to the computer, the validation program carries out a calculation similar to that used to generate the check digit originally and thus checks its validity. This kind of check will highlight transcription errors where two or more digits have been transposed or put in the wrong order. The 10th character of the 10-character ISBN is the check digit.

XML

Semi-structured data

Semi-structured data[1] is a form of structured data that does not conform with the formal structure of data models associated with relational databases or other forms of data tables, but nonetheless contains tags or other markers to separate semantic elements and enforce hierarchies of records and fields within the data. Therefore, it is also known as self-describing structure.

In the semi-structured data, the entities belonging to the same class may have different attributes even though they are grouped together, and the attributes' order is not important.

Semi-structured data is increasingly occurring since the advent of the Internet where full-text documents and databases are not the only forms of data any more and different applications need a medium for exchanging information. In object-oriented databases, one often finds semi-structured data.

Types of Semi-structured data

XML

XML,[2] other markup languages, email, and EDI are all forms of semi-structured data. OEM (Object Exchange Model) [3] was created prior to XML as a means of self-describing a data structure. XML has been popularized by web services that are developed utilizing SOAP principles.

Some types of data described here as "semi-structured", especially XML, suffer from the impression that they are incapable of structural rigor at the same functional level as Relational Tables and Rows. Indeed, the view of XML as inherently semi-structured (previously, it was referred to as "unstructured") has handicapped its use for a widening range of data-centric applications. Even documents, normally thought of as the epitome of semi-structure, can be designed with virtually the same rigor as database schema, enforced by the XML schema and processed by both commercial and custom software programs without reducing their usability by human readers.

In view of this fact, XML might be referred to as having "flexible structure" capable of human-centric flow and hierarchy as well as highly rigorous element structure and data typing.

The concept of XML as "human-readable", however, can only be taken so far. Some implementations/dialects of XML, such as the XML representation of the contents of a Microsoft Word document, as implemented in Office 2007 and later versions, utilize dozens or even hundreds of different kinds of tags that reflect a particular problem domain - in Word's case, formatting at the character and paragraph and document level, definitions of styles, inclusion of citations, etc. - which are nested within each other in complex ways. Understanding even a portion of such an XML document by reading it, let alone catching errors in its structure, is impossible without a very deep prior understanding of the specific XML implementation, along with assistance by software that understands the XML schema that has been employed. Such text is not "human-understandable" any more than a book written in Swahili (which uses the Latin alphabet) would be to an American or Western European who does not know a word of that language: the tags are symbols that are meaningless to a person unfamiliar with the domain.

JSON

JSON or JavaScript Object Notation, is an open standard format that uses human-readable text to transmit data objects consisting of attribute–value pairs. It is used primarily to transmit data between a server and web application, as an alternative to XML. JSON has been popularized by web services developed utilizing REST principles.

There is a new breed of databases such as MongoDB and Couchbase that store data natively in JSON format, leveraging the pros of semi-structured data architecture.

Pros and Cons of Using a Semi-structured Data Format

Pros

- Programmers persisting objects from their application to a database do not need to worry about object-relational impedance mismatch, but can often serialize objects via a light-weight library.
- Support for nested or hierarchical data often simplifies data models representing complex relationships between entities.
- Support for lists of objects simplifies data models by avoiding messy translations of lists into a relational data model.

Cons

- The traditional relational data model has a ready-made query language, SQL, which is not applicable to semi-structured data without the extensive use of non-standard features.
- Prone to "garbage in, garbage out"; by removing restraints from the data model, there is less fore-thought that is necessary to operate a data application.

Semi-structured model

The **semi-structured** model is a database model where there is no separation between the data and the schema, and the amount of structure used depends on the purpose.

The advantages of this model are the following:

- It can represent the information of some data sources that cannot be constrained by schema.
- It provides a flexible format for data exchange between different types of databases.
- It can be helpful to view structured data as semi-structured (for browsing purposes).
- The schema can easily be changed.
- The data transfer format may be portable.

The primary trade-off being made in using a semi-structured database model is that queries cannot be made as efficient as in a more constrained structure, such as in the relational model. Typically the records in a semi-structured database are stored with unique IDs that are referenced with pointers to their location on disk. This makes navigational or path-based queries quite efficient, but for doing searches over many records (as is typical in SQL), it is not as efficient because it has to seek around the disk following pointers.

The Object Exchange Model (OEM) is one standard to express semi-structured data, another way is XML.

Standard Generalized Markup Language

Standard Generalized Generic Markup Language

Filename extension	`.sgml`
Internet media type	`application/sgml`, `text/sgml`
Uniform Type Identifier	public.xmlWikipedia:Please clarify
Developed by	ISO
Type of format	Markup Language
Extended from	GML
Extended to	HTML, XML
Standard(s)	ISO 8879 [1]

The **Standard Generalized Markup Language** (**SGML**; ISO 8879:1986) is an ISO-standard technology for defining generalized markup languages for documents. ISO 8879 Annex A.1 defines generalized markup:

> Generalized markup is based on two novel postulates:

- Markup should be declarative: it should describe a document's structure and other attributes, rather than specify the processing to be performed on it. Declarative markup is less likely to conflict with unforeseen future processing needs and techniques.
- Markup should be rigorous so that the techniques available for processing rigorously-defined objects like programs and databases can be used for processing documents as well.

  HTML was theoretically an example of an SGML-based language until HTML 5, which admits that browsers can't parse it as SGML (for compatibility reasons) and codifies exactly what they must do instead.

  DocBook SGML and LinuxDoc are better examples, as they were used almost exclusively with actual SGML tools.

Standard versions

SGML is an ISO standard: "ISO 8879:1986 Information processing — Text and office systems — Standard Generalized Markup Language (SGML)", of which there are three versions:

- Original *SGML*, which was accepted in October 1986, followed by a minor Technical Corrigendum.
- *SGML (ENR)*, in 1996, resulted from a Technical Corrigendum to add *extended naming rules* allowing arbitrary-language and -script markup.
- *SGML (ENR+WWW or WebSGML)*, in 1998, resulted from a Technical Corrigendum [2] to better support XML and WWW requirements.

SGML is part of a trio of enabling ISO standards for electronic documents developed by ISO/IEC JTC1/SC34 (ISO/IEC Joint Technical Committee 1, Subcommittee 34 – Document description and processing languages) :

- SGML (ISO 8879)—generalized markup language
  - SGML was reworked in 1998 into XML, a successful profile of SGML. Full SGML is rarely found or used in new projects.
- DSSSL (ISO/IEC 10179)—document processing and styling language based on Scheme.
  - DSSSL was reworked intoWikipedia:Please clarify W3C XSLT and XSL-FO which use an XML syntax. Nowadays, DSSSL is rarely used in new projects apart from Linux documentation.
- HyTime—Generalized hypertext and scheduling.[3]
  - HyTime was partially reworked into W3C XLink. HyTime is rarely used in new projects.

SGML is supported by various technical reports, in particular

- ISO/IEC TR 9573 – Information processing – SGML support facilities – Techniques for using SGML
  - Part 13: Public entity sets for mathematics and science
    - In 2007, the W3C MathML working group agreed to assume the maintenance of these entity sets.

History

SGML descended from IBM's Generalized Markup Language (GML), which Charles Goldfarb, Edward Mosher, and Raymond Lorie developed in the 1960s. Goldfarb, editor of the international standard, coined the “GML” term using their surname initials. The syntax of SGML is closer to the COCOA format.Wikipedia:Please clarify As a document markup language, SGML was originally designed to enable the sharing of machine-readable large-project documents in government, law, and industry. Many such documents must remain readable for several decades—a long time in the information technology field. SGML also was extensively applied by the military, and the aerospace, technical reference, and industrial publishing industries. The advent of the XML profile has made SGML suitable for widespread application for small-scale, general-purpose use.

Document validity

A fragment of the OED (1985), showing SGML markup

SGML (ENR+WWW) defines two kinds of validity. According to the revised Terms and Definitions of ISO 8879 (from the public draft[4]):

A conforming SGML document must be either a type-valid SGML document, a tag-valid SGML document, or both. Note: A user may wish to enforce additional constraints on a document, such as whether a document instance is integrally-stored or free of entity references.

A **type-valid** SGML document is defined by the standard as

An SGML document in which, for each document instance, there is an associated document type declaration (DTD) to whose DTD that instance conforms.

A **tag-valid** SGML document is defined by the standard as

An SGML document, all of whose document instances are fully tagged. There need not be a document type declaration associated with any of the instances. Note: If there is a document type declaration, the instance can be parsed with or without reference to it.

Terminology

Tag-validity was introduced in SGML (ENR+WWW) to support XML which allows documents with no DOCTYPE declaration but which can be parsed without a grammar or documents which have a DOCTYPE declaration that makes no XML Infoset contributions to the document. The standard calls this *fully tagged*. *Integrally stored* reflects the XML requirement that elements end in the same entity in which they started. *Reference-free* reflects the HTML requirement that entity references are for special characters and do not contain markup. SGML validity commentary, especially commentary that was made before 1997 or that is unaware of SGML (ENR+WWW), covers *type-validity* only.

The SGML emphasis on validity supports the requirement for generalized markup that *markup should be rigorous.* (ISO 8879 A.1)

Syntax

An SGML document may have three parts:

1. the SGML Declaration,
2. the Prologue, containing a DOCTYPE declaration with the various *markup declarations* that together make a Document Type Definition (DTD), and
3. the instance itself, containing one top-most element and its contents.

An SGML document may be composed from many entities (discrete pieces of text). In SGML, the entities and element types used in the document may be specified with a DTD, the different character sets, features, delimiter sets, and keywords are specified in the SGML Declaration to create the *concrete syntax* of the document.

Although full SGML allows implicit markup and some other kinds of tags, the XML specification (s4.3.1) states:

Each XML document has both a logical and a physical structure. Physically, the document is composed of units called entities. An entity may refer to other entities to cause their inclusion in the document. A

document begins in a "root" or document entity. Logically, the document is composed of declarations, elements, comments, character references, and processing instructions, all of which are indicated in the document by explicit markup.

For introductory information on a basic, modern SGML syntax, see XML. The following material concentrates on features not in XML and is not a comprehensive summary of SGML syntax.

Optional features

SGML generalizes and supports a wide range of markup languages as found in the mid 1980s. These ranged from terse Wiki-like syntaxes to RTF-like bracketed languages to HTML-like matching-tag languages. SGML did this by a relatively simple default *reference concrete syntax* augmented with a large number of optional features that could be enabled in the SGML Declaration. Not every SGML parser can necessarily process every SGML document. Because each processor's *System Declaration* can be compared to the document's *SGML Declaration* it is always possible to know whether a document is supported by a particular processor.

Many SGML features relate to markup minimization. Other features relate to parallel asynchronous markup (CONCUR), to linking processing attributes (LINK), and to embedding SGML documents within SGML documents (SUBDOC).

The notion of customizable features was not appropriate for Web use, so one goal of XML was to minimize optional features. However XML's well-formedness rules cannot support Wiki-like languages, leaving them unstandardized and difficult to integrate with non-text information systems.

Concrete and abstract syntaxes

The usual (default) SGML *concrete syntax* resembles this example, which is the default HTML concrete syntax:

```
<QUOTE TYPE="example">
  typically something like <ITALICS>this</ITALICS>
</QUOTE>
```

SGML provides an *abstract syntax* that can be implemented in many different types of *concrete syntax*. Although the markup norm is using angle brackets as start- and end- tag delimiters in an SGML document (per the standard-defined *reference concrete syntax*), it is possible to use other characters—provided a suitable *concrete syntax* is defined in the document's SGML declaration. For example, an SGML interpreter might be programmed to parse GML, wherein the tags are delimited with a left colon and a right full stop, thus, an *:e* prefix denotes an end tag: `:xmp.Hello, world:exmp.`. According to the reference syntax, letter-case (upper- or lower-) is not distinguished in tag names, thus the three tags: (i) `<quote>`, (ii) `<QUOTE>`, and (iii) `<quOtE>` are equivalent. (*NOTE:* A concrete syntax might *change* this rule via the NAMECASE NAMING declarations).

Markup Minimization

SGML has features for reducing the number of characters required to mark up a document, which must be enabled in the SGML Declaration. SGML processors need not support every available feature, thus allowing applications to tolerate many types of inadvertent markup omissions; however, SGML systems usually are intolerant of invalid structures. XML is intolerant of syntax omissions, and does not require a DTD for validation.

OMITTAG

Both start tags and end tags may be omitted from a document instance, provided:

1. the OMITTAG feature is enabled in the SGML Declaration,
2. the DTD indicates that the tags are permitted to be omitted,
3. (for start tags) the element has no associated required (`#REQUIRED`) attributes, and
4. the tag can be unambiguously inferred by context.

For example, if OMITTAG YES is specified in the SGML Declaration (enabling the OMITTAG feature), and the DTD includes the following declarations:

```
<!ELEMENT chapter - - (title, section+)>
<!ELEMENT title o o (#PCDATA)>
<!ELEMENT section - - (title, subsection+)>
```

then this excerpt:

```
<chapter>Introduction to SGML
<section>The SGML Declaration
<subsection>
...
```

which omits two `<title>` tags and two `</title>` tags, would represent valid markup.

Note also that omitting tags is optional - the same excerpt could be tagged like this:

```
<chapter><title>Introduction to SGML</title>
<section><title>The SGML Declaration</title>
<subsection>
...
```

and would still represent valid markup.

Note: The OMITTAG feature is unrelated to the tagging of elements whose declared content is `EMPTY` as defined in the DTD:

```
<!ELEMENT image - o EMPTY>
```

Elements defined like this have no end tag, and specifying one in the document instance would result in invalid markup. This is syntactically different than XML empty elements in this regard.

SHORTREF

Tags can be replaced with delimiter strings, for a terser markup, via the SHORTREF feature. This markup style is now associated with wiki markup, e.g. wherein two equals-signs (==), at the start of a line, are the "heading start-tag", and two equals signs (==) after that are the "heading end-tag".

SHORTTAG

SGML markup languages whose concrete syntax enables the SHORTTAG VALUE feature, do not require attribute values containing only alphanumeric characters to be enclosed within quotation marks—either double " " (LIT) or single ' ' (LITA)—so that the previous markup example could be written:

```
<QUOTE TYPE=example>
  typically something like <ITALICS>this</>
</QUOTE>
```

One feature of SGML markup languages is the "presumptuous empty tagging", such that the empty end tag </> in <ITALICS>this</> "inherits" its value from the nearest previous full start tag, which, in this example, is <ITALICS> (in other words, it closes the most recently opened item). The expression is thus equivalent to <ITALICS>this</ITALICS>.

NET

Another feature is the *NET* (Null End Tag) construction: <ITALICS/this/, which is structurally equivalent to <ITALICS>this</ITALICS>.

Other features

Additionally, the SHORTTAG NETENABL IMMEDNET feature allows shortening tags surrounding an empty text value, but forbids shortening full tags:

```
<QUOTE></QUOTE>
```

can be written as:

```
<QUOTE// <!-- not a typo! -->
```

Wherein the first slash (/) stands for the NET-enabling "start-tag close" (NESTC), and the second slash stands for the NET. **NOTE:** XML defines NESTC with a **/**, and NET with an **>** (angled bracket)—hence the corresponding construct in XML appears as **<QUOTE/>**.

The third feature is 'text on the same line', allowing a markup item to be ended with a line-end; especially useful for headings and such, requiring using either SHORTREF or DATATAG minimization. For example, if the DTD includes the following declarations:

```
<!ELEMENT lines (line*)
<!ELEMENT line O - (#PCDATA)>
<!ENTITY   line-tagc  "</line>">
<!SHORTREF one-line "&#RE;&#RS;" line-tagc>
<!USEMAP   one-line line>
```

(and "&#RE;&#RS;" is a short-reference delimiter in the concrete syntax), then:

```
<lines>
first line
second line
```

```
</lines>
```

is equivalent to:

```
<lines>
<line>first line</line>
<line>second line</line>
</lines>
```

Formal characterization

SGML has many features that defied convenient description with the popular formal automata theory and the contemporary parser technology of the 1980s and the 1990s. The standard warns in Annex H:

> The SGML *model group* notation was deliberately designed to resemble the regular expression notation of automata theory, because automata theory provides a theoretical foundation for some aspects of the notion of conformance to a content model. No assumption should be made about the general applicability of automata to content models.

A report on an early implementation of a parser for basic SGML, the Amsterdam SGML Parser, notes

> the DTD-grammar in SGML must conform to a notion of unambiguity which closely resembles the LL(1) conditions

and specifies various differences.

There appears to be no definitive classification of full SGML against a known class of formal grammar. Plausible classes may include tree-adjoining grammars and adaptive grammars.

XML is described as being generally parsable like a two-level grammar for non-validated XML and a Conway-style pipeline of coroutines (lexer, parser, validator) for valid XML. The SGML productions in the ISO standard are reported to be LL(3) or LL(4). XML-class subsets are reported to be expressible using a W-grammar. According to one paper, and probably considered at an *information set* or parse tree level rather than a character or delimiter level:

> The class of documents that conform to a given SGML document grammar forms an LL(1) language. ...
> The SGML document grammars by themselves are, however, not LL(1) grammars.

The SGML standard does not define SGML with formal data structures, such as parse trees, however, an SGML document is constructed of a rooted directed acyclic graph (RDAG) of physical storage units known as “entities”, which is parsed into a RDAG of structural units known as “elements”. The physical graph is loosely characterized as an *entity tree*, but entities might appear multiple times. Moreover, the structure graph is also loosely characterized as an *element tree*, but the ID/IDREF markup allows arbitrary arcs.

The results of parsing can also be understood as a data tree in different notations; where the document is the root node, and entities in other notations (text, graphics) are child nodes. SGML provides apparatus for linking to and annotating external non-SGML entities.

The SGML standard describes it in terms of *maps* and *recognition modes* (s9.6.1). Each entity, and each element, can have an associated *notation* or *declared content type*, which determines the kinds of references and tags which will be recognized in that entity and element. Also, each element can have an associated *delimiter map* (and *short reference map*), which determines which characters are treated as delimiters in context. The SGML standard characterizes parsing as a state machine switching between recognition modes. During parsing, there is a stack of maps that configure the scanner, while the tokenizer relates to the recognition modes.

Parsing involves traversing the dynamically-retrieved entity graph, finding/implying tags and the element structure, and validating those tags against the grammar. An unusual aspect of SGML is that the grammar

(DTD) is used both passively — to *recognize* lexical structures, and actively — to *generate* missing structures and tags that the DTD has declared optional. End- and start- tags can be omitted, because they can be inferred. Loosely, a series of tags can be omitted only if there is a single, possible path in the grammar to imply them. It was this active use of grammars that made concrete SGML parsing difficult to formally characterize.

SGML uses the term *validation* for both recognition and generation. XML does not use the grammar (DTD) to change delimiter maps or to inform the parse modes, and does not allow tag omission; consequently, XML validation of elements is not active in the sense that SGML validation is active. SGML *without* a DTD (e.g. simple XML), is a grammar or a language; SGML *with* a DTD is a metalanguage. SGML with an SGML declaration is, perhaps, a meta-metalanguage, since it is a metalanguage whose declaration mechanism *is* a metalanguage.

SGML has an abstract syntax implemented by many possible concrete syntaxes, however, this is not the same usage as in an abstract syntax tree and as in a concrete syntax tree. In the SGML usage, a concrete syntax is a set of specific delimiters, while the abstract syntax is the set of names for the delimiters. The XML Infoset corresponds more to the programming language notion of abstract syntax introduced by John McCarthy.

Derivatives

XML

The W3C XML (Extensible Markup Language) is a profile (subset) of SGML designed to ease the implementation of the parser compared to a full SGML parser, primarily for use on the World Wide Web. In addition to disabling many SGML options present in the reference syntax (such as omitting tags and nested subdocuments) XML adds a number of additional restrictions on the kinds of SGML syntax. For example, despite enabling SGML shortened tag forms, XML does not allow unclosed start or end tags. It also relied on many of the additions made by the WebSGML Annex. XML currently is more widely used than full SGML. XML has lightweight internationalization based on Unicode. Applications of XML include XHTML, XQuery, XSLT, XForms, XPointer, JSP, SVG, RSS, Atom, XML-RPC, RDF/XML, and SOAP.

HTML

While HTML was developed partially independently and in parallel with SGML, its creator Tim Berners-Lee, intended it to be an application of SGML. The design of HTML (Hyper Text Markup Language) was therefore inspired by SGML tagging, but, since no clear expansion and parsing guidelines were established, most actual HTML documents are not valid SGML documents. Later, HTML was reformulated (version 2.0) to be more of an SGML application, however, the HTML markup language has many legacy- and exception- handling features that differ from SGML's requirements. HTML 4 is an SGML application that fully conforms to ISO 8879 – SGML.

The charter for the recently revived World Wide Web Consortium HTML Working Group says, "the Group will not assume that an SGML parser is used for 'classic HTML'". Although HTML syntax closely resembles SGML syntax with the default *reference concrete syntax*, HTML5 abandons any attempt to define HTML as an SGML application, explicitly defining its own parsing rules [5] which more closely match existing implementations and documents. It does, however, define an alternative XHTML serialization, which conforms to XML and therefore to SGML as well.

OED

The second edition of the *Oxford English Dictionary* (OED) is entirely marked up with an SGML-based markup language.

The third edition is marked up as XML.

Others

Other document markup languages are partly related to SGML and XML, but — because they cannot be parsed or validated or other-wise processed using standard SGML and XML tools — they are not considered either SGML or XML languages; the Z Format markup language for typesetting and documentation is an example.

Several modern programming languages support tags as primitive token types, or now support Unicode and regular expression pattern-matching. An example is the Scala programming language.

Applications

Document markup languages defined using SGML are called "applications" by the standard; many pre-XML SGML applications were proprietary property of the organizations which developed them, and thus unavailable in the World Wide Web. The following list is of pre-XML SGML applications.

- TEI (Text Encoding Initiative) is an academic consortium that designs, maintains, and develops technical standards for digital-format textual representation applications.
- DocBook is a markup language originally created as an SGML application, designed for authoring technical documentation; DocBook currently is an XML application.
- CALS (Continuous Acquisition and Life-cycle Support) is a US Department of Defense (DoD) initiative for electronically capturing military documents and for linking related data and information.
- EDGAR (Electronic Data-Gathering, Analysis, and Retrieval) system effects automated collection, validation, indexing, acceptance, and forwarding of submissions, by companies and others, who are legally required to file data and information forms with the US Securities and Exchange Commission (SEC).
- LinuxDoc. Documentation for Linux packages has used the LinuxDoc SGML DTD and Docbook XML DTD.

Open source implementations

Significant open source implementations of SGML have included:

- ASP-SGML [6]
- ARC-SGML [7], by Standard Generalized Markup Language Users', 1991, C language
- SGMLS [8], by James Clark, 1993, C language
- Project YAO [9], by Yuan-ze Institute of Technology, Taiwan, with Charles Goldfarb, 1994, object
- SP [10] by James Clark, C++ language

SP and Jade, the associated DSSSL processors, are maintained by the OpenJade [11] project, and are common parts of Linux distributions. A general archive of SGML software and materials resides at SUNET [12]. The original HTML parser class, in Sun System's implementation of Java, is a limited-features SGML parser, using SGML terminology and concepts.

Extensible Markup Language (XML)

Current status	Published
Year started	1996
Editors	Tim Bray, Jean Paoli, C. M. Sperberg-McQueen, Eve Maler, François Yergeau, John Cowan
Related standards	XML Schema
Domain	Data Serialization
Abbreviation	XML
Website	XML 1.0 [3]

Extensible Markup Language (**XML**) is a markup language that defines a set of rules for encoding documents in a format that is both human-readable and machine-readable. It is defined in the XML 1.0 Specification produced by the W3C, and several other related specifications, all free open standards.

The design goals of XML emphasize simplicity, generality, and usability over the Internet. It is a textual data format with strong support via Unicode for the languages of the world. Although the design of XML focuses on documents, it is widely used for the representation of arbitrary data structures, for example in web services.

Many application programming interfaces (APIs) have been developed to aid software developers with processing XML data, and several schema systems exist to aid in the definition of XML-based languages.

Applications of XML

As of 2009[4], hundreds of document formats using XML syntax have been developed, including RSS, Atom, SOAP, and XHTML. XML-based formats have become the default for many office-productivity tools, including Microsoft Office (Office Open XML), OpenOffice.org and LibreOffice (OpenDocument), and Apple's iWork. XML has also been employed as the base language for communication protocols, such as XMPP. Applications for the Microsoft .NET Framework use XML files for configuration. Apple has an implementation of a registry based on XML.[5]

XML has come into common use for the interchange of data over the Internet. RFC 3023 gives rules for the construction of Internet Media Types for use when sending XML. It also defines the media types *application/xml* and *text/xml*, which say only that the data are in XML, and nothing about its semantics. The use of *text/xml* has been criticized as a potential source of encoding problems and it has been suggested that it should be deprecated.

RFC 3023 also recommends that XML-based languages be given media types ending in *+xml*; for example *image/svg+xml* for SVG.

Further guidelines for the use of XML in a networked context may be found in RFC 3470, also known as IETF BCP 70; this document is very wide-ranging and covers many aspects of designing and deploying an XML-based language.

Key terminology

The material in this section is based on the XML Specification. This is not an exhaustive list of all the constructs that appear in XML; it provides an introduction to the key constructs most often encountered in day-to-day use.

(Unicode) character

> By definition, an XML document is a string of characters. Almost every legal Unicode character may appear in an XML document.

Processor and application

> The *processor* analyzes the markup and passes structured information to an *application*. The specification places requirements on what an XML processor must do and not do, but the application is outside its scope. The processor (as the specification calls it) is often referred to colloquially as an *XML parser*.

Markup and content

> The characters making up an XML document are divided into *markup* and *content*, which may be distinguished by the application of simple syntactic rules. Generally, strings that constitute markup either begin with the character `<` and end with a `>`, or they begin with the character `&` and end with a `;`. Strings of characters that are not markup are content. However, in a CDATA section, the delimiters `<![CDATA[` and `]]>` are classified as markup, while the text between them is classified as content. In addition, whitespace before and after the outermost element is classified as markup.

Tag

> A markup construct that begins with `<` and ends with `>`. Tags come in three flavors:

- *start-tags*; for example: `<section>`
- *end-tags*; for example: `</section>`
- *empty-element tags*; for example: `<line-break />`

Element

A logical document component which either begins with a start-tag and ends with a matching end-tag or consists only of an empty-element tag. The characters between the start- and end-tags, if any, are the element's *content*, and may contain markup, including other elements, which are called *child elements*. An example of an element is `<Greeting>Hello, world.</Greeting>` (see hello world). Another is `<line-break />`.

Attribute

A markup construct consisting of a name/value pair that exists within a start-tag or empty-element tag. In the example (below) the element *img* has two attributes, *src* and *alt*:

```
<img src="madonna.jpg" alt='Foligno Madonna, by Raphael' />
```

Another example would be

```
<step number="3">Connect A to B.</step>
```

where the name of the attribute is "number" and the value is "3".

An XML attribute can only have a single value and each attribute can appear at most once on each element. In the common situation where a list of multiple values is desired, this must be done by encoding the list into a well-formed XML attribute[6] with some format beyond what XML defines itself. Usually this is either a comma or semi-colon delimited list or, if the individual values are known not to contain spaces,[7] a space-delimited list can be used.

```
<div class="inner greeting-box" >Hello!</div>
```

where the attribute "class" has both the value "inner greeting-box", indicating the CSS class names "inner" and "greeting-box".

XML declaration

XML documents may begin by declaring some information about themselves, as in the following example:

```
<?xml version="1.0" encoding="UTF-8"?>
```

Characters and escaping

XML documents consist entirely of characters from the Unicode repertoire. Except for a small number of specifically excluded control characters, any character defined by Unicode may appear within the content of an XML document.

XML includes facilities for identifying the *encoding* of the Unicode characters that make up the document, and for expressing characters that, for one reason or another, cannot be used directly.

Valid characters

Unicode code points in the following ranges are valid in XML 1.0 documents:

- U+0009, U+000A, U+000D: these are the only C0 controls accepted in XML 1.0;
- U+0020–U+D7FF, U+E000–U+FFFD: this excludes *some* (not all) non-characters in the BMP (all surrogates, U+FFFE and U+FFFF are forbidden);
- U+10000–U+10FFFF: this includes *all* code points in supplementary planes, including non-characters.

XML 1.1 extends the set of allowed characters to include all the above, plus the remaining characters in the range U+0001–U+001F. At the same time, however, it restricts the use of C0 and C1 control characters other than U+0009, U+000A, U+000D, and U+0085 by requiring them to be written in escaped form (for example U+0001 must be written as &#x01; or its equivalent). In the case of C1 characters, this restriction is a backwards incompatibility; it was introduced to allow common encoding errors to be detected.

The code point U+0000 is the only character that is not permitted in any XML 1.0 or 1.1 document.

Encoding detection

The Unicode character set can be encoded into bytes for storage or transmission in a variety of different ways, called "encodings". Unicode itself defines encodings that cover the entire repertoire; well-known ones include UTF-8 and UTF-16. There are many other text encodings that predate Unicode, such as ASCII and ISO/IEC 8859; their character repertoires in almost every case are subsets of the Unicode character set.

XML allows the use of any of the Unicode-defined encodings, and any other encodings whose characters also appear in Unicode. XML also provides a mechanism whereby an XML processor can reliably, without any prior knowledge, determine which encoding is being used. Encodings other than UTF-8 and UTF-16 will not necessarily be recognized by every XML parser.

Escaping

XML provides *escape* facilities for including characters which are problematic to include directly. For example:

- The characters "<" and "&" are key syntax markers and may *never* appear in content outside a CDATA section.[8]
- Some character encodings support only a subset of Unicode. For example, it is legal to encode an XML document in ASCII, but ASCII lacks code points for Unicode characters such as "é".
- It might not be possible to type the character on the author's machine.
- Some characters have glyphs that cannot be visually distinguished from other characters: examples are
  - non-breaking space (` `) " "

    compare space (`&#x20;`) " "
  - Cyrillic Capital Letter A (`&#x410;`) "А"

    compare Latin Capital Letter A (`&#x41;`) "A"

There are five predefined entities:

- `<` represents "<"
- `>` represents ">"
- `&` represents "&"
- `&apos;` represents '
- `&quot;` represents "

All permitted Unicode characters may be represented with a *numeric character reference*. Consider the Chinese character "中", whose numeric code in Unicode is hexadecimal 4E2D, or decimal 20,013. A user whose keyboard offers no method for entering this character could still insert it in an XML document encoded either as `&#20013;` or `&#x4e2d;`. Similarly, the string "`I <3 Jörg`" could be encoded for inclusion in an XML document as "`I <3 J&#xF6;rg`".

"`&#0;`" is not permitted, however, because the null character is one of the control characters excluded from XML, even when using a numeric character reference. An alternative encoding mechanism such as Base64 is needed to represent such characters.

Comments

Comments may appear anywhere in a document outside other markup. Comments cannot appear before the XML declaration. Comments start with "`<!--`" and end with "`-->`". The string "`--`" (double-hyphen) is not allowed inside comments; this means comments cannot be nested. The ampersand has no special significance within comments, so entity and character references are not recognized as such, and there is no way to represent characters outside the character set of the document encoding.

An example of a valid comment: "<!-- no need to escape <code> & such in comments -->"

International use

XML 1.0 (Fifth Edition) and XML 1.1 support the direct use of almost any Unicode character in element names, attributes, comments, character data, and processing instructions (other than the ones that have special symbolic meaning in XML itself, such as the less-than sign, "<"). The following is a well-formed XML document including both Chinese and Cyrillic characters:

```
<?xml version="1.0" encoding="UTF-8"?>
<俄语>данные</俄语>
```

Well-formedness and error-handling

The XML specification defines an XML document as a well-formed text – meaning that it satisfies a list of syntax rules provided in the specification. Some key points in the fairly lengthy list include:

- The document contains only properly encoded legal Unicode characters
- None of the special syntax characters such as < and & appear except when performing their markup-delineation roles
- The begin, end, and empty-element tags that delimit the elements are correctly nested, with none missing and none overlapping
- The element tags are case-sensitive; the beginning and end tags must match exactly. Tag names cannot contain any of the characters !"#$%&'()*+,/;<=>?@[\]^`{|}~, nor a space character, and cannot start with -, ., or a numeric digit.
- A single "root" element contains all the other elements

The definition of an *XML document* excludes texts that contain violations of well-formedness rules; they are simply not XML. An XML processor that encounters such a violation is required to report such errors and to cease normal processing. This policy, occasionally referred to as "draconian error handling," stands in notable contrast to the behavior of programs that process HTML, which are designed to produce a reasonable result even in the presence of severe markup errors. XML's policy in this area has been criticized as a violation of Postel's law ("Be conservative in what you send; be liberal in what you accept").

The XML specification defines a **valid XML document** as a well-formed XML document which also conforms to the rules of a Document Type Definition (DTD). By extension, the term can also refer to documents that conform to rules in other schema languages, such as XML Schema (XSD). This term should not be confused with a **well-formed XML document**, which is defined as an XML document that has correct XML syntax according to W3C standards.

Schemas and validation

In addition to being well-formed, an XML document may be *valid*. This means that it contains a reference to a Document Type Definition (DTD), and that its elements and attributes are declared in that DTD and follow the grammatical rules for them that the DTD specifies.

XML processors are classified as *validating* or *non-validating* depending on whether or not they check XML documents for validity. A processor that discovers a validity error must be able to report it, but may continue normal processing.

A DTD is an example of a *schema* or *grammar*. Since the initial publication of XML 1.0, there has been substantial work in the area of schema languages for XML. Such schema languages typically constrain the set of elements that may be used in a document, which attributes may be applied to them, the order in which they may appear, and the allowable parent/child relationships.

Document Type Definition

The oldest schema language for XML is the Document Type Definition (DTD), inherited from SGML.

DTDs have the following benefits:

- DTD support is ubiquitous due to its inclusion in the XML 1.0 standard.
- DTDs are terse compared to element-based schema languages and consequently present more information in a single screen.
- DTDs allow the declaration of standard public entity sets for publishing characters.
- DTDs define a *document type* rather than the types used by a namespace, thus grouping all constraints for a document in a single collection.

DTDs have the following limitations:

- They have no explicit support for newer features of XML, most importantly namespaces.
- They lack expressiveness. XML DTDs are simpler than SGML DTDs and there are certain structures that cannot be expressed with regular grammars. DTDs only support rudimentary datatypes.
- They lack readability. DTD designers typically make heavy use of parameter entities (which behave essentially as textual macros), which make it easier to define complex grammars, but at the expense of clarity.
- They use a syntax based on regular expression syntax, inherited from SGML, to describe the schema. Typical XML APIs such as SAX do not attempt to offer applications a structured representation of the syntax, so it is less accessible to programmers than an element-based syntax may be.

Two peculiar features that distinguish DTDs from other schema types are the syntactic support for embedding a DTD within XML documents and for defining *entities*, which are arbitrary fragments of text and/or markup that the XML processor inserts in the DTD itself and in the XML document wherever they are referenced, like character escapes.

DTD technology is still used in many applications because of its ubiquity.

XML Schema

A newer schema language, described by the W3C as the successor of DTDs, is XML Schema, often referred to by the initialism for XML Schema instances, XSD (XML Schema Definition). XSDs are far more powerful than DTDs in describing XML languages. They use a rich datatyping system and allow for more detailed constraints on an XML document's logical structure. XSDs also use an XML-based format, which makes it possible to use ordinary XML tools to help process them.

xs:schema element that defines a schema:

```
<?xml version="1.0" encoding="ISO-8859-1" ?>
<xs:schema xmlns:xs="http://www.w3.org/2001/XMLSchema">
</xs:schema>
```

RELAX NG

RELAX NG was initially specified by OASIS and is now also an ISO/IEC International Standard (as part of DSDL). RELAX NG schemas may be written in either an XML based syntax or a more compact non-XML syntax; the two syntaxes are isomorphic and James Clark's conversion tool - 'Trang [9]', can convert between them without loss of information. RELAX NG has a simpler definition and validation framework than XML Schema, making it easier to use and implement. It also has the ability to use datatype framework plug-ins; a RELAX NG schema author, for example, can require values in an XML document to conform to definitions in XML Schema Datatypes.

Schematron

Schematron is a language for making assertions about the presence or absence of patterns in an XML document. It typically uses XPath expressions.

ISO DSDL and other schema languages

The ISO DSDL (Document Schema Description Languages) standard brings together a comprehensive set of small schema languages, each targeted at specific problems. DSDL includes RELAX NG full and compact syntax, Schematron assertion language, and languages for defining datatypes, character repertoire constraints, renaming and entity expansion, and namespace-based routing of document fragments to different validators. DSDL schema languages do not have the vendor support of XML Schemas yet, and are to some extent a grassroots reaction of industrial publishers to the lack of utility of XML Schemas for publishing.

Some schema languages not only describe the structure of a particular XML format but also offer limited facilities to influence processing of individual XML files that conform to this format. DTDs and XSDs both have this ability; they can for instance provide the infoset augmentation facility and attribute defaults. RELAX NG and Schematron intentionally do not provide these.

Related specifications

A cluster of specifications closely related to XML have been developed, starting soon after the initial publication of XML 1.0. It is frequently the case that the term "XML" is used to refer to XML together with one or more of these other technologies which have come to be seen as part of the XML core.

- XML Namespaces enable the same document to contain XML elements and attributes taken from different vocabularies, without any naming collisions occurring. Although XML Namespaces are not part of the XML specification itself, virtually all XML software also supports XML Namespaces.
- XML Base defines the `xml:base` attribute, which may be used to set the base for resolution of relative URI references within the scope of a single XML element.
- The XML Information Set or *XML infoset* describes an abstract data model for XML documents in terms of *information items*. The infoset is commonly used in the specifications of XML languages, for convenience in describing constraints on the XML constructs those languages allow.
- xml:id Version 1.0 asserts that an attribute named `xml:id` functions as an "ID attribute" in the sense used in a DTD.
- XPath defines a syntax named *XPath expressions* which identifies one or more of the internal components (elements, attributes, and so on) included in an XML document. XPath is widely used in other core-XML specifications and in programming libraries for accessing XML-encoded data.
- XSLT is a language with an XML-based syntax that is used to transform XML documents into other XML documents, HTML, or other, unstructured formats such as plain text or RTF. XSLT is very tightly coupled with XPath, which it uses to address components of the input XML document, mainly elements and attributes.
- XSL Formatting Objects, or XSL-FO, is a markup language for XML document formatting which is most often used to generate PDFs.
- XQuery is an XML-oriented query language strongly rooted in XPath and XML Schema. It provides methods to access, manipulate and return XML, and is mainly conceived as a query language for XML databases.
- XML Signature defines syntax and processing rules for creating digital signatures on XML content.
- XML Encryption defines syntax and processing rules for encrypting XML content.

Some other specifications conceived as part of the "XML Core" have failed to find wide adoption, including XInclude, XLink, and XPointer.

Programming interfaces

The design goals of XML include, "It shall be easy to write programs which process XML documents." Despite this, the XML specification contains almost no information about how programmers might go about doing such processing. The XML Infoset specification provides a vocabulary to refer to the constructs within an XML document, but also does not provide any guidance on how to access this information. A variety of APIs for accessing XML have been developed and used, and some have been standardized.

Existing APIs for XML processing tend to fall into these categories:

- Stream-oriented APIs accessible from a programming language, for example SAX and StAX.
- Tree-traversal APIs accessible from a programming language, for example DOM.
- XML data binding, which provides an automated translation between an XML document and programming-language objects.
- Declarative transformation languages such as XSLT and XQuery.

Stream-oriented facilities require less memory and, for certain tasks which are based on a linear traversal of an XML document, are faster and simpler than other alternatives. Tree-traversal and data-binding APIs typically require the use of much more memory, but are often found more convenient for use by programmers; some include declarative retrieval of document components via the use of XPath expressions.

XSLT is designed for declarative description of XML document transformations, and has been widely implemented both in server-side packages and Web browsers. XQuery overlaps XSLT in its functionality, but is designed more for searching of large XML databases.

Simple API for XML

Simple API for XML (SAX) is a lexical, event-driven interface in which a document is read serially and its contents are reported as callbacks to various methods on a handler object of the user's design. SAX is fast and efficient to implement, but difficult to use for extracting information at random from the XML, since it tends to burden the application author with keeping track of what part of the document is being processed. It is better suited to situations in which certain types of information are always handled the same way, no matter where they occur in the document.

Pull parsing

Pull parsing[10] treats the document as a series of items which are read in sequence using the Iterator design pattern. This allows for writing of recursive-descent parsers in which the structure of the code performing the parsing mirrors the structure of the XML being parsed, and intermediate parsed results can be used and accessed as local variables within the methods performing the parsing, or passed down (as method parameters) into lower-level methods, or returned (as method return values) to higher-level methods. Examples of pull parsers include StAX in the Java programming language, XMLReader in PHP, ElementTree.iterparse in Python, System.Xml.XmlReader in the .NET Framework, and the DOM traversal API (NodeIterator and TreeWalker).

A pull parser creates an iterator that sequentially visits the various elements, attributes, and data in an XML document. Code which uses this iterator can test the current item (to tell, for example, whether it is a start or end element, or text), and inspect its attributes (local name, namespace, values of XML attributes, value of text, etc.), and can also move the iterator to the next item. The code can thus extract information from the document as it traverses it. The recursive-descent approach tends to lend itself to keeping data as typed local variables in the code doing the parsing, while SAX, for instance, typically requires a parser to manually maintain intermediate data within a stack of elements which are parent elements of the element being parsed. Pull-parsing code can be more straightforward to understand and maintain than SAX parsing code.

Document Object Model

The Document Object Model (DOM) is an interface-oriented application programming interface that allows for navigation of the entire document as if it were a tree of node objects representing the document's contents. A DOM document can be created by a parser, or can be generated manually by users (with limitations). Data types in DOM nodes are abstract; implementations provide their own programming language-specific bindings. DOM implementations tend to be memory intensive, as they generally require the entire document to be loaded into memory and constructed as a tree of objects before access is allowed.

Data binding

Another form of XML processing API is XML data binding, where XML data are made available as a hierarchy of custom, strongly typed classes, in contrast to the generic objects created by a Document Object Model parser. This approach simplifies code development, and in many cases allows problems to be identified at compile time rather than run-time. Example data binding systems include the Java Architecture for XML Binding (JAXB) and XML Serialization in .NET.

XML as data type

XML has appeared as a first-class data type in other languages. The ECMAScript for XML (E4X) extension to the ECMAScript/JavaScript language explicitly defines two specific objects (XML and XMLList) for JavaScript, which support XML document nodes and XML node lists as distinct objects and use a dot-notation specifying parent-child relationships. E4X is supported by the Mozilla 2.5+ browsers (though now deprecated) and Adobe Actionscript, but has not been adopted more universally. Similar notations are used in Microsoft's LINQ implementation for Microsoft .NET 3.5 and above, and in Scala (which uses the Java VM). The open-source xmlsh application, which provides a Linux-like shell with special features for XML manipulation, similarly treats XML as a data type, using the <[ ]> notation. The Resource Description Framework defines a data type `rdf:XMLLiteral` to hold wrapped, canonical XML.

History

XML is an application profile of SGML (ISO 8879).

The versatility of SGML for dynamic information display was understood by early digital media publishers in the late 1980s prior to the rise of the Internet. By the mid-1990s some practitioners of SGML had gained experience with the then-new World Wide Web, and believed that SGML offered solutions to some of the problems the Web was likely to face as it grew. Dan Connolly added SGML to the list of W3C's activities when he joined the staff in 1995; work began in mid-1996 when Sun Microsystems engineer Jon Bosak developed a charter and recruited collaborators. Bosak was well connected in the small community of people who had experience both in SGML and the Web.

XML was compiled by a working group of eleven members,[11] supported by a (roughly) 150-member Interest Group. Technical debate took place on the Interest Group mailing list and issues were resolved by consensus or, when that failed, majority vote of the Working Group. A record of design decisions and their rationales was compiled by Michael Sperberg-McQueen on December 4, 1997. James Clark served as Technical Lead of the Working Group, notably contributing the empty-element "<empty />" syntax and the name "XML". Other names that had been put forward for consideration included "MAGMA" (Minimal Architecture for Generalized Markup Applications), "SLIM" (Structured Language for Internet Markup) and "MGML" (Minimal Generalized Markup Language). The co-editors of the specification were originally Tim Bray and Michael Sperberg-McQueen. Halfway through the project Bray accepted a consulting engagement with Netscape, provoking vociferous protests from Microsoft. Bray was temporarily asked to resign the editorship. This led to intense dispute in the Working

Group, eventually solved by the appointment of Microsoft's Jean Paoli as a third co-editor.

The XML Working Group never met face-to-face; the design was accomplished using a combination of email and weekly teleconferences. The major design decisions were reached in a short burst of intense work between August and November 1996,[12] when the first Working Draft of an XML specification was published. Further design work continued through 1997, and XML 1.0 became a W3C Recommendation on February 10, 1998.

Sources

XML is a profile of an ISO standard SGML, and most of XML comes from SGML unchanged. From SGML comes the separation of logical and physical structures (elements and entities), the availability of grammar-based validation (DTDs), the separation of data and metadata (elements and attributes), mixed content, the separation of processing from representation (processing instructions), and the default angle-bracket syntax. Removed were the SGML declaration (XML has a fixed delimiter set and adopts Unicode as the document character set).

Other sources of technology for XML were the Text Encoding Initiative (TEI), which defined a profile of SGML for use as a "transfer syntax"; and HTML, in which elements were synchronous with their resource, document character sets were separate from resource encoding, the xml:lang attribute was invented, and (like HTTP) metadata accompanied the resource rather than being needed at the declaration of a link. The Extended Reference Concrete Syntax (ERCS) project of the SPREAD (Standardization Project Regarding East Asian Documents) project of the ISO-related China/Japan/Korea Document Processing expert group was the basis of XML 1.0's naming rules; SPREAD also introduced hexadecimal numeric character references and the concept of references to make available all Unicode characters. To support ERCS, XML and HTML better, the SGML standard IS 8879 was revised in 1996 and 1998 with WebSGML Adaptations. The XML header followed that of ISO HyTime.

Ideas that developed during discussion which were novel in XML included the algorithm for encoding detection and the encoding header, the processing instruction target, the xml:space attribute, and the new close delimiter for empty-element tags. The notion of well-formedness as opposed to validity (which enables parsing without a schema) was first formalized in XML, although it had been implemented successfully in the Electronic Book Technology "Dynatext" software; the software from the University of Waterloo New Oxford English Dictionary Project; the RISP LISP SGML text processor at Uniscope, Tokyo; the US Army Missile Command IADS hypertext system; Mentor Graphics Context; Interleaf and Xerox Publishing System.

Versions

There are two current versions of XML. The first (*XML 1.0*) was initially defined in 1998. It has undergone minor revisions since then, without being given a new version number, and is currently in its fifth edition, as published on November 26, 2008. It is widely implemented and still recommended for general use.

The second (*XML 1.1*) was initially published on February 4, 2004, the same day as XML 1.0 Third Edition, and is currently in its second edition, as published on August 16, 2006. It contains features (some contentious) that are intended to make XML easier to use in certain cases. The main changes are to enable the use of line-ending characters used on EBCDIC platforms, and the use of scripts and characters absent from Unicode 3.2. XML 1.1 is not very widely implemented and is recommended for use only by those who need its unique features.

Prior to its fifth edition release, XML 1.0 differed from XML 1.1 in having stricter requirements for characters available for use in element and attribute names and unique identifiers: in the first four editions of XML 1.0 the characters were exclusively enumerated using a specific version of the Unicode standard (Unicode 2.0 to Unicode 3.2.) The fifth edition substitutes the mechanism of XML 1.1, which is more future-proof but reduces redundancy. The approach taken in the fifth edition of XML 1.0 and in all editions of XML 1.1 is that only certain characters are forbidden in names, and everything else is allowed, in order to accommodate the use of suitable name characters in future versions of Unicode. In the fifth edition, XML names may contain characters in the Balinese, Cham, or Phoenician scripts among many others which have been added to Unicode since Unicode 3.2.

Almost any Unicode code point can be used in the character data and attribute values of an XML 1.0 or 1.1 document, even if the character corresponding to the code point is not defined in the current version of Unicode. In character data and attribute values, XML 1.1 allows the use of more control characters than XML 1.0, but, for "robustness", most of the control characters introduced in XML 1.1 must be expressed as numeric character references (and #x7F through #x9F, which had been allowed in XML 1.0, are in XML 1.1 even required to be expressed as numeric character references). Among the supported control characters in XML 1.1 are two line break codes that must be treated as whitespace. Whitespace characters are the only control codes that can be written directly.

There has been discussion of an XML 2.0, although no organization has announced plans for work on such a project. XML-SW (SW for skunkworks), written by one of the original developers of XML,[13] contains some proposals for what an XML 2.0 might look like: elimination of DTDs from syntax, integration of namespaces, XML Base and XML Information Set (*infoset*) into the base standard.

The World Wide Web Consortium also has an XML Binary Characterization Working Group doing preliminary research into use cases and properties for a binary encoding of the XML infoset. The working group is not chartered to produce any official standards. Since XML is by definition text-based, ITU-T and ISO are using the name *Fast Infoset* for their own binary infoset to avoid confusion (see ITU-T Rec. X.891 | ISO/IEC 24824-1).

Criticism

XML and its extensions have regularly been criticized for verbosity and complexity.[14] Mapping the basic tree model of XML to type systems of programming languages or databases can be difficult, especially when XML is used for exchanging highly structured data between applications, which was not its primary design goal. Other criticisms attempt to refute the claim that XML is a self-describing language (though the XML specification itself makes no such claim). JSON, YAML, and S-Expressions are frequently proposed as alternatives (see Comparison of data serialization formats);[15] which focus on representing highly structured data rather than documents, which may contain both highly structured and relatively unstructured content.

XML database

An **XML database** is a data persistence software system that allows data to be stored in XML format. These data can then be queried, exported and serialized into the desired format. XML databases are usually associated with document-oriented databases.

Two major classes of XML database exist:

1. **XML-enabled**: these may either map XML to traditional database structures (such as a relational database[1]), accepting XML as input and rendering XML as output, or more recently support native XML types within the traditional database. This term implies that the database processes the XML itself (as opposed to relying on middleware).
2. **Native XML** (NXD): the internal model of such databases depends on XML and uses XML documents as the fundamental unit of storage, which are, however, not necessarily stored in the form of text files.

Rationale for XML in databases

O'Connell gives one reason for the use of XML in databases: the increasingly common use of XML for data transport, which has meant that "data is extracted from databases and put into XML documents and vice-versa".[2] It may prove more efficient (in terms of conversion costs) and easier to store the data in XML format. In content-based applications, the ability of the native XML database also minimizes the need for extraction or entry of metadata to support searching and navigation. In a native XML environment, the entire content store becomes metadata through query languages such as XPath and XQuery, including content, attributes and relationships within the XML (find string "XABr" within element <para> containing attribute 123 having value "P" or "Q", only within parent Y and siblings F or G.) While this level of search capability is possible in external metadata, it requires more complex and difficult processing to reproduce the content tree in metadata.

XML Enabled databases

XML enabled databases typically offer one or more of the following approaches to storing XML within the traditional relational structure:

1. XML is stored into a CLOB (Character large object)
2. XML is `shredded` into a series of Tables based on a Schema [3]
3. XML is stored into a native XML Type as defined by the ISO[4]

RDBMS that support the ISO XML Type are:

1. IBM DB2 (pureXML[5])
2. Microsoft SQL Server [6]
3. Oracle Database [7]
4. PostgreSQL [8]

Typically an XML enabled database is best suited where the majority of data are non-XML, for datasets where the majority of data are XML a Native XML Database is better suited.

Example of XML Type Query in IBM DB2 SQL

```
select
   id, vol, xmlquery('$j/name', passing journal as "j") as name
from
   journals
where
```

```
xmlexists('$j[publisher="Elsevier"]', passing journal as "j")
```

Native XML databases

The term "native XML database" (NXD) can lead to confusion. Many NXDs do not function as standalone databases at all, and do not really store the native (text) form.

The formal definition from the XML:DB initiative (which appears to be inactive since 2003) states that a native XML database:

- Defines a (logical) model for an XML document — as opposed to the data in that document — and stores and retrieves documents according to that model. At a minimum, the model must include elements, attributes, PCDATA, and document order. Examples of such models include the XPath data model, the XML Infoset, and the models implied by the DOM and the events in SAX 1.0.
- Has an XML document as its fundamental unit of (logical) storage, just as a relational database has a row in a table as its fundamental unit of (logical) storage.
- Need not have any particular underlying physical storage model. For example, NXDs can use relational, hierarchical, or object-oriented database structures, or use a proprietary storage format (such as indexed, compressed files).

Additionally, many XML databases provide a logical model of grouping documents, called "collections". Databases can set up and manage many collections at one time. In some implementations, a hierarchy of collections can exist, much in the same way that an operating system's directory-structure works.

All XML databases now[9] support at least one form of querying syntax. Minimally, just about all of them support XPath for performing queries against documents or collections of documents. XPath provides a simple pathing system that allows users to identify nodes that match a particular set of criteria.

In addition to XPath, many XML databases support XSLT as a method of transforming documents or query-results retrieved from the database. XSLT provides a declarative language written using an XML grammar. It aims to define a set of XPath filters that can transform documents (in part or in whole) into other formats including plain text, XML, or HTML.

Many XML databases also support XQuery to perform querying. XQuery includes XPath as a node-selection method, but extends XPath to provide transformational capabilities. Users sometimes refer to its syntax as "FLWOR" (pronounced 'Flower') because the query may include the following clauses: 'for', 'let', 'where', 'order by' and 'return'. Traditional RDBMS vendors (who traditionally had SQL-only engines), are now shipping with hybrid SQL and XQuery engines. Hybrid SQL/XQuery engines help to query XML data alongside the relational data, in the same query expression. This approach helps in combining relational and XML data.

Most XML Databases support a common vendor neutral API called the XQuery API for Java (XQJ). The XQJ API was developed at the JCP as a standard interface to an XML/XQuery data source, enabling a Java developer to submit queries conforming to the World Wide Web Consortium (W3C) XQuery 1.0 specification and to process the results of such queries. Ultimately the XQJ API is to XML Databases and XQuery as the JDBC API is to Relational Databases and SQL.

Language features

Name	License	Native Language	XQuery 3.0	XQuery Update	XQuery Full Text	EXPath Extensions	EXQuery Extensions	XSLT 2.0
BaseX	BSD License	Java	Yes	Yes	Yes	Yes	Yes	Yes
eXist	LGPL License	Java	Partial	Proprietary[10]	Proprietary	Yes	Yes	Yes
MarkLogic Server	Commercial	C++	Partial	Proprietary	Proprietary	No	No	Yes
Sedna	Apache License	C++	No	Yes	Yes	No	No	No

Supported APIs

Name	XQJ	XML:DB	RESTful	RESTXQ	WebDAV
BaseX	Yes	Yes	Yes	Yes	Yes
eXist	Yes	Yes	Yes	Yes	Yes
MarkLogic Server	Yes	No	Yes	Yes	Yes
Sedna	Yes	Yes	No	No	Yes

XML Schema Language comparison

An XML schema is a description of a type of XML document, typically expressed in terms of constraints on the structure and content of documents of that type, above and beyond the basic syntax constraints imposed by XML itself. There are several different languages available for specifying an XML schema. Each language has its strengths and weaknesses.

Note: the W3C defined schema language is called "XML Schema". However, this name can be confusing in the context of referring to a number of **XML schema languages**. As such, throughout this document, references to the term "XML schema" will be any XML schema language where the meaning might be ambiguous, while the term "W3C XML Schema" (referred to in this article as WXS) will be used for the W3C-defined XML schema language.

Overview

Though there are a number of schema languages available, the primary three languages are Document Type Definitions, W3C XML Schema, and RELAX NG. Each language has its own advantages and disadvantages.

This article also covers a brief review of other schema languages.

The primary purpose of a schema language is to specify what the structure of an XML document can be. This means which elements can reside in which other elements, which attributes are and are not legal to have on a particular element, and so forth. A schema is somewhat equivalent to a grammar for a language; a schema defines what the vocabulary for the language may be and what a valid "sentence" is.

Document Type Definitions

Tool Support

DTDs are perhaps the most widely supported schema language for XML. Because DTDs are one of the earliest schema languages for XML, defined before XML even had namespace support, they are widely supported. Internal DTDs are often supported in XML processors; external DTDs are less often supported, but only slightly. Most large XML parsers, ones that support multiple XML technologies, will provide support for DTDs as well.

W3C XML Schema

Advantages over DTDs

Compared to DTDs, W3C XML Schemas are exceptionally powerful. They provide much greater specificity than DTDs could. They are namespace aware, and provide support for types.

W3C XML Schema is written in XML itself, and therefore has a schema of its own (appropriately, written in W3C XML Schema).

W3C XML Schema has a large number of built-in and derived data types. These are specified by the W3C XML Schema specification, so all W3C XML Schema validators and processors must support them.

Due to the nature of the schema language, after an XML document is validated, the entire XML document, both content and structure, can be expressed in terms of the schema itself. This functionality, known as Post-Schema-Validation Infoset (PSVI), can be used to transform the document into a hierarchy of typed objects that can be accessed in a programming language through a neutral interface.

Commonality with RELAX NG

RELAX NG and W3C XML Schema allow for similar mechanisms of specificity. Both allow for a degree of modularity in their languages, going so far as to being able to split the schema into multiple files. And both of them are, or can be, defined in an XML language.

Advantages over RELAX NG

RELAX NG does not have any analog to PSVI. Unlike W3C XML Schema, RELAX NG was designed so that validation and augmentation (adding type information and default values) are separate (See XML_Schema_(W3C)#Criticism).

W3C XML Schema has a formal mechanism for attaching a schema to an XML document, while RELAX NG intentionally avoids such mechanisms for security and interoperability reasons (See XML_Schema_(W3C)#Criticism).

RELAX NG has no ability to apply default attribute data to an element's list of attributes (i.e., changing the XML info set), while W3C XML Schema does. Again, this design is intentional and is to separate validation and augmentation (See XML_Schema_(W3C)#Criticism).[1]

W3C XML Schema has a rich "simple type" system built in (xs:number, xs:date, etc., plus derivation of custom types), while RELAX NG has an extremely simplistic one because it's meant to use type libraries developed independently of RELAX NG, rather than grow its own. This is seen by some as a disadvantage. In practice it's common for a RELAX NG schema to use the predefined "simple types" and "restrictions" (pattern, maxLength, etc.) of W3C XML Schema.

In W3C XML Schema a specific number or range of repetitions of patterns can be expressed more elegantly than under RELAX NG. For large numbers it's practically not possible to specify at all in RELAX NG.

Disadvantages

W3C XML Schema is complex and hard to learn, although that's partially because it tries to do more than mere validation (see PSVI).

Although being written in XML is an advantage, it is also a disadvantage in some ways. The W3C XML Schema language in particular can be quite verbose, while a DTD can be terse and relatively easily editable.

Likewise, WXS's formal mechanism for associating a document with a schema can pose a potential security problem. For WXS validators that will follow a URI to an arbitrary online location, there is the potential for reading something malicious from the other side of the stream.[2]

W3C XML Schema does not implement most of the DTD ability to provide data elements to a document. While technically a comparative deficiency, it also does not have the problems that this ability can create as well, which makes it a strength.

Although W3C XML Schema's ability to add default attributes to elements is an advantage, it is a disadvantage in some ways as well. It means that an XML file may not be usable in the absence of its schema, even if the document would validate against that schema. In effect, all users of such an XML document must also implement the W3C XML Schema specification, thus ruling out minimalist or older XML parsers. It can also dramatically slow down processing of the document, as the processor must potentially download and process a second XML file (the schema).

Tool Support

WXS support exists in a number of large XML parsing packages. Xerces and the .NET Framework's Base Class Library both provide support for WXS validation.

RELAX NG

RELAX NG provides for most of the advantages that W3C XML Schema does over DTDs.

Advantages over W3C XML Schema

While the language of RELAX NG can be written in XML, it also has an equivalent form that is much more like a DTD, but with greater specifying power. This form is known as the compact syntax. Tools can easily convert between these forms with no loss of features or even commenting. Even arbitrary elements specified between RELAX NG XML elements can be converted into the compact form.

RELAX NG provides very strong support for unordered content. That is, it allows the schema to state that a sequence of patterns may appear in any order.

RELAX NG also allows for non-deterministic content models. What this means is that RELAX NG allows the specification of a sequence like the following:

```
<zeroOrMore>
  <ref name="odd" />
  <ref name="even" />
</zeroOrMore>
<optional>
  <ref name="odd" />
</optional>
```

When the validator encounters something that matches the "odd" pattern, it is unknown whether this is the optional last "odd" reference or simply one in the zeroOrMore sequence without looking ahead at the data. RELAX NG allows this kind of specification. W3C XML Schema requires all of its sequences to be fully deterministic, so mechanisms like the above must be either specified in a different way or omitted altogether.

RELAX NG allows attributes to be treated as elements in content models. In particular, this means that one can provide the following:

```
<element name="some_element">
  <choice>
    <attribute name="has_name">
      <value>false</value>
    </attribute>
    <group>
      <attribute name="has_name">
        <value>true</value>
      </attribute>
      <element name="name"><text /></element>
    </group>
  </choice>
</element>
```

This block states that the element "some_element" must have an attribute named "has_name". This attribute can only take true or false as values, and if it is true, the first child element of the element must be "name", which stores text.

If "name" did not need to be the first element, then the choice could be wrapped in an "interleave" element along with other elements. The order of the specification of attributes in RELAX NG has no meaning, so this block need not be the first block in the element definition.

W3C XML Schema cannot specify such a dependency between the content of an attribute and child elements.

RELAX NG's specification only lists two built-in types (string and token), but it allows for the definition of many more. In theory, the lack of a specific list allows a processor to support data types that are very problem-domain specific.

Most RELAX NG schemas can be algorithmically converted into W3C XML Schemas and even DTDs (except when using RELAX NG features not supported by those languages, as above). The reverse is not true. As such, RELAX NG can be used as a normative version of the schema, and the user can convert it to other forms for tools that do not support RELAX NG.

Disadvantages

Most of RELAX NG's disadvantages are covered under the section on W3C XML Schema's advantages over RELAX NG.

Though RELAX NG's ability to support user-defined data types is useful, it comes at the disadvantage of only having two data types that the user can rely upon. Which, in theory, means that using a RELAX NG schema across multiple validators requires either providing those user-defined data types to that validator or using only the two basic types. In practice however, most RELAX NG processors support the W3C XML Schema set of data types.

Tool Support

RELAX NG's tool support is significant, but it is less widespread than W3C XML Schema. The Mono Project's implementation of the .NET Framework includes a RELAX NG validator. The C library libxml2 provides RELAX NG support as well. Sun Microsystems's Multiple Schema Validator for Java also provides RELAX NG support.

Schematron

Schematron is a fairly unique schema language. Unlike the main three, it defines an XML file's syntax as a list of XPath-based rules. If the document passes these rules, then it is valid.

Advantages

Because of its rule-based nature, Schematron's specificity is very strong. It can require that the content of an element be controlled by one of its siblings. It can also request or require that the root element, regardless of what element that happens to be, have specific attributes. It can even specify required relationships between multiple XML files.

Disadvantages

While Schematron is good at relational constructs, its ability to specify the basic structure of a document, that is, which elements can go where, results in a very verbose schema.

The typical way to solve this is to combine Schematron with RELAX NG or W3C XML Schema. There are several schema processors available for both languages that support this combined form. This allows Schematron rules to specify additional constraints to the structure defined by W3C XML Schema or RELAX NG.

Tool Support

Schematron's reference implementation is actually an XSLT transformation that transforms the Schematron document into an XSLT that validates the XML file. As such, Schematron's potential toolset is any XSLT processor, though libxml2 provides an implementation that does not require XSLT. Sun Microsystems's Multiple Schema Validator for Java has an add-on that allows it to validate RELAX NG schemas that have embedded Schematron rules.

Namespace Routing Language (NRL)

This is not technically a schema language. Its sole purpose is to direct parts of documents to individual schemas based on the namespace of the encountered elements. An NRL is merely a list of XML namespaces and a path to a schema that each corresponds to. This allows each schema to be concerned with only its own language definition, and the NRL file routes the schema validator to the correct schema file based on the namespace of that element.

This XML format is schema-language agnostic and works for just about any schema language.

References

[1] While annotations in RELAX NG can support default attribute values, the RELAX NG specification does not mandate that a validator provide this ability to modify an XML infoset as part of validation. The WXS specification does mandate this behavior. An additional specification associated with RELAX NG does provide this ability. See Relax NG DTD Compatibility (default value) (http://www.oasis-open.org/committees/relax-ng/compatibility.html#default-value).

XML schema

An **XML schema** is a description of a type of XML document, typically expressed in terms of constraints on the structure and content of documents of that type, above and beyond the basic syntactical constraints imposed by XML itself. These constraints are generally expressed using some combination of grammatical rules governing the order of elements, Boolean predicates that the content must satisfy, data types governing the content of elements and attributes, and more specialized rules such as uniqueness and referential integrity constraints.

There are languages developed specifically to express XML schemas. The Document Type Definition (DTD) language, which is native to the XML specification, is a schema language that is of relatively limited capability, but that also has other uses in XML aside from the expression of schemas. Two more expressive XML schema languages in widespread use are XML Schema (with a capital *S*) and RELAX NG.

The mechanism for associating an XML document with a schema varies according to the schema language. The association may be achieved via markup within the XML document itself, or via some external means.

Capitalization

There is some confusion as to when to use the capitalized spelling "Schema" and when to use the lowercase spelling. The lowercase form is a generic term and may refer to any type of schema, including DTD, XML Schema (aka XSD), RELAX NG, or others, and should always be written using lowercase except when appearing at the start of a sentence. The form "Schema" (capitalized) in common use in the XML community always refers to W3C XML Schema.

Validation

The process of checking to see if an XML document conforms to a schema is called validation, which is separate from XML's core concept of syntactic well-formedness. All XML documents must be well-formed, but it is not required that a document be valid unless the XML parser is "validating", in which case the document is also checked for conformance with its associated schema. DTD-validating parsers are most common, but some support W3C XML Schema or RELAX NG as well.

Documents are only considered **valid** if they satisfy the requirements of the schema with which they have been associated. These requirements typically include such constraints as:

- Elements and attributes that must/may be included, and their permitted structure
- The structure as specified by a regular expression syntax
- How character data is to be interpreted, e.g. as a number, a date, a URL, a Boolean, etc.

Validation of an instance document against a schema can be regarded as a conceptually separate operation from XML parsing. In practice, however, many schema validators are integrated with an XML parser.

XML schema languages

- Document Content Description facility for XML, an RDF framework
- Document Definition Markup Language (DDML)
- Document Schema Definition Languages (DSDL)
- Document Structure Description (DSD)
- SGML's Document Type Definition (DTD)
- Namespace Routing Language (NRL)
- OASIS CAM Content Assembly Mechanism
- RELAX NG and its predecessors RELAX and TREX
- Schema for Object-Oriented XML (SOX)
- Schematron
- XML-Data Reduced (XDR)
- ASN.1 XML Encoding Rules (XER)
- XML Schema (WXS or XSD)

XML validation

XML validation is the process of checking a document written in XML (eXtensible Markup Language) to confirm that it is both well-formed and also "valid" in that it follows a defined structure. A well-formed document follows the basic syntactic rules of XML, which are the same for all XML documents. A valid document also respects the rules dictated by a particular DTD or XML schema, according to the application-specific choices for those particular .

In addition, extended tools are available such as OASIS CAM standard specification that provide contextual validation of content and structure that is more flexible than basic schema validations.

xmllint is a command line XML tool that can perform XML validation. It can be found in UNIX / Linux environments. An example with the use of this program for validation of a file called *example.xml* is

```
xmllint --valid --noout example.xml
```

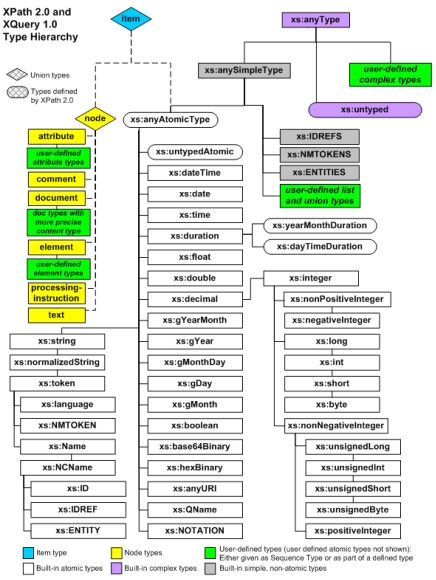
Xpath data model

The **XQuery and XPath Data Model** (XDM) is the data model shared by the XPath 2.0, XSLT 2.0 and XQuery programming languages. It is a W3C recommendation and forms an integral part of all three languages. Originally, it was based on the XPath 1.0 data model which in turn is based on the XML Information Set.

The XDM consists of flat sequences of zero or more items of different types. Items can be typed or untyped and include atomic values as well as XML nodes (with elements, attributes and text nodes, etc.). Instances of the XDM can optionally be XML schema-validated.



The XDM type hierarchy

Path expression

In query languages, **path expressions** identify an object by describing how to navigate to it in some graph (possibly implicit) of objects. For example, the path expression `p.Manager.Home.City` might refer the city of residence of someone's manager. Path expressions have been extended to support regular expression-like flexibility. XPath is an example of a path expression language.

In concurrency control, **path expressions** are a mechanism for expressing permitted sequences of execution. For example, a path expression like "`{read}, write`" might specify that either multiple simultaneous executions of `read` or a single execution of `write` but not both are allowed at any point in time.

XQuery

XQuery

Paradigm(s)	declarative, functional, modular
Appeared in	2007
Designed by	W3C
Stable release	1.0 [1] / January 23, 2007
Preview release	3.0 [2] / July 23, 2013
Typing discipline	dynamic or static, strong
Major implementations	Many [3]
Influenced by	XPath, SQL, XSLT
OS	Cross-platform
Usual filename extensions	.xq, .xqy, .xquery
Website	www.w3.org/XML/Query/ [4]
• XQuery at Wikibooks	

XQuery is a query and functional programming language that is designed to query and transform collections of structured and unstructured data, usually in the form of XML, text and with vendor-specific extensions for other data formats (JSON, binary, etc.).

XQuery 3.0 is currently being developed by the XML Query working group of the W3C and has reached Last Call Working Draft status.

XQuery 1.0 was developed by the XML Query working group of the W3C. The work was closely coordinated with the development of XSLT 2.0 by the XSL Working Group; the two groups shared responsibility for XPath 2.0, which is a subset of XQuery 1.0. XQuery 1.0 became a W3C Recommendation on January 23, 2007.

> "The mission of the XML Query project is to provide flexible query facilities to extract data from real and virtual documents on the World Wide Web, therefore finally providing the needed interaction between the Web world and the database world. Ultimately, collections of XML files will be accessed like databases".

Features

XQuery provides the means to extract and manipulate data from XML documents or any data source that can be viewed as XML, such as relational databases or office documents.

XQuery contains a superset of XPath expression syntax to address specific parts of an XML document. It supplements this with a SQL-like "FLWOR expression" for performing joins. A FLWOR expression is constructed from the five clauses after which it is named: FOR, LET, WHERE, ORDER BY, RETURN.

The language also provides syntax allowing new XML documents to be constructed. Where the element and attribute names are known in advance, an XML-like syntax can be used; in other cases, expressions referred to as dynamic node constructors are available. All these constructs are defined as expressions within the language, and can be arbitrarily nested.

The language is based on the XQuery and XPath Data Model (XDM) which uses a tree-structured model of the information content of an XML document, containing seven kinds of nodes: document nodes, elements, attributes, text nodes, comments, processing instructions, and namespaces.

XDM also models all values as sequences (a singleton value is considered to be a sequence of length one). The items in a sequence can either be XML nodes or atomic values. Atomic values may be integers, strings, booleans, and so on: the full list of types is based on the primitive types defined in XML Schema.

XQuery 1.0 does not include features for updating XML documents or databases; it also lacks full text search capability. These features are both under active development for a subsequent version of the language. However, the new standards such as XQuery Update Facility 1.0 supports update feature and XQuery and XPath Full Text 1.0 support full text search in XML documents.

XQuery is a programming language that can express arbitrary XML to XML data transformations with the following features:

1. Logical/physical data independence
2. Declarative
3. High level
4. Side-effect free
5. Strongly typed

Examples

The sample XQuery code below lists the unique speakers in each act of Shakespeare's play Hamlet, encoded in hamlet.xml [5]

```
<html><head/><body>
{
  for $act in doc("hamlet.xml")//ACT
  let $speakers := distinct-values($act//SPEAKER)
  return
    <div>
      <h1>{ string($act/TITLE) }</h1>
      <ul>
      {
        for $speaker in $speakers
        return <li>{ $speaker }</li>
      }
      </ul>
    </div>
}
</body></html>
```

All XQuery constructs for performing computations are expressions. There are no statements, even though some of the keywords appear to suggest statement-like behaviors. To execute a function, the expression within the body is evaluated and its value is returned. Thus to write a function to double an input value, one simply writes:

```
declare function local:doubler($x) { $x * 2 }
```

To write a full query saying 'Hello World', one writes the expression:

```
"Hello World"
```

This style is common in functional programming languages. However, unlike most functional programming languages, XQuery 1.0 doesn't support higher-order functions (they first appear in the drafts for XQuery 3.0).

Applications

Below are a few examples of how XQuery can be used:

1. Extracting information from a database for use in a web service.
2. Generating summary reports on data stored in an XML database.
3. Searching textual documents on the Web for relevant information and compiling the results.
4. Selecting and transforming XML data to XHTML to be published on the Web.
5. Pulling data from databases to be used for the application integration.
6. Splitting up an XML document that represents multiple transactions into multiple XML documents.

XQuery and XSLT compared

Scope

Although XQuery was initially conceived as a query language for large collections of XML documents, it is also capable of transforming individual documents. As such, its capabilities overlap with XSLT, which was designed expressly to allow input XML documents to be transformed into HTML or other formats.

The XSLT 2.0 and XQuery standards were developed by separate working groups within W3C, working together to ensure a common approach where appropriate. They share the same data model (XDM), type system, and function library, and both include XPath 2.0 as a sublanguage.

Origin

The two languages, however, are rooted in different traditions and serve the needs of different communities. XSLT was primarily conceived as a stylesheet language whose primary goal was to render XML for the human reader on screen, on the web (as web template language), or on paper. XQuery was primarily conceived as a database query language in the tradition of SQL.

Because the two languages originate in different communities, XSLT is stronger in its handling of narrative documents with more flexible structure, while XQuery is stronger in its data handling (for example, when performing relational joins).

Versions

XSLT 1.0 appeared as a Recommendation in 1999, whereas XQuery 1.0 only became a Recommendation in early 2007; as a result, XSLT is at present much more widely used. Both languages have similar expressive power, though XSLT 2.0 has many features that are missing from XQuery 1.0, such as grouping, number and date formatting, and greater control over XML namespaces. Many of these features are planned for XQuery 3.0.

Any comparison must take into account the fact that XSLT 1.0 and XSLT 2.0 are very different languages. XSLT 2.0, in particular, has been heavily influenced by XQuery in its move to strong typing and schema-awareness.

Strengths and weaknesses

Usability studies have shown that XQuery is easier to learn than XSLT, especially for users with previous experience of database languages such as SQL.[6] This can be attributed to the fact that XQuery is a smaller language with fewer concepts to learn, and to the fact that programs are more concise. It is also true that XQuery is more orthogonal, in that any expression can be used in any syntactic context. By contrast, XSLT is a two-language system in which XPath expressions can be nested in XSLT instructions but not vice versa.

XSLT is currently stronger than XQuery for applications that involve making small changes to a document (for example, deleting all the NOTE elements). Such applications are generally handled in XSLT by use of a coding pattern that involves an identity template that copies all nodes unchanged, modified by specific templates that modify selected nodes. XQuery has no equivalent to this coding pattern, though in future versions it will be possible to tackle such problems using the update facilities in the language that are under development.

Another facility lacking from XQuery is any kind of mechanism for dynamic binding or polymorphism. The absence of this capability starts to become noticeable when writing large applications, or when writing code that is designed to be reusable in different environments. XSLT offers two complementary mechanisms in this area: the dynamic matching of template rules, and the ability to override rules using `xsl:import`, that make it possible to write applications with multiple customization layers.

The absence of these facilities from XQuery is a deliberate design decision: it has the consequence that XQuery is very amenable to static analysis, which is essential to achieve the level of optimization needed in database query languages. This also makes it easier to detect errors in XQuery code at compile time.

The fact that XSLT 2.0 uses XML syntax makes it rather verbose in comparison to XQuery 1.0. However, many large applications take advantage of this capability by using XSLT to read, write, or modify stylesheets dynamically as part of a processing pipeline. The use of XML syntax also enables the use of XML-based tools for managing XSLT code. By contrast, XQuery syntax is more suitable for embedding in traditional programming languages such as Java[7] or C#. If necessary, XQuery code can also be expressed in an XML syntax called XQueryX. The XQueryX representation of XQuery code is rather verbose and not convenient for humans, but can easily be processed with XML tools, for example transformed with XSLT stylesheets.

Extensions and future work

W3C extensions

Currently, two major extensions to the XQuery are under development by the W3C:

- XQuery 1.0 and XPath 2.0 Full-Text[8]
- XQuery Update Facility

Work on XQuery 3.0 (formerly: 1.1) is well advanced: a Candidate Recommendation was published on 8 January 2013.[9]

A scripting (procedural) extension for XQuery is also being designed.[10]

The EXPath Community Group [11] develops extensions to XQuery and other related standards (XPath, XSLT, XProc, and XForms). There following extensions are currently available:

- Packaging System[12]
- File Module[13]
- Binary Module[14]
- Web Applications[15]

Third-party extensions

JSONiq is an extension of XQuery that adds support to extract and transform data from JSON documents. JSONiq is a superset of XQuery 3.0. It is published under the Creative Commons Attribution-ShareAlike 3.0 license.

The EXQuery project develops standards around creating portable XQuery applications. The following standards are currently available:

- RESTXQ

Previous version based on an article at the French language Wikipedia

XSA

In computer science, **XSA** (better known as **Cross-Server Attack**) is a networking security intrusion method which allows for a malicious client to compromise security over a website or service on a server by using implemented services on the server that may not be secure.

In general, XSA is demonstrated against websites, yet sometimes it is used in conjunction with other services located on the same server.

Basics

XSA is a method that allows for a malicious client to use services that a remote server implements in order to attack another service on the same server or network.

Most website hosting companies that offer hosting for large or even little amounts of separate websites are vulnerable to this method of attack, because of the amount of access services such as PHP and the webserver itself give to a client that allows the client to access other website configurations, files, passwords and the like.

History

The term 'XSA' was first coined by DeadlyData, a prominent Computer hacker during the early 2000s, over the voice communications software TeamSpeak. While he had not invented or pioneered this method of intrusion, he coined it as a shortened term to describe the act of performing Cross-Server Attacks (XSAs).

It was then used further in the community and now supports for most of the methods and subsets of the method that give both Computer hacker and malicious individuals the terminology to attack websites using software that is located on the same server.

XSIL

XSIL (Extensible Scientific Interchange Language) is an XML-based transport language for scientific data, supporting the inclusion of both in-file data and metadata. The language comes with an extensible Java object model. The language's elementary objects include Param (arbitrary association between a keyword and a value), Array, Table (a set of column headings followed by a set of records), and Stream, which enables one to either encapsulate data inside the XSIL file or point to an external data source.

BFD is an XML dialect based on XSIL.

SQL/XML

SQL/XML or **XML-Related Specifications** is an extension to the Structured Query Language (SQL) specification, which defines the use of XML in conjunction with SQL. The XML data type is introduced, as well as several routines, functions, and XML-to-SQL data type mappings to support manipulation and storage of XML in a SQL database.

SQL/XML is defined by **ISO/IEC 9075 Part 14**:

- SQL:2003-14 defined the basic datatypes, mappings, predicates and functions;
- SQL:2006-14, SQL:2008-14, SQL:2011-14 was augmented, as a complementary standard to XQuery .

Specification

The specification defines functions for working with XML, including element construction, mapping data from relational tables, combining XML fragments, and embedding XQuery expressions in SQL statements. Functions which can be embedded include XMLQUERY (which extracts XML or values from an XML field) and XMLEXISTS (which predicates whether an XQuery expression is matched).

Further information and examples of the SQL/XML functions are provided in the external links below.

Standard compliance

The result of Wagner's objective evaluation of the *SQL/XML*:2006 standard compliance of Oracle 11g Release 1, MS SQL Server 2008 and MySQL 5.1.30 is shown in the following table, to which the data for PostgreSQL 9.1,[1][2] and IBM DB2 has been added:

	Oracle 11g Release 1	IBM DB2 9.7	MS SQL Server 2008	MySQL 5.1.30	PostgreSQL 9.1
Datatype XML	partial (Oracle entitles the data type 'XMLType' instead of 'XML')	high	high	no	partial
SQL/XML predicates	high	high	partial	no	partial
SQL/XML functions	high	high	partial	low	high

NOTE: only Oracle, IBM DB2 and MS-SQL-Server have been augmented with XQuery.

Examples

The sample SQLXML query below has SQLXML type as output(tested on DB2 9.7 and Oracle 11g):

```
SELECT XMLELEMENT(NAME "PhoneBook", -- root element name
                  XMLAGG(           -- aggregation over the rows
                  XMLELEMENT(NAME "Contact",

                  XMLATTRIBUTES(cust.FIRST_NAME AS "Name",
                                cust.TEL)
                               )
                        )
                  )
FROM TMP.CUSTOMER AS cust;
```

And the output:

```
<PhoneBook>
    <Contact Name="Daniel" TEL="788255855"/>
    <Contact Name="Martin" TEL="889665447"/>
    <Contact Name="Eva"    TEL="111222333"/>
    <Contact Name="Alena"  TEL="444555666"/>
    <Contact Name="Oliver" TEL="777888999"/>
    <Contact Name="George" TEL="444882446"/>
    <Contact Name="Jamie"  TEL="123456789"/>
</PhoneBook>
```

Samples are taken from javalobby article.

Soma File

A specification of modeling architecture (SOMA) file, or **SOMA file** is a proprietary XML-based description of a memory model, created by Denali Software.[1] SOMA files include parameters that configure the timing and protocol requirements for a memory model as specified by the memory vendor. This file is typically encrypted.

SOMA files are read into a proprietary memory modeling object, called an MMAV, that is used in an ASIC simulation environment. This allows the simulation to model any type of memory, if a corresponding SOMA file exists.[2]

Memory vendors typically provide memory models in non-proprietary verilog format and not in SOMA files. For example, Micron memory models [3], and others are readily downloadable from the memory vendors' webpages.

Regular Language description for XML

REgular LAnguage description for XML (**RELAX**) is a specification for describing XML-based languages. A description written in RELAX is called a RELAX grammar.

RELAX Core has been approved as an ISO/IEC Technical Report 22250-1 in 2002 (ISO/IEC TR 22250-1:2002). It was developed by ISO/IEC JTC1/SC34 (ISO/IEC Joint Technical Committee 1, Subcommittee 34 - Document description and processing languages).

RELAX was designed by Murata Makoto.

In 2001, an XML schema language RELAX NG was created by unifying of RELAX Core and James Clark's TREX. It was published as ISO/IEC 19757-2 in 2003.

PureXML

pureXML is the native XML storage feature in the IBM DB2 data server. pureXML provides query languages, storage technologies, indexing technologies, and other features to support XML data. The word *pure* in pureXML was chosen to indicate that DB2 natively stores and natively processes XML data in its inherent hierarchical structure, as opposed to treating XML data as plain text or converting it into a relational format.[1]

Technical information

DB2 includes two distinct storage mechanisms: one for efficiently managing traditional SQL data types, and another for managing XML data. The underlying storage mechanism is transparent to users and applications; they simply use SQL (including SQL with XML extensions or SQL/XML) or XQuery to work with the data.

XML data is stored in columns of DB2 tables that have the XML data type. XML data is stored in a parsed format that reflects the hierarchical nature of the original XML data. As such, pureXML uses trees and nodes as its model for storing and processing XML data. If you instruct DB2 to validate XML data against an XML schema prior to storage, DB2 annotates all nodes in the XML hierarchy with information about the schema types; otherwise, it will annotate the nodes with default type information. Upon storage, DB2 preserves the internal structure of XML data, converting its tag names and other information into integer values. Doing so helps conserve disk space and also improves the performance of queries that use navigational expressions. However, users aren't aware of this internal representation. Finally, DB2 automatically splits XML nodes across multiple database pages, as needed.

XML schemas specify which XML elements are valid, in what order these elements should appear in XML data, which XML data types are associated with each element, and so on. pureXML allows you to validate the cells in a column of XML data against no schema, one schema, or multiple schemas. pureXML also provides tools to support evolving XML schemas.

IBM has enhanced its programming language interfaces to support access to its XML data. These enhancements span Java (JDBC), C (embedded SQL and call-level interface), COBOL (embedded SQL), PHP, and Microsoft's .NET Framework (through the DB2.NET provider).

History

pureXML was first included in the DB2 9 for Linux, Unix, and Microsoft Windows release, which was codenamed Viper, in June 2006.[2] It was available on DB2 9 for z/OS in March 2007.[3] In October 2007, IBM released DB2 9.5 with improved XML data transaction performance and improved storage savings.[4] In June 2009, IBM released DB2 9.7 with XML supported for database-partitioned, range-partitioned, and multi-dimensionally clustered tables as well as compression of XML data and indices.[5]

Competition

DB2 is a hybrid data server—it offers data management for traditional relational data, as well as providing native XML data management. Other vendors that offer data management for both relational data and native XML storage include Oracle with its 11g product and Microsoft with its SQL Server product.

pureXML also competes with native XML databases like BaseX, eXist, MarkLogic or Sedna.

User groups

The International DB2 Users Group (IDUG) is an independent, not-for-profit association of IT professionals who use IBM DB2. IDUG provides education, technical resources, peer networking opportunities, online resources and other programs for DB2 users.

Books

IBM International Technical Support Organization (ITSO) has published the following books, which are available in print or as free e-books:

- DB2 9: pureXML Overview and Fast Start [6]
- DB2 9 pureXML Guide [7]

The following books are also available for purchase:

- DB2 pureXML Cookbook: Master the Power of IBM Hybrid Data Server [8]

Education and training

The following pureXML classroom and online courses are available from IBM Education:

- Query and Manage XML Data with DB2 9 [9]. IBM course CG130. Classroom. Duration: 4 days.
- Query XML Data with DB2 9 [10]. IBM course CG100. Classroom. Duration: 2 days (first 2 days of CG130).
- Managing XML Data in DB2 9. IBM course CG160. Classroom. Duration: 2 days (last 2 days of CG130).
- DB2 pureXML [11]. IBM Course CT140. Self-paced study plus Live Virtual Classroom.

List of XML schemas

This is a list of XML schemas in use on the Internet sorted by purpose. XML schemas can be used to create XML documents for a wide range of purposes such as syndication, general exchange, and storage of data in a standard format.

Bookmarks

- XBEL - XML Bookmark Exchange Language

Brewing

- BeerXML: a free XML based data description standard for the exchange of brewing data [1]

Business

- ARTSXML - Retail XML schema specifications by Association for Retail Technology Standards [2]
- PCXML and TXLife - Insurance Industry XML schema specifications by Association for Cooperative Operations Research and Development [3]
- UBL - Defining a common XML library of business documents (purchase orders, invoices, etc.) by Oasis
- HR-XML - Human resources ([4])
- XBRL Extensible Business Reporting Language for International Financial Reporting Standards (IFRS) and United States generally accepted accounting principles (GAAP) business accounting.
- Strategy Markup Language (StratML [5])
- OSCRE Open Standards Consortium for Real Estate format for data exchange within the real estate industry
- IFC-XML Building Information Models for architecture, engineering, construction, and operations.

Elections

- EML, Election Markup Language, is an OASIS standard to support end-to-end management of election processes. It defines over thirty schemas, for example EML 510 for vote count reporting and EML 310 for voter registration.

Financial

- FpML, Financial products Markup Language is the industry-standard protocol for complex financial products. It is based on XML (eXtensible Markup Language), the standard meta-language for describing data shared between applications.
- FIXML, Financial Information eXchange (FIX) protocol is an electronic communications protocol initiated in 1992 for international real-time exchange of information related to the securities transactions and markets.

Geotagging

- KML, Keyhole Markup Language is used for annotation on geographical browsers including Google Earth and NASA's World Wind. These annotations are used to place events such as earthquake warnings, historical events...etc.

Graphical user interfaces

- JAXFront - JAXFront GUI generator (free community edition)
- GLADE - GNOME's User Interface Language (GTK+)
- KParts - KDE's User Interface Language (Qt)
- XUL - XML User Interface Language (Native)
- XForms - XForms
- XAML - Microsoft's Extensible Application Markup Language

Humanities texts

- TEI - Text Encoding Initiative
- EpiDoc - Epigraphic Documents
- Menota [6] - Mediaeval Nordic Texts Archive
- MEI [7] - Music Encoding Initiative

Industrial property

- TM-XML - Trade Mark Information Exchange Standard
- DS-XML - Industrial Design Information Exchange Standard

Math and science

- MathML - Mathematical Markup Language
- ANSI N42.42 or "N42" - NIST data format standard for radiation detectors used for Homeland Security[8]

Metadata

- RDF - Resource Description Framework
- ONIX for Books [9] - ONline Information eXchange, developed and maintained by EDItEUR jointly with Book Industry Communication (UK) and the Book Industry Study Group (US), and with user groups in Australia, Canada, France, Germany, Italy, the Netherlands, Norway, Spain and the Republic of Korea.
- DDML - reformulations XML DTD
- PRISM - Publishing Requirements for Industry Standard Metadata (PRISM) [10]Wikipedia:Link rot

Music playlists

- XSPF - XML Shareable Playlist Format

News syndication

- Atom - Atom
- RSS - Really Simple Syndication

Paper and forest products

- papiNet - XML format for exchange of business documents and product information in the paper and forest products industries.
- EPPML - an XML conceptual model for the interactions between parties of a postal communication system.

Publishing

- NLM DTD, journal publishing DTD from the United States National Library of Medicine [11]
- DITA—Darwin Information Typing Architecture, document authoring system
- DocBook for technical documentation
- PRISM - Publishing Requirements for Industry Standard Metadata (PRISM) [10]

Statistics

- SDMX - SDMX-ML is a format for exchange and sharing of Statistical Data and Metadata.
- DDI - "Data Documentation Initiative" is a format for information describing statistical and social science data (and the lifecycle).

Vector images

- SVG - Scalable Vector Graphics

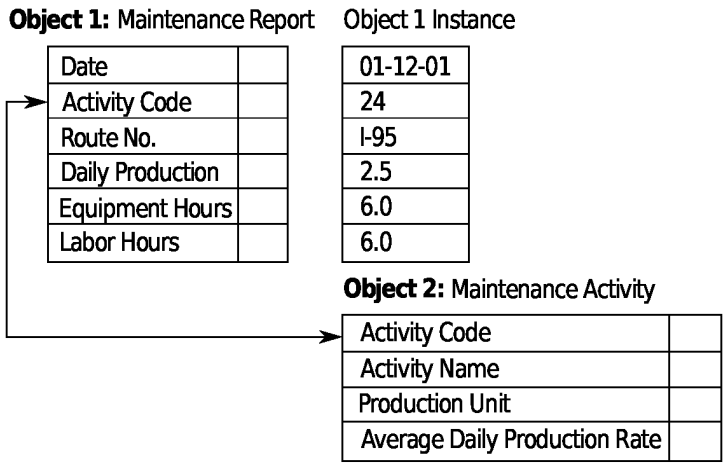
Object database

Object database

An **object database** (also **object-oriented database management system**) is a database management system in which information is represented in the form of objects as used in object-oriented programming. Object databases are different from relational databases which are table-oriented. Object-relational databases are a hybrid of both approaches.

Object databases have been considered since the early 1980s.[2]



Example of an object-oriented model[1]

Overview

Object-oriented database management systems (OODBMSs) combine database capabilities with object-oriented programming language capabilities. OODBMSs allow object-oriented programmers to develop the product, store them as objects, and replicate or modify existing objects to make new objects within the OODBMS. Because the database is integrated with the programming language, the programmer can maintain consistency within one environment, in that both the OODBMS and the programming language will use the same model of representation. Relational DBMS projects, by way of contrast, maintain a clearer division between the database model and the application.

As the usage of web-based technology increases with the implementation of Intranets and extranets, companies have a vested interest in OODBMSs to display their complex data. Using a DBMS that has been specifically designed to store data as objects gives an advantage to those companies that are geared towards multimedia presentation or organizations that utilize computer-aided design (CAD).[3]

Some object-oriented databases are designed to work well with object-oriented programming languages such as Delphi, Ruby, Python, Perl, Java, C#, Visual Basic .NET, C++, Objective-C and Smalltalk; others have their own programming languages. OODBMSs use exactly the same model as object-oriented programming languages.

History

Object database management systems grew out of research during the early to mid-1970s into having intrinsic database management support for graph-structured objects. The term "object-oriented database system" first appeared around 1985.[4] Notable research projects included Encore-Ob/Server (Brown University), EXODUS (University of Wisconsin–Madison), IRIS (Hewlett-Packard), ODE (Bell Labs), ORION (Microelectronics and Computer Technology Corporation or MCC), Vodak (GMD-IPSI), and Zeitgeist (Texas Instruments). The ORION project had more published papers than any of the other efforts. Won Kim of MCC compiled the best of those papers

in a book published by The MIT Press.[5]

Early commercial products included Gemstone (Servio Logic, name changed to GemStone Systems), Gbase (Graphael), and Vbase (Ontologic). The early to mid-1990s saw additional commercial products enter the market. These included ITASCA (Itasca Systems), Jasmine (Fujitsu, marketed by Computer Associates), Matisse (Matisse Software), Objectivity/DB (Objectivity, Inc.), ObjectStore (Progress Software, acquired from eXcelon which was originally Object Design), ONTOS (Ontos, Inc., name changed from Ontologic), O_2 [6] (O_2 Technology, merged with several companies, acquired by Informix, which was in turn acquired by IBM), POET (now FastObjects [7] from Versant which acquired Poet Software), Versant Object Database (Versant [8] Corporation), VOSS (Logic Arts) and JADE (Jade [9] Software Corporation). Some of these products remain on the market and have been joined by new open source and commercial products such as InterSystems Caché.

Object database management systems added the concept of persistence to object programming languages. The early commercial products were integrated with various languages: GemStone (Smalltalk), Gbase (LISP), Vbase (COP) and VOSS (Virtual Object Storage System for Smalltalk). For much of the 1990s, C++ dominated the commercial object database management market. Vendors added Java in the late 1990s and more recently, C#.

Starting in 2004, object databases have seen a second growth period when open source object databases emerged that were widely affordable and easy to use, because they are entirely written in OOP languages like Smalltalk, Java, or C#, such as Versant's db4o (db4objects), DTS/S1 from Obsidian Dynamics and Perst (McObject), available under dual open source and commercial licensing.

Timeline

- 1985 – Term Object Database first introduced
- 1988
  - Versant Corporation started (as Object Sciences Corp)
  - Objectivity, Inc. founded
- Early 1990s
  - Gemstone (Smalltalk)-(C++)-(Java)
  - GBase (LISP)
  - VBase (O2- ONTOS – INFORMIX)
  - Objectivity/DB
- Mid 1990's
  - Versant Object Database
  - ObjectStore
  - ODABA
  - ZODB
  - Poet
  - Jade
  - Matisse
- 2000's
  - Caché
  - db4o project started by Carl Rosenberger
  - ObjectDB
- 2001
  - IBM acquires Informix (Illustra) integrates with DB2
  - db4o shipped to first pilot customer
- 2003 - odbpp public release

- 2004 - db4o's commercial launch as db4objects, Inc.
- 2008 - db4o acquired by Versant Corporation
- 2011
  - Wakanda public Developer Preview & Beta versions
  - Gemstone acquired by VMware (at that time property of Springsource)
- 2012
  - Wakanda first production versions with open source and commercial licenses

Adoption of object databases

Object databases based on persistent programming acquired a niche in application areas such as engineering and spatial databases, telecommunications, and scientific areas such as high energy physics and molecular biology.

Another group of object databases focuses on embedded use in devices, packaged software, and real-time systems.

Technical features

Most object databases also offer some kind of query language, allowing objects to be found using a declarative programming approach. It is in the area of object query languages, and the integration of the query and navigational interfaces, that the biggest differences between products are found. An attempt at standardization was made by the ODMG with the Object Query Language, OQL.

Access to data can be faster because joins are often not needed (as in a tabular implementation of a relational database). This is because an object can be retrieved directly without a search, by following pointers.

Another area of variation between products is in the way that the schema of a database is defined. A general characteristic, however, is that the programming language and the database schema use the same type definitions.

Multimedia applications are facilitated because the class methods associated with the data are responsible for its correct interpretation.

Many object databases, for example Gemstone or VOSS, offer support for versioning. An object can be viewed as the set of all its versions. Also, object versions can be treated as objects in their own right. Some object databases also provide systematic support for triggers and constraints which are the basis of active databases.

The efficiency of such a database is also greatly improved in areas which demand massive amounts of data about one item. For example, a banking institution could get the user's account information and provide them efficiently with extensive information such as transactions, account information entries etc. The Big O Notation for such a database paradigm drops from O(n) to O(1), greatly increasing efficiency in these specific cases.

Standards

The Object Data Management Group was a consortium of object database and object-relational mapping vendors, members of the academic community, and interested parties. Its goal was to create a set of specifications that would allow for portable applications that store objects in database management systems. It published several versions of its specification. The last release was ODMG 3.0. By 2001, most of the major object database and object-relational mapping vendors claimed conformance to the ODMG Java Language Binding. Compliance to the other components of the specification was mixed. In 2001, the ODMG Java Language Binding was submitted to the Java Community Process as a basis for the Java Data Objects specification. The ODMG member companies then decided to concentrate their efforts on the Java Data Objects specification. As a result, the ODMG disbanded in 2001.

Many object database ideas were also absorbed into SQL:1999 and have been implemented in varying degrees in object-relational database products.

In 2005 Cook, Rai, and Rosenberger proposed to drop all standardization efforts to introduce additional object-oriented query APIs but rather use the OO programming language itself, i.e., Java and .NET, to express queries. As a result, Native Queries emerged. Similarly, Microsoft announced Language Integrated Query (LINQ) and DLINQ, an implementation of LINQ, in September 2005, to provide close, language-integrated database query capabilities with its programming languages C# and VB.NET 9.

In February 2006, the Object Management Group (OMG) announced that they had been granted the right to develop new specifications based on the ODMG 3.0 specification and the formation of the Object Database Technology Working Group (ODBT WG). The ODBT WG planned to create a set of standards that would incorporate advances in object database technology (e.g., replication), data management (e.g., spatial indexing), and data formats (e.g., XML) and to include new features into these standards that support domains where object databases are being adopted (e.g., real-time systems). The work of the ODBT WG was suspended in March 2009 when, subsequent to the economic turmoil in late 2008, the ODB vendors involved in this effort decided to focus their resources elsewhere.

In January 2007 the World Wide Web Consortium gave final recommendation status to the XQuery language. XQuery uses XML as its data model. Some of the ideas developed originally for object databases found their way into XQuery, but XQuery is not intrinsically object-oriented. Because of the popularity of XML, XQuery engines compete with object databases as a vehicle for storage of data that is too complex or variable to hold conveniently in a relational database. XQuery also allows modules to be written to provide encapsulation features that have been provided by Object-Oriented systems.

Comparison with RDBMSs

An object database stores complex data and relationships between data directly, without mapping to relational rows and columns, and this makes them suitable for applications dealing with very complex data. Objects have a many to many relationship and are accessed by the use of pointers. Pointers are linked to objects to establish relationships. Another benefit of an OODBMS is that it can be programmed with small procedural differences without affecting the entire system.[10]

Object Definition Language

Object Definition Language (**ODL**) is the specification language defining the interface to object types conforming to the ODMG Object Model. Often abbreviated by the acronym **ODL**.

This language's purpose is to define the structure of an Entity-relationship diagram.

Language

Class declarations

Interface < name > { elements = attributes, relationships, methods }

Element Declarations

attributes (< type > : < name >);

relationships (< rangetype > : < name >);

Example

```
Type Date Tuple (year, day, month) Type year, day, month integer
Class Manager attributes{id : string unique name : string phone : string set employees : Tuple ( [Employee], Start_Date : Date )}
Class Employee attributes{id : string unique name : string Start_Date : Date manager : [Manager]}
```

Object Query Language

Object Query Language (OQL) is a query language standard for object-oriented databases modeled after SQL. OQL was developed by the Object Data Management Group (ODMG). Because of its overall complexity no vendor has ever fully implemented the complete OQL. OQL has influenced the design of some of the newer query languages like JDOQL and EJB QL, but they can't be considered as different flavors of OQL.

General rules

The following rules apply to OQL statements:

- All complete statements must be terminated by a semi-colon.
- A list of entries in OQL is usually separated by commas but not terminated by a comma(,).
- Strings of text are enclosed by matching quotation marks.

Examples

Simple query

The following example illustrates how one might retrieve the CPU-speed of all PCs with more than 64MB of RAM from a fictional PC database:

```
SELECT pc.cpuspeed
FROM PCs pc
WHERE pc.ram > 64;
```

Query with grouping and aggregation

The following example illustrates how one might retrieve the average amount of RAM on a PC, grouped by manufacturer:

```
SELECT manufacturer, AVG(SELECT part.pc.ram FROM partition part)
FROM PCs pc
GROUP BY manufacturer: pc.manufacturer;
```

Note the use of the keyword `partition`, as opposed to aggregation in traditional SQL.

Object-oriented SQL

A functional language, a superset of SQL, used in Hewlett-Packard's OpenODB database system.

SQL1999, formerly known as SQL3, is an Object-Oriented SQL.

SQL:1999 on Wikipedia

Object Exchange Model

The **Object Exchange Model**[1] (OEM) is a model for exchanging semi-structured data between object-oriented databases. It serves as the basic Data model in numerous projects of the Stanford University Database Group, including Tsimmis, Lore, and C3 [2].

Slight variations of OEM have evolved across different Stanford projects. In Lore, labels are actually on parent-child "links" rather than objects. For example, if an OEM object has multiple parents, different parent objects may use different labels to identify that object. An atomic value encoding a person's name might be included in one complex object using the label "Author" and in another complex object using the label "Editor." In C3, additional attributes are required for each object to annotate the changes to the object that have occurred over time [2].

OEM representations

Textual OEM interchange format used in Lore [3] - The goals of this interchange format were to have textual encodings of OEM to be easy to read, easy to edit, and easy to generate or parse by a program.

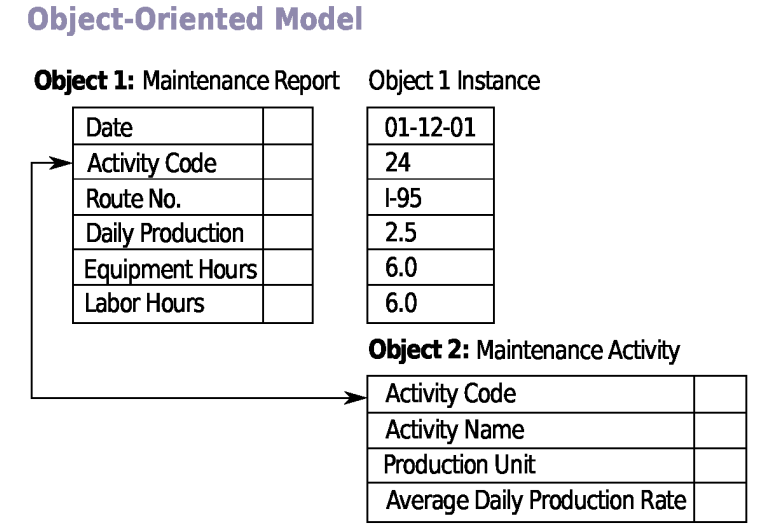
Object-relational database

An **object-relational database** (**ORD**), or **object-relational database management system** (**ORDBMS**), is a database management system (DBMS) similar to a relational database, but with an object-oriented database model: objects, classes and inheritance are directly supported in database schemas and in the query language. In addition, just as with pure relational systems, it supports extension of the data model with custom data-types and methods.

An object-relational database can be said to provide a middle ground between relational databases and *object-oriented databases* (OODBMS). In object-relational databases, the approach is essentially that of relational databases: the data resides in the database and is manipulated collectively with queries in a query language; at the other extreme are OODBMSes in which the database is essentially a persistent object store for software written in an object-oriented programming language, with a programming API for storing and retrieving objects, and little or no specific support for querying.



Example of an object-oriented database model.

Overview

The basic goal for the Object-relational database is to bridge the gap between relational databases and the object-oriented modeling techniques used in programming languages such as Java, C++, Visual Basic .NET or C#. However, a more popular alternative for achieving such a bridge is to use a standard relational database systems with some form of Object-relational mapping (ORM) software. Whereas traditional RDBMS or SQL-DBMS products focused on the efficient management of data drawn from a limited set of data-types (defined by the relevant language standards), an object-relational DBMS allows software developers to integrate their own types and the methods that apply to them into the DBMS.

The ORDBMS (like ODBMS or OODBMS) is integrated with an object-oriented programming language. The characteristic properties of ORDBMS are 1) complex data, 2) type inheritance, and 3) object behavior. **Complex data** creation in most SQL ORDBMSs is based on preliminary schema definition via the user-defined type (UDT). Hierarchy within structured complex data offers an additional property, **type inheritance**. That is, a structured type can have subtypes that reuse all of its attributes and contain additional attributes specific to the subtype. Another advantage, the **object behavior**, is related with access to the program objects. Such program objects have to be storable and transportable for database processing, therefore they usually are named as persistent objects. Inside a database, all the relations with a persistent program object are relations with its object identifier (OID). All of these points can be addressed in a proper relational system, although the SQL standard and its implementations impose arbitrary restrictions and additional complexityWikipedia:Citing sources

In object-oriented programming (OOP) object behavior is described through the methods (object functions). The methods denoted by one name are distinguished by the type of their parameters and type of objects for which they attached (method signature). The OOP languages call this the polymorphism principle, which briefly is defined as

"one interface, many implementations". Other OOP principles, inheritance and encapsulation, are related both to methods and attributes. Method inheritance is included in type inheritance. Encapsulation in OOP is a visibility degree declared, for example, through the PUBLIC, PRIVATE and PROTECTED modifiers.

History

Object-relational database management systems grew out of research that occurred in the early 1990s. That research extended existing relational database concepts by adding object concepts. The researchers aimed to retain a declarative query-language based on predicate calculus as a central component of the architecture. Probably the most notable research project, Postgres (UC Berkeley), spawned two products tracing their lineage to that research: Illustra and PostgreSQL.

In the mid-1990s, early commercial products appeared. These included Illustra[1] (Illustra Information Systems, acquired by Informix Software which was in turn acquired by IBM), Omniscience (Omniscience Corporation, acquired by Oracle Corporation and became the original Oracle Lite), and UniSQL (UniSQL, Inc., acquired by KCOMS). Ukrainian developer Ruslan Zasukhin, founder of Paradigma Software, Inc., developed and shipped the first version of Valentina database in the mid-1990s as a C++ SDK. By the next decade, PostgreSQL had become a commercially viable database and is the basis for several products today which maintain its ORDBMS features.

Computer scientists came to refer to these products as "object-relational database management systems" or ORDBMSs.[2]

Many of the ideas of early object-relational database efforts have largely become incorporated into SQL:1999 via structured types. In fact, any product that adheres to the object-oriented aspects of SQL:1999 could be described as an object-relational database management product. For example, IBM's DB2, Oracle database, and Microsoft SQL Server, make claims to support this technology and do so with varying degrees of success.

Comparison to RDBMS

An RDBMS might commonly involve SQL statements such as these:

```
CREATE TABLE Customers  (
    Id          CHAR(12)     NOT NULL PRIMARY KEY,
    Surname     VARCHAR(32) NOT NULL,
    FirstName   VARCHAR(32) NOT NULL,
    DOB         DATE         NOT NULL
 );
 SELECT InitCap(Surname) || ', ' || InitCap(FirstName)
   FROM Customers
  WHERE Month(DOB) = Month(getdate())
    AND Day(DOB) = Day(getdate())
```

Most current[3] SQL databases allow the crafting of custom functions, which would allow the query to appear as:

```
 SELECT Formal(Id)
   FROM Customers
  WHERE Birthday(DOB) = Today()
```

In an object-relational database, one might see something like this, with user-defined data-types and expressions such as `BirthDay()`:

```
CREATE TABLE Customers (
  Id          Cust_Id     NOT NULL  PRIMARY KEY,
```

```
      Name          PersonName  NOT NULL,
      DOB           DATE        NOT NULL
    );
    SELECT Formal( C.Id )
      FROM Customers C
     WHERE BirthDay ( C.DOB ) = TODAY;
```

The object-relational model can offer another advantage in that the database can make use of the relationships between data to easily collect related records. In an address book application, an additional table would be added to the ones above to hold zero or more addresses for each customer. Using a traditional RDBMS, collecting information for both the user and their address requires a "join":

```
     SELECT InitCap(C.Surname) || ', ' || InitCap(C.FirstName), A.city
       FROM Customers C join Addresses A ON A.Cust_Id=C.Id -- the join
      WHERE A.city="New York"
```

The same query in an object-relational database appears more simply:

```
    SELECT Formal( C.Name )
      FROM Customers C
     WHERE C.address.city="New York" -- the linkage is 'understood' by
the ORDB
```

Object-relational impedance mismatch

The **object-relational impedance mismatch** is a set of conceptual and technical difficulties that are often encountered when a relational database management system (RDBMS) is being used by a program written in an object-oriented programming language or style; particularly when objects or class definitions are mapped in a straightforward way to database tables or relational schema.

The term *object-relational impedance mismatch* is derived from the electrical engineering term *impedance matching*.

Mismatches

Object-oriented concepts

Encapsulation

Object-oriented programs are designed with techniques that result in encapsulated objects whose representation is hidden. In an object-oriented framework, the underlying properties of a given object are expected to be unexposed to any interface outside of the one implemented alongside the object. However, object-relational mapping necessarily exposes the underlying content of an object to interaction with an interface that the object implementation cannot specify. Hence, object-relational mapping violates the encapsulation of the object.

Accessibility

In relational thinking, "private" versus "public" access is relative to need rather than being an absolute characteristic of the data's state, as in the OO model. The relational and OO models often have conflicts over relativity versus absolutism of classifications and characteristics.

Interface, class, inheritance and polymorphism

Under an object-oriented paradigm, objects have interfaces that together provide the only access to the internals of that object. The relational model, on the other hand, utilizes derived relation variables (views) to provide varying perspectives and constraints to ensure integrity. Similarly, essential OOP concepts for classes of objects, inheritance and polymorphism are not supported by relational database systems.

Mapping to relational concepts

A proper mapping between relational concepts and object-oriented concepts can be made if relational database tables are linked to associations found in object-oriented analysis.

Data type differences

A major mismatch between existing relational and OO languages is the type system differences. The relational model strictly prohibits by-reference attributes (or pointers), whereas OO languages embrace and expect by-reference behavior. Scalar types and their operator semantics are also very often subtly to vastly different between the models, causing problems in mapping.

For example, most SQL systems support string types with varying collations and constrained maximum lengths (open-ended text types tend to hinder performance), while most OO languages consider collation only as an argument to sort routines and strings are intrinsically sized to available memory. A more subtle, but related example is that SQL systems often ignore trailing white space in a string for the purposes of comparison, whereas OO string libraries do not. It is typically not possible to construct new data types as a matter of constraining the possible values of other primitive types in an OO language.

Structural and integrity differences

Another mismatch has to do with the differences in the structural and integrity aspects of the contrasted models. In OO languages, objects can be composed of other objects—often to a high degree—or specialize from a more general definition. This may make the mapping to relational schemas less straightforward. This is because relational data tends to be represented in a named set of global, unnested relation variables. Relations themselves, being sets of tuples all conforming to the same headerWikipedia:Please clarify do not have an ideal counterpart in OO languages. Constraints in OO languages are generally not declared as such, but are manifested as exception raising protection logic surrounding code that operates on encapsulated internal data. The relational model, on the other hand, calls for declarative constraints on scalar types, attributes, relation variables, and the database as a whole.

Manipulative differences

The semantic differences are especially apparent in the manipulative aspects of the contrasted models, however. The relational model has an intrinsic, relatively small and well defined set of primitive operators for usage in the query and manipulation of data, whereas OO languages generally handle query and manipulation through custom-built or lower-level, case and physical access path specific imperative operations. Some OO languages do have support for declarative query sub-languages, but because OO languages typically deal with lists and perhaps hash-tables, the manipulative primitives are necessarily distinct from the set-based operations of the relational model.[*citation needed*]

Transactional differences

The concurrency and transaction aspects are significantly different also. In particular, relational database transactions, as the smallest unit of work performed by databases, are much larger than any operations performed by classes in OO languages. Transactions in relational databases are dynamically bounded sets of arbitrary data manipulations, whereas the granularity of transactions in OO languages is typically individual assignments of primitive typed fields. OO languages typically have no analogue of isolation or durability as well and atomicity and consistency are only ensured for said writes of primitive typed fields.

Solving impedance mismatch

Solving the impedance mismatch problem for object-oriented programs starts with recognition of the differences in the specific logic systems being employed, then either the minimization or compensation of the mismatch.

Minimization

There have been some attempts at building object-oriented database management systems (OODBMS) that would avoid the impedance mismatch problem. They have been less successful in practice than relational databases however, partly due to the limitations of OO principles as a basis for a data model.[1] There has been research performed in extending the database-like capabilities of OO languages through such notions as transactional memory.

One common solution to the impedance mismatch problem is to layer the domain and framework logic. In this scheme, the OO language is used to model certain relational aspects at runtime rather than attempt the more static mapping. Frameworks which employ this method will typically have an analogue for a tuple, usually as a "row" in a "dataset" component or as a generic "entity instance" class, as well as an analogue for a relation. Advantages of this approach may include:

- Straightforward paths to build frameworks and automation around transport, presentation, and validation of domain data.
- Smaller code size; faster compile and load times.
- Ability for the schema to change dynamically.

- Avoids the name-space and semantic mismatch issues.
- Expressive constraint checking
- No complex mapping necessary

Disadvantages may include:

- Lack of static type "safety" checks. Typed accessors are sometimes utilized as one way to mitigate this.
- Possible performance cost of runtime construction and access.
- Inability to natively utilize uniquely OO aspects, such as polymorphism.

Alternative architectures

The rise of XML databases and XML client structures has motivated other alternative architectures to get around the impedance mismatch challenges. These architectures use XML technology in the client (such as XForms) and native XML databases on the server that use the XQuery language for data selection. This allows a single data model and a single data selection language (XPath) to be used in the client, in the rules engines and on the persistence server.[2]

Compensation

The mixing of levels of discourse within OO application code presents problems, but there are some common mechanisms used to compensate. The biggest challenge is to provide framework support, automation of data manipulation and presentation patterns, within the level of discourse in which the domain data is being modeled. To address this, reflection and/or code generation are utilized. Reflection allows code (classes) to be addressed as data and thus provide automation of the transport, presentation, integrity, etc. of the data. Generation addresses the problem through addressing the entity structures as data inputs for code generation tools or meta-programming languages, which produce the classes and supporting infrastructure en masse. Both of these schemes may still be subject to certain anomalies where these levels of discourse merge. For instance, generated entity classes will typically have properties which map to the domain (e. g. Name, Address) as well as properties which provide state management and other framework infrastructure (e. g. IsModified).

Contention

It has been argued, by Christopher J. Date and others, that a truly relational DBMS would pose no such problem, as domains and classes are essentially one and the same thing. A naïve mapping between classes and relational schemata is a fundamental design mistake; and that individual tuples within a database table (relation) ought to be viewed as establishing relationships between entities; not as representations for complex entities themselves. However, this view tends to diminish the influence and role of object oriented programming, using it as little more than a field type management system.

The impedance mismatch in programming between the domain objects and the user interface. Sophisticated user interfaces, to allow operators, managers, and other non-programmers to access and manipulate the records in the database, often require intimate knowledge about the nature of the various database attributes (beyond name and type). In particular, it's considered a good practice (from an end-user productivity point of view) to design user interfaces such that the UI prevents illegal transactions (those which cause a database constraint to be violated) from being entered; to do so requires much of the logic present in the relational schemata to be duplicated in the code.

Certain code-development frameworks can leverage certain forms of logic that are represented in the database's schema (such as referential integrity constraints), so that such issues are handled in a generic and standard fashion through library routines rather than ad hoc code written on a case-by-case basis.

It has been argued that SQL, due to a very limited set of domain types (and other alleged flaws) makes proper object and domain-modelling difficult; and that SQL constitutes a very lossy and inefficient interface between a DBMS and an application program (whether written in an object-oriented style or not). However, SQL is currently the only

widely accepted common database language in the marketplace; use of vendor-specific query languages is seen as a bad practice when avoidable. Other database languages such as Business System 12 and Tutorial D have been proposed; but none of these has been widely adopted by DBMS vendors.

In current versions of mainstream "object-relational" DBMSs like Oracle and Microsoft SQL Server, the above point may be a non-issue. With these engines, the functionality of a given database can be arbitrarily extended through stored code (functions and procedures) written in a modern OO language (Java for Oracle, and a Microsoft.NET language for SQL Server), and these functions can be invoked in-turn in SQL statements in a transparent fashion: that is, the user neither knows nor cares that these functions/procedures were not originally part of the database engine. Modern software-development paradigms are fully supported: thus, one can create a set of library routines that can be re-used across multiple database schemas.

These vendors decided to support OO-language integration at the DBMS back-end because they realized that, despite the attempts of the ISO SQL-99 committee to add procedural constructs to SQL, SQL will never have the rich set of libraries and data structures that today's application programmers take for granted, and it is reasonable to leverage these as directly as possible rather than attempting to extend the core SQL language. Consequently, the difference between "application programming" and "database administration" is now blurred: robust implementation of features such as constraints and triggers may often require an individual with dual DBA/OO-programming skills, or a partnership between individuals who combine these skills. This fact also bears on the "division of responsibility" issue below.

Some, however, would point out that this contention is moot due to the fact that: (1) RDBMSes were never intended to facilitate object modelling, and (2) SQL generally should only be seen as a "lossy" or "inefficient" interface language when one is trying to achieve a solution for which RDBMSes were not designed. SQL is very efficient at doing what it was designed to do, namely, to query, sort, filter, and store large sets of data. Some would additionally point out that the inclusion of OO language functionality in the back-end simply facilitates bad architectural practice, as it admits high-level application logic into the data tier, antithetical to the RDBMS.

Here the "canonical" copy of state is located. The database model generally assumes that the database management system is the only authoritative repository of state concerning the enterprise; any copies of such state held by an application program are just that — temporary copies (which may be out of date, if the underlying database record was subsequently modified by a transaction). Many object-oriented programmers prefer to view the in-memory representations of objects themselves as the canonical data, and view the database as a backing store and persistence mechanism.

The proper division of responsibility between application programmers and database administrators (DBA). It is often the case that needed changes to application code (in order to implement a requested new feature or functionality) require corresponding changes in the database definition; in most organizations, the database definition is the responsibility of the DBA. Due to the need to maintain a production database system 24 hours a day; many DBAs are reluctant to make changes to database schemata that they deem gratuitous or superfluous; and in some cases outright refuse to do so. Use of developmental databases (apart from production systems) can help somewhat; but when the newly developed application "goes live"; the DBA will need to approve any changes. Some programmers view this as intransigence; however the DBA is frequently held responsible if any changes to the database definition cause a loss of service in a production system—as a result, many DBAs prefer to contain design changes to application code, where design defects are far less likely to have catastrophic consequences.

In organizations where the relationship between DBAs and application programmers is not dysfunctional, the above point is a non-issue, and the decision as to whether to change a schema or not is driven by business needs. If new functionality is mandated, and it requires the capture of information that must be persisted, schema enhancements to achieve persistence are the logical first step. Certain schema modifications (including addition of indexes) will also be acceptable if they dramatically improve performance of a critical application. But schema modifications that might serve no purpose beyond making a programmer's life modestly easier would be vetoed if they result in

unacceptable design decisions such as denormalization of transactional schemas.

Philosophical differences

Key philosophical differences between the OO and relational models can be summarized as follows:

- **Declarative vs. imperative interfaces —** Relational thinking tends to use data as interfaces, not behavior as interfaces. It thus has a declarative tilt in design philosophy in contrast to OO's behavioral tilt. (Some relational proponents propose using triggers, stored procedures, etc. to provide complex behavior, but this is not a common viewpoint.)
- **Schema bound —** Objects do not have to follow a "parent schema" for which attributes or accessors an object has, while table rows must follow the entity's schema. A given row must belong to one and only one entity. The closest thing in OO is inheritance, but it is generally tree-shaped and optional. A dynamic form of relational tools that allows ad hoc columns may relax schema bound-ness, but such tools are currently rare.
- **Access rules —** In relational databases, attributes are accessed and altered through predefined relational operators, while OO allows each class to create its own state alteration interface and practices. The "self-handling noun" viewpoint of OO gives independence to each object that the relational model does not permit. This is a "standards versus local freedom" debate. OO tends to argue that relational standards limit expressiveness, while relational proponents suggest the rule adherence allows more abstract math-like reasoning, integrity, and design consistency.
- **Relationship between nouns and actions —** OO encourages a tight association between operations (actions) and the nouns (entities) that the operations operate on. The resulting tightly bound entity containing both nouns and the operations is usually called a class, or in OO analysis, a concept. Relational designs generally do not assume there is anything natural or logical about such tight associations (outside of relational operators).
- **Uniqueness observation —** Row identities (keys) generally have a text-representable form, but objects do not require an externally viewable unique identifier.
- **Object identity —** Objects (other than immutable ones) are generally considered to have a unique identity; two objects which happen to have the same state at a given point in time are not considered to be identical. Relations, on the other hand, have no inherent concept of this kind of identity. That said, it is a common practice to fabricate "identity" for records in a database through use of globally unique candidate keys; though many consider this a poor practice for any database record which does not have a one-to-one correspondence with a real world entity. (Relational, like objects, can use domain keys if they exist in the external world for identification purposes). Relational systems in practice strive for and support "permanent" and inspect-able identification techniques, whereas object identification techniques tend to be transient or situational.
- **Normalization —** Relational normalization practices are often ignored by OO designs. However, this may just be a bad habit instead of a native feature of OO. An alternate view is that a collection of objects, interlinked via pointers of some sort, is equivalent to a network database; which in turn can be viewed as an extremely denormalized relational database.
- **Schema inheritance —** Most relational databases do not support schema inheritance. Although such a feature could be added in theory to reduce the conflict with OOP, relational proponents are less likely to believe in the utility of hierarchical taxonomies and sub-typing because they tend to view set-based taxonomies or classification systems as more powerful and flexible than trees. OO advocates point out that inheritance/subtyping models need not be limited to trees (though this is a limitation in many popular OO languages such as Java), but non-tree OO solutions are seen as more difficult to formulate than set-based variation-on-a-theme management techniques preferred by relational. At the least, they differ from techniques commonly used in relational algebra.
- **Structure vs. behaviour —** OO primarily focuses on ensuring that the structure of the program is reasonable (maintainable, understandable, extensible, reusable, safe), whereas relational systems focus on what kind of behaviour the resulting run-time system has (efficiency, adaptability, fault-tolerance, liveness, logical integrity, etc.). Object-oriented methods generally assume that the primary user of the object-oriented code and its

interfaces are the application developers. In relational systems, the end-users' view of the behaviour of the system is sometimes considered to be more important. However, relational queries and "views" are common techniques to re-represent information in application- or task-specific configurations. Further, relational does not prohibit local or application-specific structures or tables from being created, although many common development tools do not directly provide such a feature, assuming objects will be used instead. This makes it difficult to know whether the stated non-developer perspective of relational is inherent to relational, or merely a product of current practice and tool implementation assumptions.

- **Set vs. graph relationships —** The relationship between different items (objects or records) tend to be handled differently between the paradigms. Relational relationships are usually based on idioms taken from set theory, while object relationships lean toward idioms adopted from graph theory (including trees). While each can represent the same information as the other, the approaches they provide to access and manage information differ.

As a result of the object-relational impedance mismatch, it is often argued by partisans on both sides of the debate that the other technology ought to be abandoned or reduced in scope. Some database advocates view traditional "procedural" languages as more compatible with an RDBMS than many OO languages; or suggest that a less OO-style ought to be used. (In particular, it is argued that long-lived domain objects in application code ought not to exist; any such objects that do exist should be created when a query is made and disposed of when a transaction or task is complete). On the other hand, many OO advocates argue that more OO-friendly persistence mechanisms, such as OODBMS, ought to be developed and used, and that relational technology ought to be phased out. Of course, it should be pointed out that many (if not most) programmers and DBAs do not hold either of these viewpoints; and view the object-relational impedance mismatch as a mere fact of life that information technology has to deal with.

It is also argued that the O/R mapping is paying off in some situations, but is probably oversold: it has advantages besides drawbacks. Skeptics point out that it is worth to think carefully before using it, as it will add little value in some cases.[3]

Object-relational mapping

Not to be confused with Object-Role Modeling.

Object-relational mapping (**ORM**, **O/RM**, and **O/R mapping**) in computer software is a programming technique for converting data between incompatible type systems in object-oriented programming languages. This creates, in effect, a "virtual object database" that can be used from within the programming language. There are both free and commercial packages available that perform object-relational mapping, although some programmers opt to create their own ORM tools.

Overview

Data management tasks in object-oriented (OO) programming are typically implemented by manipulating objects that are almost always non-scalar values. For example, consider an address book entry that represents a single person along with zero or more phone numbers and zero or more addresses. This could be modeled in an object-oriented implementation by a "Person object" with attributes/fields to hold each data item that the entry comprises: the person's name, a list of phone numbers, and a list of addresses. The list of phone numbers would itself contain "PhoneNumber objects" and so on. The address book entry is treated as a single object by the programming language (it can be referenced by a single variable containing a pointer to the object, for instance). Various methods can be associated with the object, such as a method to return the preferred phone number, the home address, and so on.

However, many popular database products such as structured query language database management systems (SQL DBMS) can only store and manipulate scalar values such as integers and strings organized within tables. The programmer must either convert the object values into groups of simpler values for storage in the database (and convert them back upon retrieval), or only use simple scalar values within the program. Object-relational mapping is used to implement the first approach.

The heart of the problem is translating the logical representation of the objects into an atomized form that is capable of being stored on the database, while somehow preserving the properties of the objects and their relationships so that they can be reloaded as an object when needed. If this storage and retrieval functionality is implemented, the objects are then said to be persistent.

Comparison with traditional data access techniques

Compared to traditional techniques of exchange between an object-oriented language and a relational database, ORM often reduces the amount of code that needs to be written.[1]

Disadvantages of O/R mapping tools generally stem from the high level of abstraction obscuring what is actually happening in the implementation code. Also, heavy reliance on ORM software has been cited as a major factor in producing poorly designed databases.[2]

NoSQL (Not Only SQL) databases

Another approach is to use an object-oriented database management system (OODBMS) or document-oriented databases such as native XML databases that provide more flexibility in data modeling. OODBMSs are databases designed specifically for working with object-oriented values. Using an OODBMS eliminates the need for converting data to and from its SQL form, as the data is stored in its original object representation and relationships are directly represented, rather than requiring join tables/operations.

Document oriented databases also prevent the user from having to "shred" objects into table rows. Many of these systems also support the XQuery query language to retrieve datasets.

Object-oriented databases tend to be used in complex, niche applications. One of the arguments against using an OODBMS is that switching from an SQL DBMS to a purely object-oriented DBMS means that you may lose the capability to create application independent queries for retrieving ad hoc combinations of data without restriction to access path.[*citation needed*] For this reason, many programmers find themselves more at home with an object-SQL mapping system, even though most object-oriented databases are able to process SQL queries to a limited extent. Other OODBMS (such as RavenDB) provide replication to SQL databases, as a means of addressing the need for ad hoc queries, while preserving has well-known query patterns.

Challenges

There are a variety of difficulties that arise when considering how to match an object system to a relational database. These difficulties are referred to as the object-relational impedance mismatch.

An alternative to implementing ORM is use of the native procedural languages provided with every major database on the market. These can be called from the client using SQL statements. The Data Access Object (DAO) design pattern is used to abstract these statements and offer a lightweight object-oriented interface to the rest of the application.

Polymorphic association

Polymorphic association is a term used in discussions of Object-Relational Mapping with respect to the problem of representing in the relational database domain, a relationship from one class to multiple classes. In statically typed languages such as Java these multiple classes are subclasses of the same superclass. In languages with duck typing, such as Ruby, this is not necessarily the case.

Polyinstantiation

Polyinstantiation in computer science is the concept of type (class, database row or otherwise) being instantiated into multiple independent instances (objects, copies). It may also indicate, such as in the case of database polyinstantiation, that two different instances have the same name (identifier, primary key).

Operating system security

In Operating system security, polyinstantiation is the concept of creating a user or process specific view of a shared resource. I.e. Process **A** cannot affect process **B** by writing malicious code to a shared resource, such as UNIX directory **/tmp**.

Polyinstantiation of shared resources have similar goals as process isolation, an application of virtual memory, where processes are assigned their own isolated virtual address space to prevent process **A** writing into the memory space of process **B**.

Database

In databases, polyinstantiation is database-related SQL (structured query language) terminology. It allows a relation to contain multiple rows with the same primary key; the multiple instances are distinguished by their security levels. It occurs because of mandatory policy. Depending on the security level established, one record contains sensitive information, and the other one does not, that is, a user will see the record's information depending on his/her level of confidentiality previously dictated by the company's policy

Consider the following table, where the primary key is **Name** and **λ(x)** is the security level:

Name	λ(Name)	Age	λ(Age)	λ
Alice	S	18	TS	TS
Bob	S	22	S	S
Bob	S	33	TS	TS
Trudy	TS	15	TS	TS

Although useful from a security standpoint, polyinstantiation raises several problems:

- Moral scrutiny, since it involves lying
- Providing consistent views
- Explosion in the number of rows

Cryptography

In cryptography, polyinstantiation is the existence of a cryptographic key in more than one secure physical location.

Single Table Inheritance

Single table inheritance is a way to emulate object-oriented inheritance in a relational database. When mapping from a database table to an object in an object-oriented language, a field in the database identifies what class in the hierarchy the object belongs to.[1] In Ruby on Rails the field in the table called 'type' identifies the name of the class. In .NET Framework, it is called the Discriminator column.

Versant Object Database

Versant Object Database

Developer(s)	Versant Corporation
Stable release	8.0.2.15 / October 1, 2012
Development status	Active
Written in	Java, C, C#, C++, Smalltalk, Python
Operating system	Cross-platform Solaris, Linux, Windows (NT thru Vista), AIX, HP-UX (both 32 and 64 bit for all platforms)
Type	Object Database
License	All rights reserved
Website	www.versant.com [1]

Versant Object Database (VOD) is an object database software product developed by Versant Corporation.

The Versant Object Database enables developers using object oriented languages to transactionally store their information by allowing the respective language to act as the Data Definition Language (DDL) for the database. In other words, the memory model is the database schema model.[2]

In general, persistence in VOD in implemented by declaring a list of classes, then providing a transaction demarcation application programming interface to use cases. Respective language integrations adhere to the constructs of that language, including syntactic and directive sugars.

Additional APIs exist, beyond simple transaction demarcation, providing for the more advanced capabilities necessary to address practical issues found when dealing with performance optimization and scalability for systems with large amounts of data, many concurrent users, network latency, disk bottlenecks, etc.

Feature highlights

- Transparent object persistence from C++, Java and .NET
- Support for standards, e.g., JDO
- Seamless database distribution
- Enterprise-class high availability
- Dynamic schema evolution
- Low administration
- Multithreading, multisession
- End-to-end object architecture
- Fine-grained concurrency control

Supported languages

Primary supported languages are Java, C# and C++. Versant also has language support for Smalltalk and Python.

Query systems

VOD supports queries via a server side indexing and query execution engine. Query support includes both a Versant-specific and a standards-based query language syntax. Versant provides this query capability in a number of forms depending on the developer's chosen language binding. For example, in Java VOD provides VQL (Versant Query Language), JDOQL, EJB QL and OQL. In C++ Versant provides VQL and OQL, with C# support for VQL, OQL and LINQ. VOD will do optimization of query execution based on available attribute indexes. Versant also has support for standard SQL queries against the Versant database using ODBC/JDBC drivers.

Versant Query Language

The native Versant Query Language (VQL) is similar to SQL92. It is a string based implementation which allows parameterized runtime binding. The difference is that instead of targeting tables and columns, it targets classes and attributes.

Other object-oriented elements apply to query processing. For example, a query targeting a super class will return all instances of concrete subclasses that satisfy the query predicate. VOD is a distributed database: a logical database can be composed of many physical database nodes, with queries are performed in parallel.

Versant query support includes most of the core concepts found in relational query languages including: pattern matching, join, set operators, orderby, existence, distinct, projections, numerical expressions, indexing, cursors, etc.

Indexing

VOD supports indexes on large collections. However it is not necessary to have a collection in order to have a queryable object with a usable index. Unlike other OODB implementations, any object in a Versant database is indexable and accessible via query. Indexes can be placed on attributes of classes and those classes can then be the target of a query operation. Indexes can be hash, b-tree, unique, compound, virtual and can be created online either using a utility, via a graphical user interface or via an API call.

Large collection support

VOD provides pagination support for large collections using a special node based implementation. These collections are designed in such a way that access is done so that only nodes needed by the client are brought resident into memory, instead of having to load the entire collection.

These large collections are created and operated on just as other persistent collection classes. The interface is also consistent with the appropriate language constructs. For example C++ Standard Template Library, Java iterators, C# enumerables, etc.

Collections of objects by default are only a collection of object identifiers. So, these can be very large, yet have a small resident memory footprint. To iterate the collection, objects are dereferenced into client memory space in either a configurable batch mode or one at a time. A query on the collection can be done using the “in” operator (or other set based operators like subset_of, superset_of, etc.) without loading the collection to the client memory space.

Data replication

There are several mechanisms for replication on VOD that depend on the motivation behind the replication. It is for high availability or for distribution or integration.

High availability

Versant does synchronous pair replication. Full replication for fault tolerance only requires installation of one configuration file specifying the buddy node names: New connections notice the existence of the replica file and on connect, check the file for a buddy pair and if it exists, connect to both buddies. This could be a distributed database so that there are many buddy pairs. Then all transactional changes are committed synchronously to the buddy database server processes.

If any one of the databases in the buddy pair should become unreachable, the in-flight transactions are handled so that there is no commit failure, instead in-flight transactions on node failure will continue to the node that is still alive in the buddy pair. On the machine where the node is still alive and processing transactions, a new process will start that monitors for the crashed database to become accessible again. Once the previously failed node is alive, the monitoring process starts replicating all changes that have occurred since the time of failure to bring the two buddies back into full synchronization. Once they are in full sync, a flag is set and on the next transaction clients will move back to full synchronous operation. All of this is handled without any user involvement.

In the case of extreme failure, like a broken disk drive, etc., the replicated node can be recreated from an online backup of the live node. Simply install a new disk drive, take an online backup of the live node, restore on the failed machine, start the monitor to sync the last few transactions and restore full replication at clients.

Distribution

Distribution is handled using Versant Asynchronous Replication (VAR), a channel driven, master-slave or peer-to-peer replication framework with rule based conflict detection and resolution.

An administrator uses a utility to define replication channels. Channels are named entities that define a scope of replication within a physical node. The “scope” can be anything from full database replication to something as fine grained as anything definable by a Versant query. Once the channels are defined, applications can register as listeners on these channels, at which point changes from those channel begin to flow to the respective clients.

These channels provide both persistence and reliable messaging. In the event that a connection is lost between a registered listener and a channel, ongoing changes will be guaranteed delivery once the connection is re-established. There are multiple transport protocols that can be configured for optimization in highly reliable LAN networks or high reliability in unreliable WAN type of environments.

In bi-directional channel replication, a set of conflict detection rules are put in place so that conflicting changes can be resolved at runtime without disrupting channel activity. There are other forms of data distribution.

Integration

Usually, integration requires some kind of custom code. Users can connect to both relational and Versant databases using ORM products. They can load objects either from a relational database or Versant and then with some minor code implementation, disconnect those objects from the source and write them to a target. This can be used for import/export in a batch processing mode for integration with other database systems.

Data distribution architecture

VOD handles distributed data processing using a distributed two-phase commit protocol across multiply connected databases. In this process, VOD uses an internal resource manager that is handling the distributed transactions. Versant also supports the XA protocol allowing external transaction monitors to control the transactional context, so for example plug into a CORBA or J2EE application server.

Versant allows object relationships to span physical resource (database) nodes. Shared information referenced from object graphs that reside in other databases and resolution of that information is transparent at runtime. For example, several physical databases may hold user information models that are partitioned by account number holding aggregations on account activities such as trades and then have some more databases holding actual trade models and these users and trades can be related. A query across all of the user databases and return a user (or set of users), then as messages are sent to user objects involving trades, the trade models will automatically be resolved across the distribution. After updates of any of those objects, at commit time Versant will ensure that all changes commit back to their respective physical nodes in a completely ACID 2phase commit process.

Object id's are guaranteed to be unique across all physical nodes. Objects could be "moved" from one physical node to another without any application code changes required.

Schema evolution

Schema evolution is handled via a normal update of the application's class models and then applying those changes to the operational database. Those schema changes can be applied to an existing database either via a utility or API. The result is a versioning of the database schema.

Existing objects in the database are lazily evolved to the latest schema version. No object is actually evolved unless it is made dirty (marked for update) and committed back to the database. In general this means an application with the new schema will not cause evolution, expect for new and updated objects.

There are utilities that can "crawl" a database slowly evolving all instanced to the latest version by grabbing sets of them, marking them dirty, committing. This is sometimes desired for embedded or real-time systems where performance and space needs to be optimized.

In most cases, older clients get patch updates with the new schema in conjunction with updates to the server. The clients schema version is in sync with the database server. Versant's loose schema mapping facility can also be used. This is enabled by a flag in the client so that it does not complain about a mismatch in schema version and instead filters the incoming objects to match the old schema. Using this facility requires some forethought to avoid any unintended side effects.

The process goes as follows:

1. class definitions are updated, i.e. add new subclasses, add attributes, rename attributes, remove attributes, etc. and recompile. When the application connects to a Versant database, a schema version mismatch will be detected and you would normally get an error unless you take some action to avoid the mismatch.
2. The schema mismatch can be avoided using a number of techniques.
    1. a utility can be used to describe the new schema to the database. The utility will show a list of incompatibilities and ask how you want them to be resolved. Your action will depend on whether you are in

development, QA, production, etc. Regardless, actions like dropping the existing class, evolving the schema version and keeping all existing objects, rename and retype, etc, are also possible.

2. the evolution process can be automated via connection options. This is normally used in development mode and allows the schema to automatically evolve any mismatches on connect and continue preserving the existing objects.
3. specific API's can be used to dynamically evolve the database schema. This is an advanced topic, involving what's called Versant runtime classes. Basically, you can create completely dynamic schema structure for the database so that new classes and attributes can be created on the fly.

3. If clients with the older schema continue to operate on the database, loose_schema_mapping in the application profile file should be set to true.
4. Optionally, a utility can be started to crawl the database and force version migration of all existing instances.

The general guidelines for schema evolution are that any schema changes can be made and existing instances preserved, without having to write custom evolution code, with the exception of two things:

1. Changes to the middle of an inheritance hierarchy. Inserting a new class into the middle of a hierarchy is impossible without losing your existing objects, unless custom code is written to do this operation in a series of steps.
2. Incompatible type changes like Array to a String.

All other forms of evolution like renaming attributes, deleting leaf classes, adding leaf classes, adding new classes, adding or removing attributes, etc. can be done online and without custom code. If actions like setting non standard default values for newly added attributes are necessary, this can be done in callback functions within the objects. There are a set of standard object lifecycle callbacks that get invoked in activities like cache load. Those callbacks can be used to check for default values and take action if necessary.

Persistent object lifecycle

The lifecycle of an object load can be controlled on a use case basis.

By default, objects are loaded only when they are sent a message. This includes the default behavior for queries which only return a collection of references to objects that satisfied the query predicate, not the actual objects. When an object is loaded, all it's non-reference attributes (primitives) are also loaded and remaining reference types follow the same pattern as the referencing object.

When a message is sent to an object VOD looks into internal structures to see if the object is already in client memory. If not, VOS does an RPC to load the object. At the time VOD loads the object, it will also look at the connections locking strategy to decide how to deal with locking the object on load. VOD supports both global locking strategies that can be applied to a connection and extremely fine grained control to override behavior for a particular use case.

Once an object is loaded and locked it stays in the client cache, with an equivalent lock in the server, until one of a number of events occurs.

The most common event, the current transaction ends with commit. In the default case, this will release the lock and object from memory. However, note that there are forms of commit that will do combinations of things like, keep the cache and the locks and start a new transaction, keep the cache, but release the locks and start a new transaction. These forms and others are used to optimize cache effectiveness when using non-default locking strategies like optimistic locking or when you have a series of transactions that form a task and operate on the same set of objects.

Another possibility is that your client cache starts to get full. In this case, VOD may decide to swap objects back to the server process to make space and do some work that will have to be done at commit anyway. VOD does this in a fully transactional way, so that even if modified objects get swapped to the server, they will still be undone if the transaction is rolled back. Also, you have the ability to "pin" objects into the client cache to prevent swapping of

important sets of objects, enabling the use of direct memory pointers without concern for memory faults.

Another possible event is a query call which has the option set to flush the cache of objects in the target class, so that changed objects currently in your cache become part of the current query execution evaluation.

Other possibilities include API calls that result in explicit release of the object, like a call to refresh or a call to release.

There are many ways to override the default behavior. Those are in fact commonly used to performance tune on a use case basis. For example, if you are going to iterate over a collection of 1000 objects, you don't want to do 1000 RPC's. Giving the collection of references to a call to groupRead will use a single RPC and load all objects. Similarly, you can make a call to getClosure which will use groupRead behavior to load all referenced objects in a graph from the starting point, down to your specified level of reachability. Further, queries have options to set a lock and load result sets rather than just references or to use cursors. There are API's to explicitly load objects into cache and set higher lock levels than the connection defaults, etc.

Achieving persistence

For users of C++, Versant requires that the uppermost class in an inheritance hierarchy inherit from a base class "PObject", which handles database activities.

Then there is a file setup, `schema.imp`, that declares which classes in the model are to be made persistent and that file is used in a pre-compilation phase where Versant's necessary magicWikipedia:Please clarify is added to the persistent classes. Finally, the resulting `schema.cxx` file is compiled and linked with the application.

The pre-compilation phase is done with a utility though note this is typically automatically set up in one's visual development environment so the process is automatic when a build is done.

When using Java or .NET, this same procedure described above with C++ is accomplished using post-processing byte code enhancement. One sets up a file that declares which classes are to be persistent and then uses a utility, or API, or IDE integration to enhance the classes before running or debugging.

Versant provides other Java APIs based on standards JDO and JPA. In those versions of the API, the system adheres to the standards defined for declaring persistence whether it be some kind of XML or annotation. Enhancement is then done using a utility (similarly with .NET) or more commonly with Eclipse plug-in or Microsoft Visual Studio integration during the build process.

Integration with relational databases

A large percentage of Versant's customers do some form of integration with relational tables. This can be accomplished in a couple of ways depending on the requirements such as: on-line/off-line, batch based, transactional, etc.

XA

Versant supports the XA protocol for distributed transactions. This allows participation in online distributed transactions with relational databases. The interaction with the relational tables can take many forms from custom code to ORM solutions to J2EE application servers (Entity Relationship Modeling) to message passing to ORBs, etc. The XA API allows the Versant database to act as a resource controlled by an external transaction monitor coordinating changes to both Versant and relational databases in the same transactional context.

ORM

Versant can interact with relational databases using Java ORM technology such as JDO (Java Data Objects) and Hibernate JPA. These standards-based implementations have the ability to detach objects from their transactional context and then attach them to another connection. There are restrictions in that Versant requires the application to use a concept known as database identity in order for replication to work with relations intact. Versant does not support the ORM form of application identity in anything other than a disconnected data form.

XML

Versant has tools that enable the import and export of XML data. For example, batch based replication of data can be accomplished by exporting objects from the Versant database as XML, if necessary applying an XSLT transform and then importing into relational tables. The opposite direction is also possible. With Java, the most common approach using XML is to dynamically replicate information using JAXB which runtime converts objects into and out of an XML form. Using JAXB, the Versant database only needs to work with objects rather than importing an XML form. In essence, XML coming from relational databases are converted to objects at runtime using JAXB and those objects are then persisted into the Versant database.

Custom code

Users of C++ are especially challenged in integrating with relational databases. Versant provides consulting to help these customers with their integration challenges, but does not make those solutions, which require customization for each application, available in a productized form.

Transactions

Versant by default is always implicitly in a transaction when connected to the database. In addition, VOD supports the XA protocol and apply that to certain standards based API' such as JDO and JPA which require explicit transaction demarcation. There is a non-implicit form of transaction where transaction begin/end must be declared.

In order to discard from memory objects that have been modified in the current transaction you can either do it globally for the current transaction by issuing a rollback which also implicitly starts another transaction or you can do it in isolation or globally using specific calls within the same transaction.

Locking and caching strategies

Versant by default uses a pessimistic locking strategy to ensure that objects in the database server are in sync with client access in an ACID way. This is done by using a combination of locks against both schema and instance objects.

The database server process maintains lock request queues at the object level to control concurrency of access to the same object. A request for update will establish a queue if there are any existing readers of an object. The request either goes through when all current readers release their locks or times-out (an exception which can be handled by client is thrown). Locks are generally released at transaction boundaries. When a queue is established by an update request, all other subsequent requests fall in queue behind the update request. Once the update request has been filled, all read requests in the queue rush in and get their read lock, return the object, and if there are no other updates, the queue disappears. In this architecture, locks are done at the object level so false waits and false deadlocks do not occur.

Other ways of keeping client caches in sync are, for example, an optimistic locking strategy, using a classic timestamp mechanism. VOD also provides forms of client cache synchronization using multi-cast. Additionally it provides an event mechanism where clients can register for triggering events within the database server to be used for synchronization or for business logic work flow.

Scalability

Storage

Versant supports, multiple file and multiple process configurations. Data storage is done in a single or multiple files, but there are supporting files for the logging subsystem (logical and physical log files). These logging files are used for high performance and scalability under concurrent user loads and for online database backup processes.

Clients

Versant is a multi-user client server database and has production applications with thousands of concurrently connected users. Thus, Versant can also run linked and embedded in the same address space as the application process (so it can be also an embedded database).

Performance

Versant uses internal performance and scalability benchmarks to monitor and measure behavior over time across releases, patches and generations of new hardware.

Versant has done other non-standard benchmarking activities in a public forum.[3] .[4]

Versant ran the 007 benchmarks in the early 90's but currently doesn't provide any comparisons because there are no industry benchmarks that make sense for object databases,

One of the candidates considered was TPC-E, which was supposed to be the new OLTP standard database benchmark with new complex models aimed at being representative of today's computing environment. The TPC-E is based on a financial trading system model. Still, comparative results could not be obtained. The reason is that the TPC specifies requirements regarding what part of the code resides in the "driver" of the benchmark and what part resides in "database" functionality. However, the driver to application logic interface is completely defined at the data level. This means that when measuring relational access you would not incur any overhead for mapping into a C++ object. The mapping of the raw data into what ever form was necessary in the driver to implement the business logic was completely outside of the benchmark measurements. When it comes to the object database, you need to now un-map the C++ objects into the driver data structures and in doing so, measure the cost of that activity as part of the benchmark timings.

But this is the opposite of a real world application where people write object oriented applications resulting in object oriented models. In a relational database, you need to map/un-map from objects to the relational data structures. The TPC-E was written in a way as to exclude the "mapping effect" from the measurements, which by the very nature of how an object database works means the TPC-E was written in a way that forces measurement of an "un-mapping effect", an activity which does not occur in a real world application. Thus with TPC-E, the true cost of computing is removed for relational and even worse added to object databases.

Add-on Modules

Versant provides add-on modules for deployment or access to its Object Database.

- V/Management Center: V/MC delivers real-time views of performance data and analytical information about the Versant Object Database. For example, it alerts administrators about potential issues before the database availability is affected. It's designed as an Eclipse-based RCP client.
- Versant Compact: Online Database Maintenance.
- Versant FTS: High Availability Database Server.
- Versant Async Server: Production Database Replication.
- Versant HA Backup: High Availability Backup Solution.
- Versant SQL: SQL Access & Reporting.

Applications

Usually the “best kind of application” to use a Versant database are those applications requiring an application specific database of an OLTP nature. There are certain application characteristics where Versant technology provides better performance and scalability than traditional relational technology: complex models, large amount of data, large number of concurrent users.

Thus, VOD is found in applications within many different vertical industries: global trading platforms for large stock exchanges, network management for large telecommunications providers, intelligence analytics for defense agencies, reservation systems for large airline/hotel companies, risk management analytics for banking and transportation organizations, Massively multiplayer online game systems, network security and fraud detection, local number portability, advanced simulations, social networking, etc..

Terminology-oriented database

A **terminology-oriented database** or **terminology-oriented database management system** is a conceptual extension of an object-oriented database. It implements concepts defined in a terminology model. Compared with object-oriented databases, the terminology-oriented database requires some minor conceptual extensions on the schema level as supporting set relations (super-set, subset, intersection etc.), weak-typed collections or shared inheritance.

The data model of a terminology-oriented database is high-level; the terminology-oriented database provides facilities for transforming a terminology model provided by subject area experts completely into a database schema. The target schema might be the database schema for an object-oriented database as well as a relational database schema, or even an XML schema. Typically, terminology-oriented databases are not bound on a specific database type. Since the information content, which can be stored in object-oriented databases and in relational databases, is identical, data for a terminology-oriented database can be stored theoretically in any type of database as well as in an XML file. Thus, terminology-oriented databases may support several database systems for storing application data.

References

Odaba

ODABA is a terminology-oriented database management system, which is a conceptual extension of an object-oriented database system, and implements concepts defined in a terminology model. ODABA supports typical standards and technologies for object-oriented databases, but also terminology-oriented database extensions. ODABA also behaves like an object-relational database management system, i.e. data is seen as being stored in a database rather than accessing persistent objects in a programming environment. ODABA supports active data link[1] (ADL) and provides an ADL-based GUI frame work.

Features

Database access is supported via an application program interface for C++ or .NET programming languages and via the ODABA Script Interface[2] (OSI). Object Definition Language (ODL) and Object Query Language (OQL) provided with OSI are ODMG 3.0 conform.

Beside standard models (object model, functional model and dynamic model), ODABA supports a documentation model and an administration model. In order to be terminology model compliant, several conceptual extensions are supported as set relations, multilingual attributes, weak-typed collections or hierarchical enumerations (classifications).

ODABA supports semi-automatic conversion from terminology models to object models and schema conversion from object model to relational models (MS SQL Server, MySQL, Oracle) which allows storing or mirroring ODABA data in relational databases or in XML files.

Object Data Management Group

The **Object Data Management Group** (**ODMG**) was conceived in the summer of 1991 at a breakfast with object database vendors that was organized by Rick Cattell of Sun Microsystems. In 1998, the ODMG changed its name from the Object Database Management Group to reflect the expansion of its efforts to include specifications for both object database and object-relational mapping products.

The primary goal of the ODMG was to put forward a set of specifications that allowed a developer to write portable applications for object database and object-relational mapping products. In order to do that, the data schema, programming language bindings, and data manipulation and query languages needed to be portable.

Between 1993 and 2001, the ODMG published five revisions to its specification. The last revision was ODMG version 3.0, after which the group disbanded.

Major components of the ODMG 3.0 specification

- *Object Model.* This was based on the Object Management Group's Object Model. The OMG core model was designed to be a common denominator for object request brokers, object database systems, object programming languages, etc. The ODMG designed a profile by adding components to the OMG core object model.
- *Object Specification Languages.* The ODMG Object Definition Language (ODL) was used to define the object types that conform to the ODMG Object Model. The ODMG Object Interchange Format (OIF) was used to dump and load the current state to or from a file or set of files.
- *Object Query Language (OQL).* The ODMG OQL was a declarative (nonprocedural) language for query and updating. It used SQL as a basis, where possible, though OQL supports more powerful object-oriented capabilities.
- *C++ Language Binding.* This defined a C++ binding of the ODMG ODL and a C++ Object Manipulation Language (OML). The C++ ODL was expressed as a library that provides classes and functions to implement the concepts defined in the ODMG Object Model. The C++ OML syntax and semantics are those of standard C++ in the context of the standard class library. The C++ binding also provided a mechanism to invoke OQL.
- *Smalltalk Language Binding.* This defined the mapping between the ODMG ODL and Smalltalk, which was based on the OMG Smalltalk binding for the OMG Interface Definition Language (IDL). The Smalltalk binding also provided a mechanism to invoke OQL.
- *Java Language Binding.* This defined the binding between the ODMG ODL and the Java programming language as defined by the Java 2 Platform. The Java binding also provided a mechanism to invoke OQL.

Status

ODMG 3.0 was published in book form in 2000.[1] By 2001, most of the major object database and object-relational mapping vendors claimed conformance to the ODMG Java Language Binding. Compliance to the other components of the specification was mixed.[2] In 2001, the ODMG Java Language Binding was submitted to the Java Community Process as a basis for the Java Data Objects specification. The ODMG member companies then decided to concentrate their efforts on the Java Data Objects specification. As a result, the ODMG disbanded in 2001.

In 2004, the Object Management Group (OMG) was granted the right to revise the ODMG 3.0 specification as an OMG specification by the copyright holder, Morgan Kaufmann Publishers. In February 2006, the OMG announced the formation of the Object Database Technology Working Group (ODBT WG) and plans to work on the 4th generation of an object database standard [3].

List of object database management systems

This is a **comparison of notable object database management systems**, showing what fundamental object database features are implemented natively.

Name	Current Stable Version	Language(s)	SQL support	Datatypes	License	Description
Caché	2012.1	ObjectScript (dynamic language), Basic. Java/.NET object mapping supported.	SQL subset. Object notation allowed. Supports embedded SQL, dynamic SQL and xDBC access.		Proprietary	MUMPS ancestry. Includes built-in support for XML, Web/AJAX and an EMB system called Ensemble. Supports embedded, client/server and distributed implementations.
ConceptBase		Telos	CBQL (based on Datalog)	no types but classes	open source, FreeBSD-style license	historical db, active rules, meta-modeling, deductive rules
Db4o	8.0	C#, Java	db4o-sql [1]	.NET and Java data types	GPL, custom,[2] proprietary	Native Queries, LINQ support, automatic schema evolution, Transparent Activation/Persistence, replication to RDBMS, Object Manager plugin for Visual Studio and Eclipse
GemStone/S	3.1.0.5	Smalltalk	None	Objects and code	Proprietary, free version available	Persistent, transactional, multi-user Smalltalk developed by GemTalk Systems.
NeoDatis ODB		C#, Java, Mono			LGPL	Embedded and Client/Server

ObjectDatabase++	3.4	C++, TScript, .NET			Proprietary	Embedded
ObjectDB	2.4.6	Java	None, uses JPA or JDO		Proprietary	
Objectivity/DB	10.2.1	C++, C#, Java, Python, Smalltalk and XML	SQL superset		Proprietary	Distributed, Parallel Query Engine
ObjectStore	7.2 (July 2011)	C++, Java, interoperable with .NET	SQL subset (also has own object query language)		Proprietary	Embedded database supporting efficient, distributed management of C++ and Java objects. Avoids the complexities and limitations of ORM products such as Hibernate by storing objects directly with their relationships intact. Uses a page-based mapping system for fast locking and efficient, distributed, client-side caching.
ODABA		C++, .NET			GPL	Terminology-oriented database
OpenAccess	2.2	C++	no		Proprietary	EDA database
OpenLink Virtuoso	5.0.11	C++, Java/JSP, ASP, ASPX, Mono, RDF, SPARQL, SPARUL, SQL, Perl, Python, PHP, Ruby, XML, ODBC, JDBC, ADO.NET, more	SQL 9x/200x		GPL or proprietary	
Perst	4.2	Java (including Java SE, Java ME & Android), C# (including .NET, .NET Compact Framework, Mono & Silverlight)	JSQL - object-oriented subset of SQL	Java and .NET data types	GPL, Proprietary	Small footprint embedded database. Diverse indexes and specialized collection classes; LINQ; replication; ACID transactions; native full text search; includes Silverlight, Android and Java ME demo apps.
Picolisp	3.1.1	Picolisp			MIT License	DB built into the language
siaqodb [3]	3.7	C#, .NET, Mono, WinRT, Silverlight, Windows Phone, Android, iOS, Unity3D, .NET Compact Framework	LINQ	.NET data types, classes	Commercial	NoSQL embedded database for .NET that runs on .NET, Mono, WinRT, iOS, Android, WindowsPhone, Unity3D,Compact Framework

Comparison of object database management systems

This is a **comparison of notable object database management systems**, showing what fundamental object database features are implemented natively.

Name	Current Stable Version	Language(s)	SQL support	Datatypes	License	Description
Caché	2012.1	ObjectScript (dynamic language), Basic. Java/.NET object mapping supported.	SQL subset. Object notation allowed. Supports embedded SQL, dynamic SQL and xDBC access.		Proprietary	MUMPS ancestry. Includes built-in support for XML, Web/AJAX and an EMB system called Ensemble. Supports embedded, client/server and distributed implementations.
ConceptBase		Telos	CBQL (based on Datalog)	no types but classes	open source, FreeBSD-style license	historical db, active rules, meta-modeling, deductive rules
Db4o	8.0	C#, Java	db4o-sql [1]	.NET and Java data types	GPL, custom,[1] proprietary	Native Queries, LINQ support, automatic schema evolution, Transparent Activation/Persistence, replication to RDBMS, Object Manager plugin for Visual Studio and Eclipse
GemStone/S	3.1.0.5	Smalltalk	None	Objects and code	Proprietary, free version available	Persistent, transactional, multi-user Smalltalk developed by GemTalk Systems.
NeoDatis ODB		C#, Java, Mono			LGPL	Embedded and Client/Server
ObjectDatabase++	3.4	C++, TScript, .NET			Proprietary	Embedded
ObjectDB	2.4.6	Java	None, uses JPA or JDO		Proprietary	
Objectivity/DB	10.2.1	C++, C#, Java, Python, Smalltalk and XML	SQL superset		Proprietary	Distributed, Parallel Query Engine

ObjectStore	7.2 (July 2011)	C++, Java, interoperable with .NET	SQL subset (also has own object query language)		Proprietary	Embedded database supporting efficient, distributed management of C++ and Java objects. Avoids the complexities and limitations of ORM products such as Hibernate by storing objects directly with their relationships intact. Uses a page-based mapping system for fast locking and efficient, distributed, client-side caching.
ODABA		C++, .NET			GPL	Terminology-oriented database
OpenAccess	2.2	C++	no		Proprietary	EDA database
OpenLink Virtuoso	5.0.11	C++, Java/JSP, ASP, ASPX, Mono, RDF, SPARQL, SPARUL, SQL, Perl, Python, PHP, Ruby, XML, ODBC, JDBC, ADO.NET, more	SQL 9x/200x		GPL or proprietary	
Perst	4.2	Java (including Java SE, Java ME & Android), C# (including .NET, .NET Compact Framework, Mono & Silverlight)	JSQL - object-oriented subset of SQL	Java and .NET data types	GPL, Proprietary	Small footprint embedded database. Diverse indexes and specialized collection classes; LINQ; replication; ACID transactions; native full text search; includes Silverlight, Android and Java ME demo apps.
Picolisp	3.1.1	Picolisp			MIT License	DB built into the language
siaqodb [3]	3.7	C#, .NET, Mono, WinRT, Silverlight, Windows Phone, Android, iOS, Unity3D, .NET Compact Framework	LINQ	.NET data types, classes	Commercial	NoSQL embedded database for .NET that runs on .NET, Mono, WinRT, iOS, Android, WindowsPhone, Unity3D,Compact Framework
Twig		Java			Apache license 2.0	Built on Google App Engine's low-level Datastore API
Versant Object Database					Proprietary	
WakandaDB	4	JavaScript, C++	No support. Use REST & SSJS instead	JavaScript and 4D data types	AGPL, proprietary[2]	NoSQL REST / Server-Side JavaScript engine. Integrates Webkit JavaScriptCore engine with HTML5 JS APIs supported on the server. Tables and columns are replaced by JavaScript DataClasses and attributes.
Zope Object Database		Python, C	No support. Object indexing and searching is done through ZCatalog facility.		Zope Public License

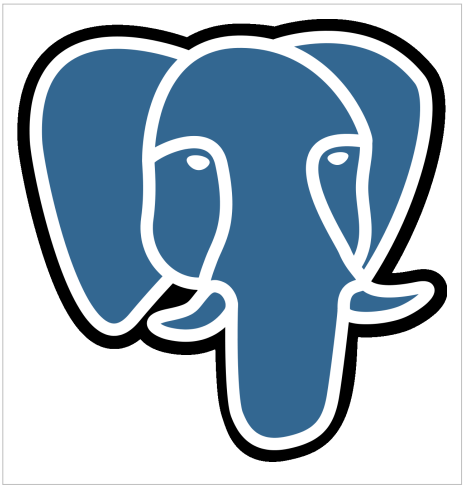
PostgreSQL

PostgreSQL



Developer(s)	PostgreSQL Global Development Group
Initial release	1 May 1995
Stable release	9.3.3, 9.2.7, 9.1.12, 9.0.16, 8.4.20 / February 20, 2014
Written in	C
Operating system	Cross-platform
Type	ORDBMS
License	PostgreSQL license
Website	www.postgresql.org [1]

PostgreSQL, often simply **"Postgres"**, is an open-source object-relational database management system (ORDBMS) with an emphasis on extensibility and standards-compliance. It is released under the PostgreSQL License, a free/open source software license, similar to the MIT License. PostgreSQL is developed by the PostgreSQL Global Development Group, consisting of a handful of volunteers employed and supervised by companies such as Red Hat and EnterpriseDB. It implements the majority of the SQL:2011 standard, is ACID-compliant, is fully transactional (including all DDL statements), has extensible updateable views, data-types, operators, index methods, functions, aggregates, procedural languages, and has a large number of extensions written by third parties. PostgreSQL runs on many operating-systems including Linux, FreeBSD, Solaris, Microsoft Windows and Mac OS X.

The vast majority of Linux distributions have PostgreSQL available in supplied packages. OS X, starting with Lion, has PostgreSQL server as its standard default database in the server edition, and PostgreSQL client tools in the desktop edition.

Name

PostgreSQL's developers pronounce it /ˈpoʊstgrɛsHelp:IPA for English#Key˛kjuːHelp:IPA for English#Keyˈɛl/; (Audio sample [2], 5.6k MP3). It is abbreviated as *Postgres*, its original name. Because of ubiquitous support for the SQL Standard amongst most relational databases, the community considered changing the name back to Postgres. However, the PostgreSQL Core Team announced in 2007 that the product would continue to use the name PostgreSQL. The name refers to the project's origins as a "post-Ingres" database, being a development from University Ingres DBMS (*Ingres* being an abbreviation for *IN*teractive *G*raphics *RE*trieval *S*ystem).[3]

History

PostgreSQL evolved from the Ingres project at the University of California, Berkeley. In 1982, the project leader, Michael Stonebraker, left Berkeley to make a proprietary version of Ingres. He returned to Berkeley in 1985 and started a post-Ingres project to address the problems with contemporary database systems that had become increasingly clear during the early 1980s. The new project, POSTGRES, aimed to add the fewest features needed to completely support types. These features included the ability to define types and to fully describe relationships – something used widely before but maintained entirely by the user. In Postgres, the database "understood" relationships, and could retrieve information in related tables in a natural way using *rules*. Postgres used many of the ideas of Ingres, but not its code.

Starting in 1986, the team published a number of papers describing the basis of the system, and by 1988 had a prototype version. The team released version 1 to a small number of users in June 1989, then version 2 with a re-written rules system in June 1990. Version 3, released in 1991, again re-wrote the rules system, and added support for multiple storage managers and an improved query engine. By 1993 the great number of users began to overwhelm the project with requests for support and features. After releasing version 4—primarily a cleanup—the project ended.

But open-source developers could obtain copies and develop the system further, because Berkeley had released Postgres under an MIT-style license. In 1994, Berkeley graduate students Andrew Yu and Jolly Chen replaced the Ingres-based QUEL query language interpreter with one for the SQL query language, creating Postgres95. The code was released on the web.

In July 1996, Marc Fournier at Hub.Org Networking Services provided the first non-university development server for the open-source development effort. Along with Bruce Momjian and Vadim B. Mikheev, work began to stabilize the code inherited from Berkeley. The first open-source version was released on August 1, 1996.

In 1996, the project was renamed to PostgreSQL to reflect its support for SQL. The first PostgreSQL release formed version 6.0 in January 1997. Since then, the software has been maintained by a group of database developers and volunteers around the world, coordinating via the Internet.

The PostgreSQL project continues to make major releases (approximately annually) and minor "bugfix" releases, all available under the same license. Code comes from contributions from proprietary vendors, support companies, and open-source programmers at large.

Features

MVCC

PostgreSQL manages concurrency through a system known as multiversion concurrency control (MVCC), which gives each transaction a "snapshot" of the database, allowing changes to be made without being visible to other transactions until the changes are committed. This largely eliminates the need for read locks, and ensures the database maintains the ACID (atomicity, consistency, isolation, durability) principles in an efficient manner. PostgreSQL offers three levels of transaction isolation: Read Committed, Repeatable Read and Serializable. Because PostgreSQL is immune to dirty reads, requesting a Read Uncommitted transaction isolation level provides read committed instead. Prior to PostgreSQL 9.1, requesting Serializable provided the same isolation level as Repeatable Read. PostgreSQL 9.1 and later support full serializability via the serializable snapshot isolation (SSI) technique.

Procedural languages

Procedural languages allow developers to extend the database with custom subroutines (functions), often called *stored procedures*. These functions can be used to build triggers (functions invoked upon modification of certain data) and custom aggregate functions. Procedural languages can also be invoked without defining a function, using the "DO" command at SQL level.

Languages are divided into two groups: "Safe" languages are sandboxed and can be safely used by any user. Procedures written in "unsafe" languages can only be created by superusers, because they allow bypassing the database's security restrictions, but can also access sources external to the database. Some languages like Perl provide both safe and unsafe versions.

PostgreSQL has built-in support for three procedural languages:

- Plain SQL (safe). Simpler SQL functions can get expanded inline into the calling (SQL) query, which saves function call overhead and allows the query optimizer to "see inside" the function.
- PL/pgSQL (safe), which resembles Oracle's PL/SQL procedural language and SQL/PSM.
- C (unsafe), which allows loading custom shared libraries into the database. Functions written in C offer the best performance, but bugs in code can crash and potentially corrupt the database. Most built-in functions are written in C.

In addition, PostgreSQL allows procedural languages to be loaded into the database through extensions. Three language extensions are included with PostgreSQL to support Perl, Python and Tcl. There are external projects to add support for many other languages, including Java, JavaScript (PL/V8), R.

Indexes

PostgreSQL includes built-in support for regular B-tree and hash indexes, and two types of inverted indexes: generalized search trees (GiST) and generalized inverted indexes (GIN). Hash indexes are implemented, but discouraged because they cannot be recovered after a crash or power loss. In addition, user-defined index methods can be created, although this is quite an involved process. Indexes in PostgreSQL also support the following features:

- Expression indexes can be created with an index of the result of an expression or function, instead of simply the value of a column.
- Partial indexes, which only index part of a table, can be created by adding a `WHERE` clause to the end of the `CREATE INDEX` statement. This allows a smaller index to be created.
- The planner is capable of using multiple indexes together to satisfy complex queries, using temporary in-memory bitmap index operations.
- As of PostgreSQL 9.1, *k*-nearest neighbor (also referred to KNN-GiST) indexing provides efficient searching of "closest values" to that specified, useful to finding similar words, or close objects or locations with geospatial

data. This is achieved without exhaustive matching of values.
- In PostgreSQL 9.2 and above, index-only scans often allow the system to fetch data from indexes without ever having to access the main table.

Triggers

Triggers are events triggered by the action of SQL DML statements. For example, an INSERT statement might activate a trigger that checks if the values of the statement are valid. Most triggers are only activated by either INSERT or UPDATE statements.

Triggers are fully supported and can be attached to tables. In PostgreSQL 9.0 and above, triggers can be per-column and conditional, in that UPDATE triggers can target specific columns of a table, and triggers can be told to execute under a set of conditions as specified in the trigger's WHERE clause. As of PostgreSQL 9.1, triggers can be attached to views by utilising the INSTEAD OF condition. Views in versions prior to 9.1 can have rules, though. Multiple triggers are fired in alphabetical order. In addition to calling functions written in the native PL/PgSQL, triggers can also invoke functions written in other languages like PL/Python or PL/Perl.

Schemas

In PostgreSQL, all objects (with the exception of roles and tablespaces) are held within a schema. Schemas effectively act like namespaces, allowing objects of the same name to co-exist in the same database. Schemas are analogous to directories in a file system, except that they cannot be nested, nor is it possible to create a "symbolic link" pointing to another schema or object.

By default, databases are created with the "public" schema, but any additional schemas can be added, and the public schema isn't mandatory. A "search_path" determines the order in which schemas are checked on unqualified objects (those without a prefixed schema), which can be configured on a database or role level. The search path, by default, contains the special schema name of "$user", which first looks for a schema named after the connected database user (e.g. if the user "dave" were connected, it would first look for a schema also named "dave" when referring to any objects). If such a schema is not found, it then proceeds to the next schema. New objects are created in whichever valid schema (one that presently exists) is listed first in the search path.

Data types

A wide variety of native data types are supported, including:

- Boolean
- Arbitrary precision numerics
- Character (text, varchar, char)
- Binary
- Date/time (timestamp/time with/without timezone, date, interval)
- Money
- Enum
- Bit strings
- Text search type
- Composite
- HStore (an extension enabled key-value store within Postgres)
- Arrays (variable length and can be of any data type, including text and composite types) up to 1 GB in total storage size.
- Geometric primitives
- IPv4 and IPv6 addresses
- CIDR blocks and MAC addresses

- XML supporting XPath queries
- UUID
- JSON (versions 9.2 and up)

In addition, users can create their own data types which can usually be made fully indexable via PostgreSQL's GiST infrastructure. Examples of these include the geographic information system (GIS) data types from the PostGIS project for PostgreSQL.

There is also a data type called a "domain", which is the same as any other data type but with optional constraints defined by the creator of that domain. This means any data entered into a column using the domain will have to conform to whichever constraints were defined as part of the domain.

Range Types

Starting with PostgreSQL 9.2, a data type that represents a range of data can be used which are called range types. These can be discrete ranges (e.g. all integer values 1 to 10) or continuous ranges (e.g. any point in time between 10:00am and 11:00am). The built-in range types available include ranges of integers, big integers, decimal numbers, time stamps (with and without time zone) and dates.

Custom range types can be created to make new types of ranges available, such as IP address ranges using the inet type as a base, or float ranges using the float data type as a base. Range types support inclusive and exclusive range boundaries using the [] and () characters respectively. (e.g. '[4,9)' represents all integers starting from and including 4 up to but not including 9.) Range types are also compatible with existing operators used to check for overlap, containment, right of etc.

User-defined objects

New types of almost all objects inside the database can be created, including:

- Casts
- Conversions
- Data types
- Domains
- Functions, including aggregate functions and window functions
- Indexes including custom indexes for custom types
- Operators (existing ones can be overloaded)
- Procedural languages

Inheritance

Tables can be set to inherit their characteristics from a "parent" table. Data in child tables will appear to exist in the parent tables, unless data is selected from the parent table using the ONLY keyword, i.e. `SELECT * FROM ONLY parent_table`. Adding a column in the parent table will cause that column to appear in the child table.

Inheritance can be used to implement table partitioning, using either triggers or rules to direct inserts to the parent table into the proper child tables.

As of 2010[4] this feature is not fully supported yet—in particular, table constraints are not currently inheritable. All check constraints and not-null constraints on a parent table are automatically inherited by its children. Other types of constraints (unique, primary key, and foreign key constraints) are not inherited.

Inheritance provides a way to map the features of generalization hierarchies depicted in Entity Relationship Diagrams (ERD) directly into the PostgreSQL database.

Rules

Rules allow the "query tree" of an incoming query to be rewritten. Rules, or more properly, "Query Re-Write Rules", are attached to a table/class and "Re-Write" the incoming DML (select, insert, update, and/or delete) into one or more queries that either replace the original DML statement or execute in addition to it. Query Re-Write occurs after DML statement parsing, but before query planning.

Replication

Binary replication

PostgreSQL, beginning from version 9.0, includes built-in binary replication, based on shipping the changes (write-ahead logs) to slave systems asynchronously.

Version 9.0 also introduced the ability to run read-only queries against these replicated slaves, where earlier versions would only allow that after promoting them to be a new master. This allows splitting read traffic among multiple nodes efficiently. Earlier replication software that allowed similar read scaling normally relied on adding replication triggers to the master, introducing additional load onto it.

Beginning from version 9.1, PostgreSQL also includes built-in synchronous replication that ensures that, for each write transaction, the master waits until at least one slave node has written the data to its transaction log. Unlike other database systems, the durability of a transaction (whether it's asynchronous or synchronous) can be specified per-database, per-user, per-session or even per-transaction. This can be useful for work loads that don't require such guarantees, and may not be wanted for all data as it will have some negative effect on performance due to the requirement of the confirmation of the transaction reaching the synchronous standby.

There can be a mixture of synchronous and asynchronous standby servers. A list of synchronous standby servers can be specified in the configuration which determines which servers are candidates for synchronous replication. The first in the list which is currently connected and actively streaming is the one that will be used as the current synchronous server. When this fails, it falls to the next in line.

Synchronous multi-master replication is currently not included in the PostgreSQL core. Postgres-XC which is based on PostgreSQL provides scalable synchronous multi-master replication and is licensed under the BSD license.

The community has also written some tools to make managing replication clusters easier, such as repmgr.

Trigger-based replication

There are also several asynchronous trigger-based replication packages for PostgreSQL. These remain useful even after introduction of the expanded core capabilities, for situations where binary replication of an entire database cluster isn't the appropriate approach:

- Slony-I
- Londiste, part of SkyTools (developed by Skype)
- Bucardo multi-master replication (developed by Backcountry.com)
- SymmetricDS multi-master, multi-tier replication

Asynchronous notifications

PostgreSQL provides an asynchronous messaging system that is accessed through the NOTIFY, LISTEN and UNLISTEN commands. A session can issue a NOTIFY command, along with the user-specified channel and an optional payload, to mark a particular event occurring. Other sessions are able to detect these events by issuing a LISTEN command, which can listen to a particular channel. This functionality can be used for a wide variety of purposes, such as letting other sessions know when a table has updated or for separate applications to detect when a particular action has been performed. Such a system prevents the need for continuous polling by applications to see if anything has yet changed, and reducing unnecessary overhead. Notifications are fully transactional, in that

messages aren't sent until the transaction they were sent from is committed. This eliminates the problem of messages being sent for an action being performed which is then rolled back.

Many of the connectors for PostgreSQL provide support for this notification system (including libpq, JDBC, Npgsql, psycopg and node.js) so it can be used by external applications.

Security

Internal

Security within the database is managed on a per-role-basis. A role is generally regarded to be a user (a role that can log in), or a group (a role which other roles are members of). Permissions can be granted or revoked on any object down to the column level, and can also allow/prevent the creation of new objects at the database, schema or table levels.

The sepgsql extension (provided with PostgreSQL as of version 9.1) provides an additional layer of security by integrating with SELinux. This utilises PostgreSQL's SECURITY LABEL feature.

External

PostgreSQL natively supports a broad number of authentication mechanisms including:

- trust (no enforcement)
- password (either MD5 or plain-text)
- GSSAPI
- SSPI
- Kerberos
- ident (maps O/S user name as provided by an ident server to database user name)
- peer (maps local user name to database user name)
- LDAP
- RADIUS
- certificate
- PAM

The GSSAPI, SSPI, Kerberos, peer, ident and certificate methods can also use a specified "map" file that lists which users matched by that authentication system are allowed to connect as a specific database user.

These methods are specified in the cluster's host-based authentication configuration file (pg_hba.conf), which determines what connections are allowed. This allows control over which user can connect to which database, where they can connect from (IP address/IP address range/domain socket), which authentication system will be enforced, and whether the connection must use SSL.

Foreign data wrappers

As of version 9.1, PostgreSQL can link to other systems to retrieve data via foreign data wrappers (FDWs). These can take the form of any data source, such as a file system, another RDBMS, or a web service. This means regular database queries can use these data sources like regular tables, and even join multiple data sources together.

Other features

- Referential integrity constraints including foreign key constraints, column constraints, and row checks
- Views
  - Materialized views
  - Updatable views
  - Recursive views

- Inner, outer (full, left and right), and cross joins
- Sub-selects
  - Correlated sub-queries
- Transactions
- Supports most of the major features of SQL:2008 standard
- Encrypted connections via SSL
- Binary and textual large-object storage
- Online backup
- In-place upgrades with pg_upgrade (available for upgrading to new major versions from 8.3 upwards)
- Domains
- Tablespaces
- Savepoints
- Point-in-time recovery, implemented using write-ahead logging
- Two-phase commit
- TOAST (**T**he **O**versized-**A**ttribute **S**torage **T**echnique) is used to transparently store large table attributes (such as big MIME attachments or XML messages) in a separate area, with automatic compression.
- Regular expressions
- Common table expressions and writable common table expressions
- Embedded SQL is implemented using preprocessor. SQL code is first written embedded into C code. Then code is run through ECPG preprocessor, which replaces SQL with calls to code library. Then code can be compiled using a C compiler. Embedding works also with C++ but it does not recognize all C++ constructs.
- Full text search
- Per-column collation (from 9.1)

Add-ons

- MADlib - an open source analytics library for PostgreSQL providing mathematical, statistical and machine-learning methods for structured and unstructured data.
- MySQL migration wizard - included with EnterpriseDB's PostgreSQL installer. (source code also available)
- Performance Wizard - included with EnterpriseDB's PostgreSQL installer. (source code also available)
- pgRouting - extended PostGIS to provide geospatial routing functionality (GNU GPL)
- PostGIS - a popular add-on which provides support for geographic objects GNU GPL.
- Postgres Enterprise Manager - a non-free tool consisting of a service, multiple agents, and a GUI which provides remote monitoring, management, reporting, capacity planning and tuning.
- ST-Links SpatialKit - Extension for directly connecting to spatial databases.

Upcoming features in 9.4

In order of commit:

- Concurrent refresh for materialised views
- FILTER clause for aggregate functions
- WITH CHECK clause for auto-updatable views
- WITH ORDINALITY support
- Multi-argument UNNEST(), and TABLE() syntax
- ALTER SYSTEM command to change persistent configuration from within database
- pg_prewarm extension to load relation data into the buffer cache of either the OS or PostgreSQL
- Ordered-set (WITHIN GROUP) aggregates
- ALTER TABLESPACE ... MOVE command for moving objects in bulk between tablespaces

- Replication slots for automatic WAL tracking to eliminate replication conflicts
- Many GIN Index enhancements to speed up searching and significantly reduce index size
- Logical decoding of WAL data into logical changes

Interfaces

PostgreSQL has several forms of interface available and is also widely supported among programming language libraries. These include:

Built-in

- libpq - PostgreSQL's official C application interface
- ECPG - An embedded C system

External

- libpqxx - C++ interface
- PostgresDAC - PostgresDAC (for Embarcadero RadStudio/Delphi/CBuilder XE-XE3)
- DBD::Pg - Perl DBI driver
- JDBC - JDBC interface
- Lua - Lua interface
- Npgsql - .NET data provider
- ST-Links SpatialKit - Link Tool to ArcGIS
- node-postgres - Node.js interface
- pgoledb - OLEDB interface
- psqlODBC - ODBC interface
- psycopg - Python interface (also used by HTSQL)
- pgtclng - Tcl interface
- pyODBC - Python library

Platforms

Operating systems

PostgreSQL is available for the following operating systems: Linux (all recent distributions), Windows (Windows 2000 SP4 and later) (compilable by eg. Visual Studio, now with up to most recent 2013 version), DragonFly_BSD, FreeBSD, OpenBSD, NetBSD, Mac OS X, AIX, BSD/OS, HP-UX, IRIX, OpenIndiana, OpenSolaris, SCO OpenServer, SCO UnixWare, Solaris and Tru64 Unix. As of 2012, support for the following obsolete systems was removed: DG/UX, NeXTSTEP, SunOS 4, SVR4, Ultrix 4, and Univel. Most other Unix-like systems should also work.

Instruction set architectures

PostgreSQL works on any of the following instruction set architectures: x86 and x86-64 on Windows and other operatings systems; other than Windows: IA-64 Itanium, PowerPC, PowerPC 64, S/390, S/390x, SPARC, SPARC 64, Alpha, ARMv8-A (64-bit)[5] and older ARM (32-bit), MIPS, MIPSel, M68k, and PA-RISC. It is also known to work on M32R, NS32k, and VAX. In addition to these, it is possible to build PostgreSQL for an unsupported CPU by disabling spinlocks.

Database administration

Open source front-ends and tools

psql

The primary front-end for PostgreSQL is the `psql` command-line program, which can be used to enter SQL queries directly, or execute them from a file. In addition, psql provides a number of meta-commands and various shell-like features to facilitate writing scripts and automating a wide variety of tasks; for example tab completion of object names and SQL syntax.

pgAdmin

The pgAdmin package is a free and open source graphical user interface administration tool for PostgreSQL, which is supported on many computer platforms. The program is available in more than a dozen languages. The first prototype, named pgManager, was written for PostgreSQL 6.3.2 from 1998, and rewritten and released as pgAdmin under the GPL License in later months. The second incarnation (named pgAdmin II) was a complete rewrite, first released on January 16, 2002. The third version, pgAdmin III, was originally released under the Artistic License and then released under the same license as PostgreSQL. Unlike prior versions that were written in Visual Basic, pgAdmin III is written in C++, using the wxWidgets framework allowing it to run on most common operating systems.

phpPgAdmin

phpPgAdmin is a web-based administration tool for PostgreSQL written in PHP and based on the popular phpMyAdmin interface originally written for MySQL administration.

PostgreSQL Studio

PostgreSQL Studio allows users to perform essential PostgreSQL database development tasks from a web-based console. PostgreSQL Studio allows users to work with cloud databases without the need to open firewalls.

TeamPostgreSQL

AJAX/JavaScript-driven web interface for PostgreSQL. Allows browsing, maintaining and creating data and database objects via a web browser. The interface offers tabbed SQL editor with auto-completion, row-editing widgets, click-through foreign key navigation between rows and tables, 'favorites' management for commonly used scripts, among other features. Supports SSH for both the web interface and the database connections. Installers are available for Windows, Mac and Linux, as well as a simple cross-platform archive that runs from a script.

LibreOffice/OpenOffice.org Base

LibreOffice/OpenOffice.org Base can be used as a front-end for PostgreSQL.

pgFouine

The pgFouine PostgreSQL log analyzer generates detailed reports from a PostgreSQL log file and provides VACUUM analysis.

Proprietary front-ends and tools

A number of companies offer proprietary tools for PostgreSQL. They often consist of a universal core that is adapted for various specific database products. These tools mostly share the administration features with the open source tools but offer improvements in data modeling, importing, exporting or reporting.

Benchmarks and performance

Many informal performance studies of PostgreSQL have been done. Performance improvements aimed at improving scalability started heavily with version 8.1. Simple benchmarks between version 8.0 and version 8.4 showed that the latter was more than 10 times faster on read-only workloads and at least 7.5 times faster on both read and write workloads.

The first industry-standard and peer-validated benchmark was completed in June 2007 using the Sun Java System Application Server (proprietary version of GlassFish) 9.0 Platform Edition, UltraSPARC T1-based Sun Fire server and Postgres 8.2. This result of 778.14 SPECjAppServer2004 JOPS@Standard compares favourably with the 874 JOPS@Standard with Oracle 10 on an Itanium-based HP-UX system.

In August 2007, Sun submitted an improved benchmark score of 813.73 SPECjAppServer2004 JOPS@Standard. With the system under test at a reduced price, the price/performance improved from $US 84.98/JOPS to $US 70.57/JOPS.

The default configuration of PostgreSQL uses only a small amount of dedicated memory for performance-critical purposes such as caching database blocks and sorting. This limitation is primarily because older operating systems required kernel changes to allow allocating large blocks of shared memory. PostgreSQL.org provides advice on basic recommended performance practice in a wiki.

In April 2012, Robert Haas of EnterpriseDB demonstrated PostgreSQL 9.2's linear CPU scalability using a server with 64 cores.

Prominent users

- Yahoo! for web user behavioral analysis, storing two petabytes and claimed to be the largest data warehouse using a heavily modified version of PostgreSQL with an entirely different column-based storage engine and different query processing layer. While for performance, storage, and query purposes the database bears little resemblance to PostgreSQL, the front-end maintains compatibility so that Yahoo can use many off-the-shelf tools already written to interact with PostgreSQL.
- In 2009, social networking website MySpace used Aster Data Systems's nCluster database for data warehousing, which was built on unmodified PostgreSQL.
- State Farm uses PostgreSQL on their Aster Data Systems's nCluster Analytics server.
- Geni.com uses PostgreSQL for their main genealogy database.
- OpenStreetMap, a collaborative project to create a free editable map of the world.
- Afilias, domain registries for .org, .info and others.
- Sony Online multiplayer online games.
- BASF, shopping platform for their agribusiness portal.
- Reddit social news website.
- Skype VoIP application, central business databases.
- Sun xVM, Sun's virtualization and datacenter automation suite.
- MusicBrainz, open online music encyclopedia.
- International Space Station for collecting telemetry data in orbit and replicating it to the ground.
- MyYearbook social networking site.
- Instagram, a popular mobile photo sharing service
- Disqus, an online discussion and commenting service

PostgreSQL as a service

Heroku, a platform as a service provider, has supported PostgreSQL since the start in 2007. They offer value-add features like full database "roll-back" (ability to restore a database from any point in time), which is based on WAL-E, open source software developed by Heroku.

In January 2012 EnterpriseDB released a cloud version of both PostgreSQL and their own proprietary Postgres Plus Advanced Server with automated provisioning for failover, replication, load-balancing, and scaling. It runs on Amazon Web Services.

VMware offers vFabric Postgres for private clouds on vSphere since 2012 May.

In 2013 November, Amazon announced that they are adding PostgreSQL to their Relational Database Service offering.

Proprietary derivatives and support

Although the license allowed proprietary products based on Postgres, the code did not develop in the proprietary space at first. The first main offshoot originated when Paula Hawthorn (an original Ingres team member who moved from Ingres) and Michael Stonebraker formed Illustra Information Technologies to make a proprietary product based on Postgres.

In 2000, former Red Hat investors created the company Great Bridge to make a proprietary product based on PostgreSQL and compete against proprietary database vendors. Great Bridge sponsored several PostgreSQL developers and donated many resources back to the community, but by late 2001 closed due to tough competition from companies like Red Hat and to poor market conditions.

In 2001 Command Prompt, Inc. released Mammoth PostgreSQL, a proprietary product based on PostgreSQL. In 2008 Command Prompt, Inc. released the source under the original license. Command Prompt, Inc. continues to support the PostgreSQL community actively through developer sponsorships and projects including PL/Perl, PL/php, and hosting of community projects such as the PostgreSQL build farm.

In January 2005, PostgreSQL received backing by database vendor Pervasive Software, known for its Btrieve product which was ubiquitous on the Novell NetWare platform. Pervasive announced commercial support and community participation and achieved some success. In July 2006, Pervasive left the PostgreSQL support market.

In mid-2005 two other companies announced plans to make proprietary products based on PostgreSQL with focus on separate niche markets. EnterpriseDB added functionality to allow applications written to work with Oracle to be more readily run with PostgreSQL. Greenplum contributed enhancements directed at data warehouse and business intelligence applications, including the BizGres project.

In October 2005 John Loiacono, executive vice president of software at Sun Microsystems, commented: "We're not going to OEM Microsoft but we are looking at PostgreSQL right now," although no specifics were released at that time. By November 2005 Sun had announced support for PostgreSQL. By June 2006 Sun Solaris 10 (6/06 release) shipped with PostgreSQL.

In August 2007, EnterpriseDB announced EnterpriseDB Postgres, a pre-configured distribution of PostgreSQL including many contrib modules and add-on components. EnterpriseDB Postgres was renamed to Postgres Plus in March 2008. Postgres Plus is available in two versions: Postgres Plus Solution Pack (comprising PostgreSQL delivered in a GUI one-click install plus Solution Pack components that include; Postgres Enterprise Manager, Update Monitor, xDB Replication Server, SQL Profiler, SQL Protect, Migration Toolkit and PL/Secure), and Postgres Plus Advanced Server which has all the features of Postgres Plus Solutions Pack plus Oracle compatibility, performance features not available in PostgreSQL, as well as advanced security features not available in PostgreSQL. Both versions are available for download at no cost and are fully supported. The Solution Pack components and Advanced Server are restricted by a "limited use" license for evaluation purposes only unless purchased though a subscription. In 2011, EnterpriseDB announced Postgres Plus Cloud Database, which easily

provisions PostgreSQL and Postgres Plus Advanced Server databases (with Oracle compatibility) in single instances, high availability clusters, or development sandboxes for Database-as-a-Service environments.

In 2011, 2ndQuadrant became a Platinum Sponsor of PostgreSQL, in recognition of their long-standing contributions and developer sponsorship. 2ndQuadrant employ one of the largest teams of PostgreSQL contributors and provide professional support for open source PostgreSQL.

Many other companies have used PostgreSQL as the base for their proprietary database projects. e.g. Truviso, Netezza, ParAccel. In many cases the products have been enhanced so much that the software has been forked, though with some features cherry-picked from later releases.

Release history

Release	First release	Latest minor version	Latest release	Milestones
0.01	1995-05-01	0.03	1995-07-21	Initial release as Postgres95
1.0	1995-09-05	1.09	1996-11-04	Changed copyright to a more liberal license
6.0	1997-01-29	—		Name change from Postgres95 to PostgreSQL, unique indexes, pg_dumpall utility, ident authentication.
6.1	1997-06-08	6.1.1	1997-07-22	Multi-column indexes, sequences, money data type, GEQO (GEnetic Query Optimizer).
6.2	1997-10-02	6.2.1	1997-10-17	JDBC interface, triggers, server programming interface, constraints.
6.3	1998-03-01	6.3.2	1998-04-07	SQL92 subselect capability, PL/pgTCL
6.4	1998-10-30	6.4.2	1998-12-20	VIEWs and RULEs, PL/pgSQL
6.5	1999-06-09	6.5.3	1999-10-13	MVCC, temporary tables, more SQL statement support (CASE, INTERSECT, and EXCEPT)
7.0	2000-05-08	7.0.3	2000-11-11	Foreign keys, SQL92 syntax for joins
7.1	2001-04-13	7.1.3	2001-08-15	Write-ahead log, Outer joins
7.2	2002-02-04	7.2.8	2005-05-09	PL/Python, OIDs no longer required, internationalization of messages
7.3	2002-11-27	7.3.21	2008-01-07	Schema, Internationalization
7.4	2003-11-17	7.4.30	2010-10-04	Optimization all-round
8.0	2005-01-19	8.0.26	2010-10-04	Native server on Microsoft Windows, savepoints, tablespaces, exception handling in functions, point-in-time recovery
8.1	2005-11-08	8.1.23	2010-12-16	Performance optimization, two-phase commit, table partitioning, index bitmap scan, shared row locking, roles
8.2	2006-12-05	8.2.23	2011-09-26	Performance optimization, online index builds, advisory locks, warm standby
8.3	2008-02-04	8.3.23	2013-02-07	Heap-only tuples, full text search, SQL/XML, ENUM types, UUID types
8.4	2009-07-01	8.4.20	2014-02-20	Windowing functions, default and variadic parameters for functions, column-level permissions, parallel database restore, per-database collation, common table expressions and recursive queries
9.0	2010-09-20	9.0.16	2014-02-20	Built-in binary streaming replication, Hot standby, 64-bit Windows, per-column triggers and conditional trigger execution, exclusion constraints, anonymous code blocks, named parameters, password rules
9.1	2011-09-12	9.1.12	2014-02-20	Synchronous replication, per-column collations, unlogged tables, *k*-nearest-neighbor indexing, serializable snapshot isolation, writeable common table expressions, SE-Linux integration, extensions, SQL/MED attached tables (Foreign Data Wrappers), triggers on views
9.2	2012-09-10	9.2.7	2014-02-20	Cascading streaming replication, index-only scans, native JSON support, improved lock management, range types, pg_receivexlog tool, space-partitioned GiST indexes

9.3	2013-09-09	9.3.3	2014-02-20	Custom background workers, data checksums, dedicated JSON operators, LATERAL JOIN, faster pg_dump, new pg_isready server monitoring tool, trigger features, view features, writeable foreign tables, materialized views, replication improvements

PL/pgSQL

PL/pgSQL (**Procedural Language/PostgreSQL**) is a procedural programming language supported by the PostgreSQL ORDBMS. It closely resembles Oracle's PL/SQL language. With PosgreSQL v9.X some ISO SQL/PSM features, like overloading of SQL-invoked functions and procedures,[1] are supported.

PL/pgSQL, as a fully featured programming language, allows much more procedural control than SQL, including the ability to use loops and other control structures. Functions created in the PL/pgSQL language can be called from an SQL statement, or as the action that a trigger performs.

PL/pgSQL was created to be able to perform more complex operations and computations than SQL, while being easy to use, and is able to be defined as trusted by the server.

PL/pgSQL is the only programming language installed by default for PostgreSQL, but many others are available, including PL/Java [2], PL/Perl [3], PL/php [4], PL/Python [5], PL/R [6], PL/Ruby [7], PL/sh [8], PL/Tcl [9], and PL/Lua [10]. PostgreSQL use Bison in its parser-stage,[11] so it is easy to port many open source languages, as well as reuse code.

Comparing with PSM

The SQL/PSM language is specified by an ISO standard, but also inspired by Oracle's PL/SQL and pgPL/SQL, so there are few differences. The main features of PSM that differ from PL/pgSQL:[12]

- Exception handlers are subroutines (continue handlers);
- Warnings can be handled like an exception;
- Declaration of variables should be based on SQL query result.

PL/Perl

PL/Perl (Procedural Language/Perl) is a procedural language supported by the PostgreSQL RDBMS.

PL/Perl, as an imperative programming language, allows more control than the relational algebra of SQL. Programs created in the PL/Perl language are called functions and can use most of the features that the Perl programming language provides, including common flow control structures and syntax that has incorporated regular expressions directly. These functions can be evaluated as part of a SQL statement, or in response to a trigger or rule.

The design goals of PL/Perl were to create a loadable procedural language that:

- can be used to create functions and trigger procedures,
- adds control structures to the SQL language,
- can perform complex computations,
- can be defined to be either trusted or untrusted [1] by the server,
- is easy to use.

PL/Perl is one of many "PL" languages available for PostgreSQL PL/pgSQL PL/Java [2], plPHP [2], PL/Python [5], PL/R [6], PL/Ruby [3], PL/sh [8], and PL/Tcl [9].

JADE (programming language)

JADE is a proprietary object-oriented software development and deployment platform product from the New Zealand-based Jade Software Corporation, first released in 1996. It consists of the JADE programming language, IDE and debugger, integrated application server and object database management system.

Designed as an end-to-end development environment to allow systems to be coded in one language from the database server down to the clients, it also provides APIs for other languages, including .NET Framework, Java, C/C++ and Web services.

As a programming language, its main competitors are Java and C#, while as a database it competes with other object-oriented databases and post-relational databases such as Versant, Caché and Matisse as well as traditional relational database software packages such as Oracle and Microsoft SQL Server.

Although a free limited licence is available for development, using the JADE platform requires per-process fees to be paid.

Language

In syntax, JADE is very similar to Pascal; its syntax is based on the language Modula-2, which was derived from Pascal. While it includes innovations lacking in Pascal or Modula-2, it lacks certain features of other modern object-oriented languages such as C# and Java.

Programming model

Like all of the other popular programming languages used to create database-driven software, JADE is fully object-oriented. JADE was designed to have all the most important features of object-oriented programming, but does not support the overloading of methods or operators, and lacks parameterised constructors.

Classes in JADE are kept together in schemas. Schemas serve the same purpose as Java packages or namespaces in .NET, but have a hierarchy, and inherit classes from superschemas. This becomes useful especially when programming using the model-view-controller methodology, as model classes can be put in one schema, then the controller and view classes can be built on top of the model classes in a subschema.

Program structure

JADE programs are developed using a user interface that allows programmers to visually create classes and define their properties and methods. Instead of locating methods in large files, programmers select the method they would like to edit and only the code for that particular method is displayed. Also instead of compiling all the code of a program at once, in JADE, each method is compiled individually as soon as the method is completed, meaning code can be checked immediately.

All the code for a JADE application is stored in its object-oriented database. This allows for multi-user development as the database maintains concurrency control, and with each piece of the code being a separate object in the database, it is often possible to recode a system while it is live and online as long as the parts of the system being changed are not in use.

Features

The main goal of JADE was to create a seamlessly integrated programming language that would allow developers to create one application that would go from end-to-end instead of having to write three separate applications for the database server, application server and presentation client and then write the code for them to communicate with each other.

Object database

The most striking difference between JADE and other object-oriented programming languages is that its object database is a native part of its language. For example, when creating an object in JADE, it can be created as transient or persistent. Creating an object as *transient* is similar to creating objects in other object-oriented programming languages - the object is simply created in memory, and then lost when the program ends. On the other hand, when an object is created as *persistent*, when the program ends, the object will still exist and be there the next time the program starts up. So, when an object is *persistent* JADE automatically works in the background to store and retrieve the object in the database when necessary. Persistent objects can be distributed across multiple co-operating servers, with JADE automatically handling object caching and cache coherency.

There are very few differences between manipulating transient and persistent objects so JADE makes it *appear* to the programmer as if all the objects in the entire database were in local memory. Most of the time, JADE's object-oriented database is used in a multi-user system, and so JADE makes it appear to the programmer as if all the objects in the database were stored in shared memory that all users connected to the system can access, even from different computers.

With all of the program code centralised on the database server as well the data, all client nodes can be programmed as if they were running on the database server.

JADE's database is inherently object-oriented, and [ACID]-compliant, and has all of the standard features such as atomic transactions, locking, rollback, crash recovery and the ability to keep one or more secondary database servers synchronised with the main database for backup, disaster recovery and performance reasons.

To interoperate with relational databases for reporting, business intelligence and data warehouse purposes JADE since 2010 has provided a "Relational Population Service" that enables automatically replicating objects from its native object-orientated database to one or more relational database. This feature supports Microsoft SQL Server versions 2000, 2005 and 2008.

Three-tier model

Database-driven software, often uses a three-tier methodology with applications being split into three tiers — data storage, processing and presentation. In the data storage and processing tiers, JADE systems are a collection of co-operating servers, called nodes, and multiple nodes may be involved in each tier. Each type of node has a different name and all are capable of manipulating objects and executing business logic. A collection of nodes can be deployed across one or several machines. Database servers handle data storage and can also execute business logic, while application servers handle processing. In a three-tier model, presentation clients provide the user interface. JADE also provides a two-tier client that combines the abilities of an application server and presentation client. Traditionally, these three tiers would be created by combining three programs and having them communicate to form one system. Having the different programs separate like this has many advantages, the main one is that the system becomes scalable, that is, raising the power of the system involves simply adding more nodes.

Designing a system like this gives the programmer a decision to consider every time they want to code in a particular function. They need to decide whether the function would run best on the database server, application server or presentation client before they begin coding as it will be difficult to change that decision once the functionality is coded into one of the tiers.

This is different for JADE applications, as they are coded as one application from end-to-end. When creating a JADE application, the programmer can think as if they were creating a program that will be running on the database server — as if all the data storage, processing and presentation were happening on one computer. When the program runs on three tiers, JADE automatically knows to run all the code by default on the application server, and to send database requests up to the database server and user interface information down to the presentation client. However, it is very easy for the programmer to switch the location at which a particular method is run and move it to a different tier by changing the method signature. Because of this, the decision on where a particular piece of code should run can be made late in the development cycle, and refactoring code to run on different parts of the system ends up being a lot easier because of the way JADE allows end-to-end development of software.

Types of Clients

Programmers have the facility to allow three different kinds of clients to connect to a JADE system. These three types of clients are named:

- JADE Forms
- HTML Documents
- Web Services

In the same schema, a JADE developer can create many completely separate applications which may provide different interfaces to access the same database.

JADE Forms

JADE Forms applications are made up of forms, as the name suggests. Clients need to connect through the JADE Smart Thin Client or Standard Client to be able to run applications that use JADE Forms.

The Smart Thin Client works by connecting to an Application Server which generally does all the processing on behalf of the Smart Thin Client, meaning the thin client only needs to be responsible for displaying forms and taking input. This means the computer running the thin client does not have to be a very powerful computer, and it does not require a fast network connection as it is not loading data from the database — JADE thin clients are often run over a dial-up connection. This is the reason they are called thin clients, as there is not a heavy requirement on computational power to run these clients.

The Standard Client is just the Smart Thin Client combined with the Application Server on one machine. In this case, the node running the client does all of the processing as well as the presentation. Standard clients have greater demands on computational power than thin clients, as they must load data from the database as well as do their own processing.

The advantages of using JADE Forms include:

- Out of the three kinds of clients, JADE Forms provide the shortest development time of JADE applications.
- Allows developers to use the same technology end-to-end.
- Smart thin clients can be packaged up so they can be installed and run on client computers in several clicks.

The disadvantages are:

- Cannot reach a worldwide audience as is possible on the World Wide Web.

JADE Forms have an interesting twist to them though. It is actually possible to run a JADE Forms application through a web browser by changing its mode to *web-enabled*. When this happens, JADE automatically generates HTML code to make pages that resemble the forms and controls, without any modifications to the code. This is a very quick way for programmers that are not competent with HTML and other web technologies to deliver a program through the web.

HTML documents

JADE supports deployment of applications to the web through its HTML documents feature. These work very similarly to ASP.NET, where developers create templates of HTML pages and leave parts in the template for the program to fill in.

The advantages of using HTML documents are:

- Allows the application to reach a worldwide audience.

The disadvantages are:

- When JADE applications use HTML documents, they are no longer using the same technology from end to end. Checking at the front end of the system may be done through JavaScript for example.
- Offloading some of the processing to front-end clients is no longer as easy or secure.

Web services

Web services are used to allow different programs to communicate with each other from remote locations in an object-oriented form. Web services cannot be accessed directly by human users. One of the uses of Web services with JADE is to allow other technologies such as .NET or Java to use JADE as the backend object-oriented database. Web services also allow JADE systems to interoperate with services provided by other non-JADE systems.

Interoperability

In addition to Web services, JADE is also capable of interfacing with other programs through language APIs (including .NET, Java, C/C++), DLL calls, ActiveX/COM objects and .NET assemblies. This allows other programs to access objects and execute methods, and can be used to provide a different interface to a JADE application. JADE 6.2 provided a Java API, .NET Assembly integration and the ability to run Smart Thin Clients on Windows Mobile devices. JADE 6.3 provides an API for .NET languages.

Multilingual abilities

JADE natively supports multilingual programs. It does this in several ways:

- Strings can be marked as *translatable*, which means they will be change depending on the current language.
- Many versions of the same form can be created to suit each language. This means interfaces can look entirely different from one language to the next.
- The developer has methods available to access the current locale of the system and so they can implement their own language-dependent features.

JADE will automatically switch to the language it detects on the system if the language is provided by the developer.

Portability

Currently JADE applications can be run on Windows and Linux. Similar to Java, JADE strives to allow programmers to develop applications once and be able to allow them to run on both of these platforms with minimal changes. JADE 6.2 allows Smart Thin Clients and a specialised Standard Client to run on Windows Mobile devices.

Code Examples

In this section are some short examples of JADE code.

Hello World!

This is the "Hello World!" code in JADE:

```
helloWorld();

begin
   app.msgBox("Hello, World!", "Hello, World!", MsgBox_OK_Only + MsgBox_Information_Icon);
end;
```

or

```
helloWorld();

begin
   write "Hello, World!";
end;
```

History

JADE was originally conceived by Sir Gilbert Simpson and is currently developed by the Jade Software Corporation.[1]

The first version of JADE was JADE 3, released September 1996.

The current version is JADE 7.

ObjectDB

ObjectDB Object Database

Developer(s)	ObjectDB Software
Stable release	2.5.3 / September 4, 2013
Written in	Java
Operating system	Cross-platform
Type	Object database
License	Proprietary[1]
Website	www.objectdb.com [2]

ObjectDB is an object database for Java. It can be used in client-server mode and in embedded (in process) mode.

Unlike other object databases, ObjectDB does not provide its own proprietary API. Accordingly, working with ObjectDB requires using one of the two standard Java APIs - JPA or JDO. Both APIs are built-in in ObjectDB,[3][4] so an intermediate ORM software is not needed.[5][6]

Features

ObjectDB is a cross platform software and can be used on various operating systems with Java SE 5 or higher. It can be integrated into Java EE and Spring web applications and deployed on servlet containers (Tomcat, Jetty) as well as on Java EE application servers (GlassFish, JBoss).[7][8] It was tested on various JVMs, including HotSpot, JRockit and IBM J9.[9]

The maximum database size is 128 TB (131,072 GB). The number of objects in a database is unlimited (except by the database size).

All the persistable types of JPA and JDO are supported by ObjectDB, including user defined entity classes, user defined embeddable classes, standard Java collections, basic data types (primitive values, wrapper values, String, Date, Time, Timestamp) and any other serializable classes.

Every object in the database has a unique ID. ObjectDB supports both traditional object database IDs, as well as RDBMS like primary keys, including composite primary keys and auto value generation and assignment, as part of its support of JPA, which is mainly an API for RDBMS.

Two query languages are supported. The JDO Query Language (JDOQL), which is based on Java syntax, and the JPA Query Language (JPQL), which is based on SQL syntax. JPA 2 criteria queries are also supported.

ObjectDB automatic schema evolution handles most changes to classes transparently, including adding and removing of persistent fields, changing types of persistent fields, and modifying class hierarchy. Renaming persistable classes and persistent fields is also supported.

Tools and Utilities

The following tools and utilities are included in the ObjectDB distribution:[10]

- **Database Explorer** - GUI tool for querying, viewing and editing database content.
- **Database Doctor** - Diagnoses and repairs possible database problems.
- **Replication** - Master-Slave replication (clustering) with unlimited number of slave nodes.
- **Online Backup** - Database backup by a simple query on an EntityManager.
- **Class Enhancer** - Boosts performance by preparing classes for persistence.
- **Transaction Replayer** - Recorder and replayer of database transactions.
- **BIRT Reports Driver** - Adds ObjectDB as a BIRT data source and JPQL / JDOQL queries as data sets.

Versant Object Database

Versant Object Database

Developer(s)	Versant Corporation
Stable release	8.0.2.15 / October 1, 2012
Development status	Active
Written in	Java, C, C#, C++, Smalltalk, Python
Operating system	Cross-platform Solaris, Linux, Windows (NT thru Vista), AIX, HP-UX (both 32 and 64 bit for all platforms)
Type	Object Database
License	All rights reserved
Website	www.versant.com [1]

Versant Object Database (VOD) is an object database software product developed by Versant Corporation.

The Versant Object Database enables developers using object oriented languages to transactionally store their information by allowing the respective language to act as the Data Definition Language (DDL) for the database. In other words, the memory model is the database schema model.[1]

In general, persistence in VOD in implemented by declaring a list of classes, then providing a transaction demarcation application programming interface to use cases. Respective language integrations adhere to the constructs of that language, including syntactic and directive sugars.

Additional APIs exist, beyond simple transaction demarcation, providing for the more advanced capabilities necessary to address practical issues found when dealing with performance optimization and scalability for systems with large amounts of data, many concurrent users, network latency, disk bottlenecks, etc.

Feature highlights

- Transparent object persistence from C++, Java and .NET
- Support for standards, e.g., JDO
- Seamless database distribution
- Enterprise-class high availability
- Dynamic schema evolution
- Low administration
- Multithreading, multisession
- End-to-end object architecture
- Fine-grained concurrency control

Supported languages

Primary supported languages are Java, C# and C++. Versant also has language support for Smalltalk and Python.

Query systems

VOD supports queries via a server side indexing and query execution engine. Query support includes both a Versant-specific and a standards-based query language syntax. Versant provides this query capability in a number of forms depending on the developer's chosen language binding. For example, in Java VOD provides VQL (Versant Query Language), JDOQL, EJB QL and OQL. In C++ Versant provides VQL and OQL, with C# support for VQL, OQL and LINQ. VOD will do optimization of query execution based on available attribute indexes. Versant also has support for standard SQL queries against the Versant database using ODBC/JDBC drivers.

Versant Query Language

The native Versant Query Language (VQL) is similar to SQL92. It is a string based implementation which allows parameterized runtime binding. The difference is that instead of targeting tables and columns, it targets classes and attributes.

Other object-oriented elements apply to query processing. For example, a query targeting a super class will return all instances of concrete subclasses that satisfy the query predicate. VOD is a distributed database: a logical database can be composed of many physical database nodes, with queries are performed in parallel.

Versant query support includes most of the core concepts found in relational query languages including: pattern matching, join, set operators, orderby, existence, distinct, projections, numerical expressions, indexing, cursors, etc.

Indexing

VOD supports indexes on large collections. However it is not necessary to have a collection in order to have a queryable object with a usable index. Unlike other OODB implementations, any object in a Versant database is indexable and accessible via query. Indexes can be placed on attributes of classes and those classes can then be the target of a query operation. Indexes can be hash, b-tree, unique, compound, virtual and can be created online either using a utility, via a graphical user interface or via an API call.

Large collection support

VOD provides pagination support for large collections using a special node based implementation. These collections are designed in such a way that access is done so that only nodes needed by the client are brought resident into memory, instead of having to load the entire collection.

These large collections are created and operated on just as other persistent collection classes. The interface is also consistent with the appropriate language constructs. For example C++ Standard Template Library, Java iterators, C# enumerables, etc.

Collections of objects by default are only a collection of object identifiers. So, these can be very large, yet have a small resident memory footprint. To iterate the collection, objects are dereferenced into client memory space in either a configurable batch mode or one at a time. A query on the collection can be done using the “in” operator (or other set based operators like subset_of, superset_of, etc.) without loading the collection to the client memory space.

Data replication

There are several mechanisms for replication on VOD that depend on the motivation behind the replication. It is for high availability or for distribution or integration.

High availability

Versant does synchronous pair replication. Full replication for fault tolerance only requires installation of one configuration file specifying the buddy node names: New connections notice the existence of the replica file and on connect, check the file for a buddy pair and if it exists, connect to both buddies. This could be a distributed database so that there are many buddy pairs. Then all transactional changes are committed synchronously to the buddy database server processes.

If any one of the databases in the buddy pair should become unreachable, the in-flight transactions are handled so that there is no commit failure, instead in-flight transactions on node failure will continue to the node that is still alive in the buddy pair. On the machine where the node is still alive and processing transactions, a new process will start that monitors for the crashed database to become accessible again. Once the previously failed node is alive, the monitoring process starts replicating all changes that have occurred since the time of failure to bring the two buddies back into full synchronization. Once they are in full sync, a flag is set and on the next transaction clients will move back to full synchronous operation. All of this is handled without any user involvement.

In the case of extreme failure, like a broken disk drive, etc., the replicated node can be recreated from an online backup of the live node. Simply install a new disk drive, take an online backup of the live node, restore on the failed machine, start the monitor to sync the last few transactions and restore full replication at clients.

Distribution

Distribution is handled using Versant Asynchronous Replication (VAR), a channel driven, master-slave or peer-to-peer replication framework with rule based conflict detection and resolution.

An administrator uses a utility to define replication channels. Channels are named entities that define a scope of replication within a physical node. The “scope” can be anything from full database replication to something as fine grained as anything definable by a Versant query. Once the channels are defined, applications can register as listeners on these channels, at which point changes from those channel begin to flow to the respective clients.

These channels provide both persistence and reliable messaging. In the event that a connection is lost between a registered listener and a channel, ongoing changes will be guaranteed delivery once the connection is re-established. There are multiple transport protocols that can be configured for optimization in highly reliable LAN networks or high reliability in unreliable WAN type of environments.

In bi-directional channel replication, a set of conflict detection rules are put in place so that conflicting changes can be resolved at runtime without disrupting channel activity. There are other forms of data distribution.

Integration

Usually, integration requires some kind of custom code. Users can connect to both relational and Versant databases using ORM products. They can load objects either from a relational database or Versant and then with some minor code implementation, disconnect those objects from the source and write them to a target. This can be used for import/export in a batch processing mode for integration with other database systems.

Data distribution architecture

VOD handles distributed data processing using a distributed two-phase commit protocol across multiply connected databases. In this process, VOD uses an internal resource manager that is handling the distributed transactions. Versant also supports the XA protocol allowing external transaction monitors to control the transactional context, so for example plug into a CORBA or J2EE application server.

Versant allows object relationships to span physical resource (database) nodes. Shared information referenced from object graphs that reside in other databases and resolution of that information is transparent at runtime. For example, several physical databases may hold user information models that are partitioned by account number holding aggregations on account activities such as trades and then have some more databases holding actual trade models and these users and trades can be related. A query across all of the user databases and return a user (or set of users), then as messages are sent to user objects involving trades, the trade models will automatically be resolved across the distribution. After updates of any of those objects, at commit time Versant will ensure that all changes commit back to their respective physical nodes in a completely ACID 2phase commit process.

Object id's are guaranteed to be unique across all physical nodes. Objects could be "moved" from one physical node to another without any application code changes required.

Schema evolution

Schema evolution is handled via a normal update of the application's class models and then applying those changes to the operational database. Those schema changes can be applied to an existing database either via a utility or API. The result is a versioning of the database schema.

Existing objects in the database are lazily evolved to the latest schema version. No object is actually evolved unless it is made dirty (marked for update) and committed back to the database. In general this means an application with the new schema will not cause evolution, expect for new and updated objects.

There are utilities that can "crawl" a database slowly evolving all instanced to the latest version by grabbing sets of them, marking them dirty, committing. This is sometimes desired for embedded or real-time systems where performance and space needs to be optimized.

In most cases, older clients get patch updates with the new schema in conjunction with updates to the server. The clients schema version is in sync with the database server. Versant's loose schema mapping facility can also be used. This is enabled by a flag in the client so that it does not complain about a mismatch in schema version and instead filters the incoming objects to match the old schema. Using this facility requires some forethought to avoid any unintended side effects.

The process goes as follows:

1. class definitions are updated, i.e. add new subclasses, add attributes, rename attributes, remove attributes, etc. and recompile. When the application connects to a Versant database, a schema version mismatch will be detected and you would normally get an error unless you take some action to avoid the mismatch.
2. The schema mismatch can be avoided using a number of techniques.
    1. a utility can be used to describe the new schema to the database. The utility will show a list of incompatibilities and ask how you want them to be resolved. Your action will depend on whether you are in

development, QA, production, etc. Regardless, actions like dropping the existing class, evolving the schema version and keeping all existing objects, rename and retype, etc, are also possible.

2. the evolution process can be automated via connection options. This is normally used in development mode and allows the schema to automatically evolve any mismatches on connect and continue preserving the existing objects.
3. specific API's can be used to dynamically evolve the database schema. This is an advanced topic, involving what's called Versant runtime classes. Basically, you can create completely dynamic schema structure for the database so that new classes and attributes can be created on the fly.

3. If clients with the older schema continue to operate on the database, loose_schema_mapping in the application profile file should be set to true.
4. Optionally, a utility can be started to crawl the database and force version migration of all existing instances.

The general guidelines for schema evolution are that any schema changes can be made and existing instances preserved, without having to write custom evolution code, with the exception of two things:

1. Changes to the middle of an inheritance hierarchy. Inserting a new class into the middle of a hierarchy is impossible without losing your existing objects, unless custom code is written to do this operation in a series of steps.
2. Incompatible type changes like Array to a String.

All other forms of evolution like renaming attributes, deleting leaf classes, adding leaf classes, adding new classes, adding or removing attributes, etc. can be done online and without custom code. If actions like setting non standard default values for newly added attributes are necessary, this can be done in callback functions within the objects. There are a set of standard object lifecycle callbacks that get invoked in activities like cache load. Those callbacks can be used to check for default values and take action if necessary.

Persistent object lifecycle

The lifecycle of an object load can be controlled on a use case basis.

By default, objects are loaded only when they are sent a message. This includes the default behavior for queries which only return a collection of references to objects that satisfied the query predicate, not the actual objects. When an object is loaded, all it's non-reference attributes (primitives) are also loaded and remaining reference types follow the same pattern as the referencing object.

When a message is sent to an object VOD looks into internal structures to see if the object is already in client memory. If not, VOS does an RPC to load the object. At the time VOD loads the object, it will also look at the connections locking strategy to decide how to deal with locking the object on load. VOD supports both global locking strategies that can be applied to a connection and extremely fine grained control to override behavior for a particular use case.

Once an object is loaded and locked it stays in the client cache, with an equivalent lock in the server, until one of a number of events occurs.

The most common event, the current transaction ends with commit. In the default case, this will release the lock and object from memory. However, note that there are forms of commit that will do combinations of things like, keep the cache and the locks and start a new transaction, keep the cache, but release the locks and start a new transaction. These forms and others are used to optimize cache effectiveness when using non-default locking strategies like optimistic locking or when you have a series of transactions that form a task and operate on the same set of objects.

Another possibility is that your client cache starts to get full. In this case, VOD may decide to swap objects back to the server process to make space and do some work that will have to be done at commit anyway. VOD does this in a fully transactional way, so that even if modified objects get swapped to the server, they will still be undone if the transaction is rolled back. Also, you have the ability to "pin" objects into the client cache to prevent swapping of

important sets of objects, enabling the use of direct memory pointers without concern for memory faults.

Another possible event is a query call which has the option set to flush the cache of objects in the target class, so that changed objects currently in your cache become part of the current query execution evaluation.

Other possibilities include API calls that result in explicit release of the object, like a call to refresh or a call to release.

There are many ways to override the default behavior. Those are in fact commonly used to performance tune on a use case basis. For example, if you are going to iterate over a collection of 1000 objects, you don't want to do 1000 RPC's. Giving the collection of references to a call to groupRead will use a single RPC and load all objects. Similarly, you can make a call to getClosure which will use groupRead behavior to load all referenced objects in a graph from the starting point, down to your specified level of reachability. Further, queries have options to set a lock and load result sets rather than just references or to use cursors. There are API's to explicitly load objects into cache and set higher lock levels than the connection defaults, etc.

Achieving persistence

For users of C++, Versant requires that the uppermost class in an inheritance hierarchy inherit from a base class "PObject", which handles database activities.

Then there is a file setup, `schema.imp`, that declares which classes in the model are to be made persistent and that file is used in a pre-compilation phase where Versant's necessary magicWikipedia:Please clarify is added to the persistent classes. Finally, the resulting `schema.cxx` file is compiled and linked with the application.

The pre-compilation phase is done with a utility though note this is typically automatically set up in one's visual development environment so the process is automatic when a build is done.

When using Java or .NET, this same procedure described above with C++ is accomplished using post-processing byte code enhancement. One sets up a file that declares which classes are to be persistent and then uses a utility, or API, or IDE integration to enhance the classes before running or debugging.

Versant provides other Java APIs based on standards JDO and JPA. In those versions of the API, the system adheres to the standards defined for declaring persistence whether it be some kind of XML or annotation. Enhancement is then done using a utility (similarly with .NET) or more commonly with Eclipse plug-in or Microsoft Visual Studio integration during the build process.

Integration with relational databases

A large percentage of Versant's customers do some form of integration with relational tables. This can be accomplished in a couple of ways depending on the requirements such as: on-line/off-line, batch based, transactional, etc.

XA

Versant supports the XA protocol for distributed transactions. This allows participation in online distributed transactions with relational databases. The interaction with the relational tables can take many forms from custom code to ORM solutions to J2EE application servers (Entity Relationship Modeling) to message passing to ORBs, etc. The XA API allows the Versant database to act as a resource controlled by an external transaction monitor coordinating changes to both Versant and relational databases in the same transactional context.

ORM

Versant can interact with relational databases using Java ORM technology such as JDO (Java Data Objects) and Hibernate JPA. These standards-based implementations have the ability to detach objects from their transactional context and then attach them to another connection. There are restrictions in that Versant requires the application to use a concept known as database identity in order for replication to work with relations intact. Versant does not support the ORM form of application identity in anything other than a disconnected data form.

XML

Versant has tools that enable the import and export of XML data. For example, batch based replication of data can be accomplished by exporting objects from the Versant database as XML, if necessary applying an XSLT transform and then importing into relational tables. The opposite direction is also possible. With Java, the most common approach using XML is to dynamically replicate information using JAXB which runtime converts objects into and out of an XML form. Using JAXB, the Versant database only needs to work with objects rather than importing an XML form. In essence, XML coming from relational databases are converted to objects at runtime using JAXB and those objects are then persisted into the Versant database.

Custom code

Users of C++ are especially challenged in integrating with relational databases. Versant provides consulting to help these customers with their integration challenges, but does not make those solutions, which require customization for each application, available in a productized form.

Transactions

Versant by default is always implicitly in a transaction when connected to the database. In addition, VOD supports the XA protocol and apply that to certain standards based API' such as JDO and JPA which require explicit transaction demarcation. There is a non-implicit form of transaction where transaction begin/end must be declared.

In order to discard from memory objects that have been modified in the current transaction you can either do it globally for the current transaction by issuing a rollback which also implicitly starts another transaction or you can do it in isolation or globally using specific calls within the same transaction.

Locking and caching strategies

Versant by default uses a pessimistic locking strategy to ensure that objects in the database server are in sync with client access in an ACID way. This is done by using a combination of locks against both schema and instance objects.

The database server process maintains lock request queues at the object level to control concurrency of access to the same object. A request for update will establish a queue if there are any existing readers of an object. The request either goes through when all current readers release their locks or times-out (an exception which can be handled by client is thrown). Locks are generally released at transaction boundaries. When a queue is established by an update request, all other subsequent requests fall in queue behind the update request. Once the update request has been filled, all read requests in the queue rush in and get their read lock, return the object, and if there are no other updates, the queue disappears. In this architecture, locks are done at the object level so false waits and false deadlocks do not occur.

Other ways of keeping client caches in sync are, for example, an optimistic locking strategy, using a classic timestamp mechanism. VOD also provides forms of client cache synchronization using multi-cast. Additionally it provides an event mechanism where clients can register for triggering events within the database server to be used for synchronization or for business logic work flow.

Scalability

Storage

Versant supports, multiple file and multiple process configurations. Data storage is done in a single or multiple files, but there are supporting files for the logging subsystem (logical and physical log files). These logging files are used for high performance and scalability under concurrent user loads and for online database backup processes.

Clients

Versant is a multi-user client server database and has production applications with thousands of concurrently connected users. Thus, Versant can also run linked and embedded in the same address space as the application process (so it can be also an embedded database).

Performance

Versant uses internal performance and scalability benchmarks to monitor and measure behavior over time across releases, patches and generations of new hardware.

Versant has done other non-standard benchmarking activities in a public forum.[2] .[3]

Versant ran the 007 benchmarks in the early 90's but currently doesn't provide any comparisons because there are no industry benchmarks that make sense for object databases,

One of the candidates considered was TPC-E, which was supposed to be the new OLTP standard database benchmark with new complex models aimed at being representative of today's computing environment. The TPC-E is based on a financial trading system model. Still, comparative results could not be obtained. The reason is that the TPC specifies requirements regarding what part of the code resides in the "driver" of the benchmark and what part resides in "database" functionality. However, the driver to application logic interface is completely defined at the data level. This means that when measuring relational access you would not incur any overhead for mapping into a C++ object. The mapping of the raw data into what ever form was necessary in the driver to implement the business logic was completely outside of the benchmark measurements. When it comes to the object database, you need to now un-map the C++ objects into the driver data structures and in doing so, measure the cost of that activity as part of the benchmark timings.

But this is the opposite of a real world application where people write object oriented applications resulting in object oriented models. In a relational database, you need to map/un-map from objects to the relational data structures. The TPC-E was written in a way as to exclude the "mapping effect" from the measurements, which by the very nature of how an object database works means the TPC-E was written in a way that forces measurement of an "un-mapping effect", an activity which does not occur in a real world application. Thus with TPC-E, the true cost of computing is removed for relational and even worse added to object databases.

Add-on Modules

Versant provides add-on modules for deployment or access to its Object Database.

- V/Management Center: V/MC delivers real-time views of performance data and analytical information about the Versant Object Database. For example, it alerts administrators about potential issues before the database availability is affected. It's designed as an Eclipse-based RCP client.
- Versant Compact: Online Database Maintenance.
- Versant FTS: High Availability Database Server.
- Versant Async Server: Production Database Replication.
- Versant HA Backup: High Availability Backup Solution.
- Versant SQL: SQL Access & Reporting.

Applications

Usually the “best kind of application” to use a Versant database are those applications requiring an application specific database of an OLTP nature. There are certain application characteristics where Versant technology provides better performance and scalability than traditional relational technology: complex models, large amount of data, large number of concurrent users.

Thus, VOD is found in applications within many different vertical industries: global trading platforms for large stock exchanges, network management for large telecommunications providers, intelligence analytics for defense agencies, reservation systems for large airline/hotel companies, risk management analytics for banking and transportation organizations, Massively multiplayer online game systems, network security and fraud detection, local number portability, advanced simulations, social networking, etc..

Zope Object Database

Zope Object Database

Developer(s)	Zope Corporation
Stable release	3.10.3 / April 12, 2011[1]
Written in	Python
Operating system	Cross-platform
Type	Object Database
License	Zope Public License
Website	www.zodb.org [2]

The **Zope Object Database** (**ZODB**) is an object-oriented database for transparently and persistently storing Python objects. It is included as part of the Zope web application server, but can also be used independently of Zope.

Features of the ZODB include: transactions, history/undo, transparently pluggable storage, built-in caching, multiversion concurrency control (MVCC), and scalability across a network (using ZEO).

History

- Created by Jim Fulton of Zope Corporation in the late 90s.
- Started as simple Persistent Object System (POS) during Principia development (which later became Zope)
- ZODB 3 was renamed when a significant architecture change was landed.
- ZODB 4 was a short lived project to re-implement the entire ZODB 3 package using 100% Python.

Implementation

Basics

A ZODB storage is basically a directed graph of (Python) objects pointing at each other, with a Python dictionary at the root. Objects are accessed by starting at the root, and following pointers until the target object. In this respect, ZODB can be seen as a sophisticated Python persistence layer.

Example

For example, say we have a car described using 3 classes Car, Wheel and Screw. In Python, this could be represented that way (coding style is awful, but this is for an illustration purpose):

```
class Car: [...]
class Wheel: [...]
class Screw: [...]

myCar = Car()
myCar.wheel1 = Wheel()
myCar.wheel2 = Wheel()
for wheel in (myCar.wheel1, myCar.wheel2):
    wheel.screws = [Screw(), Screw()]
```

(Car() creates a new instance of class Car).

If the variable zodb is the root of persistence, then

```
zodb['mycar'] = mycar
```

puts all the objects (the instances of car, wheel, screws and so on) into the storage, and can be retrieved later. If for example, another program gets a connection to the database through the zodb object, performing:

```
carzz = zodb['mycar']
```

retrieves all the objects, the pointer to the car being held in the carzz variable.

The object can then be altered, for example if some later Python code reads:

```
carzz.wheel3 = Wheel()
carzz.wheel3.screws = [Screw()]
```

the storage is altered to reflect the change of data (after a commit is ordered).

There is no declaration of the data structure in Python, so there is none in ZODB, new fields can be freely added to an existing object.

Storage unit

Actually, the above oversimplifies a bit. For persistence to take place, the Python Car class must be derived from the persistence.Persistent class — this class both holds the data necessary for the persistence machinery to work, such as the internal object id, state of the object, and so on, but also defines the boundary of the persistence in the following sense: every object whose class derives from Persistent is the atomic unit of storage (the whole object is copied to the storage when a field is modified).

In the example above, if Car is the only class deriving from Persistent, when wheel3 is added to car, all the objects must be written to the storage (the Car, wheel1, wheel2, the screws and so on). In contrast, if Wheel also derives from Persistent, then when carzz.wheel3 = Wheel is performed, a new record is written to the storage to hold the new value of the Car, but the existing Wheel are kept, and the new record for the Car points to the already existing Wheel record inside the storage.

The ZODB machinery doesn't chase modification down through the graph of pointers. In the example above, carzz.wheel3 = something is a modification automatically tracked down by the ZODB machinery, because carzz is of (Persistent) class Car. The ZODB machinery does this basically by marking the record as `dirty`. However, if there is a list (for example), a change inside the list isn't noticed by the ZODB machinery, and the programmer must help by manually adding

```
carzz._p_changed = 1
```

to notify ZODB that the record actually changed. Thus the programmer must be aware to a certain point of the working of the persistence machinery.

Atomicity

The storage unit (that is, an object whose class derives from Persistent) is also the atomicity unit. In the example above, if Cars is the only Persistent class, a thread modifies a Wheel (the Car record must be notified), and another thread modifies another Wheel inside another transaction, the second commit will fail. If Wheel is also Persistent, both Wheels can be modified independently by two different threads in two different transactions.

Class persistence

The class persistence (that is, writing the class of a particular object into the storage), is obtained by writing a kind of "fully qualified" name of the class into each record on the disk. It should be noted than, in Python, the name of the class involves the hierarchy of directory the source file of the class resides in. A consequence is that the *source* file of persisting object cannot be moved. If it is, the ZODB machinery is unable to locate the class of an object when retrieving it from the storage, resulting into a broken object.

Log file

(missing)

ZEO

ZEO (Zope Enterprise Objects) is a ZODB storage implementation that allows multiple client processes to persist objects to a single ZEO server. This allows transparent scaling, but the ZEO server is still a single point of failure.

Pluggable Storages

- Network Storage (aka ZEO) - Enables multiple python processes load and store persistent instances concurrently.
- File Storage - Enables a single python process to talk to a file on disk.
- relstorage - Enables the persistence backing store to be a RDBMS.
- Directory Storage - Each persistent data is stored as a separate file on the filesystem. Similar to FSFS in Subversion.
- Demo Storage - An in-memory back end for the persistent store.
- BDBStorage - Which uses Berkeley DB back end. Now abandoned.

Failover Technologies:

- Zope Replication Services (ZRS) - A commercial add-on (open-source since May 2013) that removes the single point of failure, providing hot backup for writes and load-balancing for reads.
- zeoraid - An open source solution that provides a proxy Network Server that distributes object stores and recovery across a series of Network Servers.
- relstorage - since RDBMS technologies are used this obviates need for ZEO server.
- NEO - Distributed (fault tolerance, load-balancing) storage implementation.

No-SQL Databases

Strozzi NoSQL (RDBMS)

Strozzi NoSQL (RDBMS)

Original author(s)	Carlo Strozzi
Initial release	1998
Stable release	4.1.10 / September 13, 2010
Platform	Unix-like (e.g., Cygwin)
Type	RDBMS
License	GPL
Website	www.strozzi.it/cgi-bin/CSA/tw7/I/en_US/nosql/Home%20Page [1]

Strozzi NoSQL is a shell-based relational database management system initialized and developed by Carlo Strozzi that runs under Unix-like operating systems, or others with compatibility layers (e.g., Cygwin under Windows). Its file name *NoSQL* merely reflects the fact that it does not express its queries using Structured Query Language; the NoSQL RDBMS is distinct from the circa-2009 general concept of NoSQL databases, which are typically non-relational, unlike the NoSQL RDBMS. Strozzi NoSQL is released under the GNU GPL.

Construction

NoSQL uses the operator-stream paradigm, where a number of "operators" perform a unique function on the passed data. The stream used is supplied by the UNIX input/output redirection system so that over the pipe system, the result of the calculation can be passed to other operators. As UNIX pipes run in memory, it is a very efficient way of implementation.

NoSQL, with development led by Carlo Strozzi, is the latest and perhaps the most active in a line of implementations of the stream-operator database design originally described by Evan Shaffer, Rod Manis, and Robert Jorgensen in a 1991 Unix Review article and an associated paper [2]. Other implementations include the Perl-based rdb, a commercial version by the original authors called /rdb [3], and Starbase [4], a version with added astronomical data operators by John Roll of Harvard and the Smithsonian Astrophysical Observatory. Because of its strengths in dealing with pipe data, most implementations are a mixture of awk and other programming languages, usually C or Perl.

The concept was originally described in a 1991 Unix Review article, and later expanded in a paper (see reference above), as well as in the book, "Unix Relational Database Management". NoSQL (along with other similar stream-operator databases) is well-suited to a number of fast, analytical database tasks, and has the significant advantage of keeping the tables in ASCII text form, allowing many powerful text processing tools to be used as an adjunct to the database functions themselves. Popular tools for use with NoSQL include Python, Perl, awk, and shell scripts using the ubiquitous Unix text processing tools (cut, paste, grep, sort, uniq, etc.)

NoSQL is written mostly in interpretive languages, slowing actual process execution, but its ability to use ordinary pipes and filesystems means that it can be extremely fast for many applications when using RAM filesystems or heavily leveraging pipes, which are mostly memory-based in many implementations.

Philosophy

The reasons for avoiding SQL are as follows:

1. Complexity: Most commercial database products are often too costly for minor projects, and free databases are too complex. They also do not have the shell-level approach that NoSQL has.
2. Portability:
    1. Data: The data from NoSQL can be easily ported to other types of machines, like Macintoshes or Windows computers, since tables exist as simple ASCII text and can be easily read from or redirected to files at any point in processing.
    2. Software: NoSQL can run on any UNIX machine that has the Perl and the AWK programming languages installed, and perhaps even on the Cygwin UNIX-like environment for Microsoft Windows.
3. Unlimited: NoSQL has no arbitrary limits, like a data field size, column number, or file size limit, and can principally work where other products cannot. (The number of columns in a table may actually be limited to 32,768 by some implementations of the AWK1 programming language).
4. Usability: With its straight forward and logical concept, NoSQL can easily be used by non-computer people. For instance, rows of data are selected with the 'row' operator, columns with the 'column' operator.

In contrast to other RDBMS, NoSQL has the full power of UNIX during application development and usage. Its user interface uses the UNIX shell. So, it is not necessary to learn a set of new commands to administer the database. From the view of NoSQL, the database is not more than a set of files similar to any other user file. No scripting or other type of database language is used besides the UNIX shell. This shell-nature encourages casual use of this database, which makes its use familiar, resulting in formal use. In other words, NoSQL is a set of shell routines that access normal files of the operating system.

Examples

To retrieve information about a particular employee, a query in SQL might look like this:

```
select e.*, a.*, mgr.* from EMPLOYEES e, ADDRESSES a, MANAGERS mgr
WHERE .....
```

Since a document-oriented NoSQL database often retrieves a pre-connected document representing the entire employee, the query might look like this:

```
$e = doc("/employee/emp_1234")
return $e/address/zip
```

The stream-operator paradigm differs from conventional SQL, but since the NoSQL DB is relational, it is possible to map NoSQL operators to their SQL equivalents:

SQL	NoSQL or /rdb
select col1 col2 from filename	column col1 col2 < filename
where column - expression	row 'column == expression'
compute column = expression	compute 'column = expression'
group by	subtotal
having	row
order by column	sorttable column
unique	uniq
count	wc -l

outer join	jointable -al
update	delete, replace
nesting	pipes

NoSQL

A **NoSQL** database provides a mechanism for storage and retrieval of data that is modeled in means other than the tabular relations used in relational databases. Motivations for this approach include simplicity of design, horizontal scaling and finer control over availability. The data structure (e.g., tree, graph, key-value) differs from the RDBMS, and therefore some operations are faster in NoSQL and some in RDBMS. There are differences though and the particular suitability of a given NoSQL DB depends on the problem to be solved (e.g., does the solution use tree algorithms?).

NoSQL databases are finding significant and growing industry use in big data and real-time web applications. NoSQL systems are also referred to as "Not only SQL" to emphasize that they may in fact allow SQL-like query languages to be used. In the context of the CAP theorem, NoSQL stores often compromise consistency in favor of availability and partition tolerance. Barriers to the greater adoption of NoSQL data stores in practice include: the lack of full ACID transaction support, the use of low-level query languages, the lack of standardized interfaces, and the huge investments already made in SQL by enterprises.

History

Carlo Strozzi used the term *NoSQL* in 1998 to name his lightweight, open-source relational database that did not expose the standard SQL interface. Strozzi suggests that, as the current NoSQL movement "departs from the relational model altogether; it should therefore have been called more appropriately 'NoREL'.

Eric Evans (then a Rackspace employee) reintroduced the term *NoSQL* in early 2009 when Johan Oskarsson of Last.fm wanted to organize an event to discuss open-source distributed databases. The name attempted to label the emergence of a growing number of non-relational, distributed data stores that often did not attempt to provide atomicity, consistency, isolation and durability guarantees that are key attributes of classic relational database systems.

Taxonomy

There have been various approaches to classify NoSQL databases, each with different categories and subcategories. Because of the variety of approaches and overlaps it is difficult to get and maintain an overview of non-relational databases. Nevertheless, the basic classification that most would agree on is based on data model. A few of these and their prototypes are:

- **Column**: HBase, Accumulo, Cassandra
- **Document**: MarkLogic, MongoDB, Couchbase
- **Key-value**: Dynamo, Riak, Redis, MemcacheDB, Project Voldemort
- **Graph**: Neo4J, OrientDB, Allegro, Virtuoso

Classification based on data model

Stephen Yen in his blog post "NoSQL is a Horseless Carriage" suggests the following:[1]

Term	**Matching Database**
KV Cache	Memcached, Repcached, Coherence, Hazelcast, Infinispan, eXtreme Scale, JBoss Cache, Velocity, Terracotta, GigaSpaces
KV Store	Keyspace, Flare, SchemaFree, RAMCloud
KV Store - Eventually consistent	Dynamo, Voldemort, Dynomite, SubRecord, MotionDb, DovetailDB
Data-structures server	Redis
KV Store - Ordered	TokyoTyrant, Lightcloud, NMDB, Luxio, MemcacheDB, Actord
Tuple Store	GigaSpaces, Coord, Apache River
Object Database	ZopeDB, DB4O, Shoal, Perst
Document Store	MarkLogic, CouchDB, MongoDB, Jackrabbit, XML-Databases, ThruDB, CloudKit, Persevere, Riak Basho, Scalaris
Wide Columnar Store	BigTable, HBase, Cassandra, Hypertable, KAI, OpenNeptune, Qbase, KDI

Classification based on feature

Ben Scofield categorized NoSQL databases based on nonfunctional categories ("(il)ities") plus a rating of their feature coverage: [*citation needed*]

Data Model	Performance	Scalability	Flexibility	Complexity	Functionality
Key–value Stores	high	high	high	low	variable (none)
Column Store	high	high	moderate	low	minimal
Document Store	high	variable (high)	high	low	variable (low)
Graph Database	variable	variable	high	high	graph theory
Relational Database	variable	variable	low	moderate	relational algebra

Examples

Document store

The central concept of a document store is the notion of a "document". While each document-oriented database implementation differs on the details of this definition, in general, they all assume that documents encapsulate and encode data (or information) in some standard formats or encodings. Encodings in use include XML, YAML, and JSON as well as binary forms like BSON, PDF and Microsoft Office documents (MS Word, Excel, and so on).

Different implementations offer different ways of organizing and/or grouping documents:

- Collections
- Tags
- Non-visible Metadata
- Directory hierarchies

Compared to relational databases, for example, collections could be considered as tables as well as documents could be considered as records. But they are different: every record in a table has the same sequence of fields, while documents in a collection may have fields that are completely different.

Documents are addressed in the database via a unique **key** that represents that document. One of the other defining characteristics of a document-oriented database is that, beyond the simple key-document (or key–value) lookup that you can use to retrieve a document, the database will offer an API or query language that will allow retrieval of documents based on their contents.

Name	Language	Notes
BaseX	Java, XQuery	XML database
Cloudant	Erlang, Java, Scala, C	JSON store (online service)
Clusterpoint	C++	XML, geared for Full text search
Couchbase Server	Erlang, C, C++	Support for JSON and binary documents
Apache CouchDB	Erlang	JSON database
djondb[2][3][4]	C++	JSON, ACID Document Store
Solr	Java	Search engine
ElasticSearch	Java	JSON, Search engine
eXist	Java, XQuery	XML database
Jackrabbit	Java	Java Content Repository implementation

IBM Lotus Notes and Lotus Domino	LotusScript, Java, IBM X Pages, others	MultiValue
MarkLogic Server	XQuery, Java, REST	XML database with support for JSON, text, and binaries
MongoDB	C++, C#, Go	BSON store (binary format JSON)
ObjectDatabase++	C++, C#, TScript	Binary Native C++ class structures
Oracle NoSQL Database	Java, C	
OrientDB	Java	JSON, SQL support
CoreFoundation Property list	C, C++, Objective-C	JSON, XML, binary
Sedna	XQuery, C++	XML database
SimpleDB	Erlang	online service
TokuMX	C++, C#, Go	MongoDB with Fractal Tree indexing
OpenLink Virtuoso	C++, C#, Java, SPARQL	middleware and database engine hybrid

Graph

This kind of database is designed for data whose relations are well represented as a graph (elements interconnected with an undetermined number of relations between them). The kind of data could be social relations, public transport links, road maps or network topologies, for example.

Name	**Language**	**Notes**
AllegroGraph	SPARQL	RDF GraphStore
IBM DB2	SPARQL	RDF GraphStore added in DB2 10
DEX/Sparksee	Java, C++, .NET, Python	High-performance graph database
FlockDB	Scala	
InfiniteGraph	Java	High-performance, scalable, distributed graph database
Neo4j	Java	
OpenLink Virtuoso	C++, C#, Java, SPARQL	middleware and database engine hybrid
OrientDB	Java	
Sones GraphDB	C#	
Sqrrl Enterprise	Java	Distributed, real-time graph database featuring cell-level security
OWLIM	Java, SPARQL 1.1	RDF graph store with reasoning

Key–value stores

Key–value stores allow the application to store its data in a schema-less way. The data could be stored in a datatype of a programming language or an object. Because of this, there is no need for a fixed data model. The following types exist:

KV - eventually consistent

- Apache Cassandra
- Dynamo
- Hibari
- OpenLink Virtuoso
- Project Voldemort
- Riak

KV - hierarchical

- GT.M
- InterSystems Caché

KV - cache in RAM

- memcached
- redis
- OpenLink Virtuoso
- Hazelcast
- Oracle Coherence

KV - solid state or rotating disk

- Aerospike
- BigTable
- CDB
- Couchbase Server
- Keyspace
- LevelDB
- MemcacheDB (using Berkeley DB)
- MongoDB
- OpenLink Virtuoso
- Tarantool
- Tokyo Cabinet
- Tuple space
- Oracle NoSQL Database

KV - ordered

- Berkeley DB
- FoundationDB
- IBM Informix C-ISAM
- InfinityDB
- MemcacheDB
- NDBM

Object database

- db4o
- GemStone/S
- InterSystems Caché
- JADE
- NeoDatis ODB
- ObjectDatabase++
- ObjectDB
- Objectivity/DB
- ObjectStore
- ODABA
- Perst
- OpenLink Virtuoso

- Versant Object Database
- WakandaDB
- ZODB

Tabular

- Apache Accumulo
- BigTable
- Apache Hbase
- Hypertable
- Mnesia
- OpenLink Virtuoso

Tuple store

- Apache River
- OpenLink Virtuoso
- Tarantool
- GigaSpaces

Triple/Quad Store (RDF) database

- SparkleDB
- Virtuoso Universal Server
- Ontotext-OWLIM
- Apache JENA
- Oracle NoSQL database
- MarkLogic

Hosted

- Freebase
- OpenLink Virtuoso
- Datastore on Google Appengine
- Amazon DynamoDB
- Cloudant Data Layer (CouchDB)

Multivalue databases

- Northgate Information Solutions Reality, the original Pick/MV Database
- Extensible Storage Engine (ESE/NT)
- OpenQM
- Revelation Software's OpenInsight
- Rocket U2
- D3 Pick database
- InterSystems Caché
- InfinityDB

NoSQL databases on the cloud

NoSQL databases can be run on-premises, but are also often run on IaaS or PaaS platforms like Amazon Web Services, RackSpace or Heroku. There are three common deployment models for NoSQL on the cloud:

- **Virtual machine image** - cloud platforms allow users to rent virtual machine instances for a limited time. It is possible to run a NoSQL database on these virtual machines. Users can upload their own machine image with a database installed on it, use ready-made machine images that already include an optimized installation of a database, or install the NoSQL database on a running machine instance.
- **Database as a service** - some cloud platforms offer options for using familiar NoSQL database products as a service, such as MongoDB, Redis and Cassandra, without physically launching a virtual machine instance for the database. The database is provided as a managed service, meaning that application owners do not have to install and maintain the database on their own, and pay according to usage. Some database as a service providers provide additional features, such as clustering or high availability, that are not available in the on-premise version of the database (see the table below for several examples).
- **Native cloud NoSQL databases** - some providers offer a NoSQL database service which is available only on the cloud. A well-known example is Amazon's SimpleDB, a simple NoSQL key-value store. SimpleDB cannot be installed on a local machine and cannot be used on any cloud platform except Amazon's.

The following table provides notable examples of NoSQL databases available on the cloud in each of these deployment models:

Deployment Model	**Database Technology**	**Provider**	**Cloud-Specific Features**	**Pricing Model**
Virtual machine image	MongoDB	MongoDB - machine images for Amazon EC2[5] and Windows Azure[6]	None	• Database and machine image - open source • Amazon/Azure instances - pay per use
Virtual Machine Image	Redis	• Redis - standard open source installation • Script for installation on Amazon EC2 [7] • Recommended installation on Windows Azure [8]	None	• Database and machine image - open source • Amazon/Azure instances - pay per use
Virtual machine image	Cassandra	Apache Cassandra - machine image for Amazon EC2[9]	None	• Database and machine image - open source • Amazon instances - pay per use
Database as a Service	MongoDB	MongoLab[10] - available on Amazon, Google, Joyent, Rackspace and Windows Azure	• Managed service • High availability • Automatic failover • Pre-configured clustering	• Free up to 500MB (on disk)[11] • Paid plans based on architecture and storage size
Database as a Service	Redis/Memcached	Amazon Web Services - ElastiCache[12]	• Managed service • Automatic healing of failed nodes • Resilient system to prevent overloaded DBs • Performance monitoring	• Free for 750 hours on micro instance[13] • Pay per use for machine utilization, no separate charge for data usage[14]

Database as a Service	Redis	RedisToGo[15] - available on Amazon EC2, RackSpace, Heroku, AppHarbor, Orchestra	• Managed service • Daily backups • API enabling creation, deletion, or download of Redis instances	• Free up to 5MB (memory) • Paid plans based on memory usage
Database as a Service	Redis	Redis Cloud (Redis Labs)[16] - available on Amazon EC2, Windows Azure, Heroku, Cloud Foundry, OpenShift, AppFog, AppHarbor	• Managed service • Automatic scaling, unlimited Redis nodes • High availability • Built-in clustering	• Free up to 25MB (memory)[17] • Pay per use
Database as a Service	Cassandra	Instaclustr[18] - available on Amazon EC2, RackSpace, Windows Azure, Joyent, Google Compute Engine	• Managed service • Performance tuning • Monitoring • Automated backups • DataStax OpsCenter for cluster administration	Paid plans based on disk storage, memory usage and CPU cores[19]
Native cloud NoSQL database	Amazon SimpleDB	Amazon Web Services	• Managed service • High availability • Unlimited scale • Data durability	• Free for 750 hours on micro instance[20] • Pay per use - separate charge for machine utilization and data usage
Native cloud NoSQL database	Google App Engine Datastore[21]	Google	• No planned downtime • Atomic transactions • High availability of reads and writes	• Free with quota system limiting instance hours, storage and throughput[22] • Pay per use based on instance hours, storage, throughput and other parameters
Native cloud NoSQL database	SalesForce Database.com[23]	SalesForce	• Unlimited scale • Access to SalesForce meta data • Social API • Support for mobile clients • Multi-tenancy	• Free up to 100K records and 50K transactions[24] • Pay per use based on users, number of records and transactions

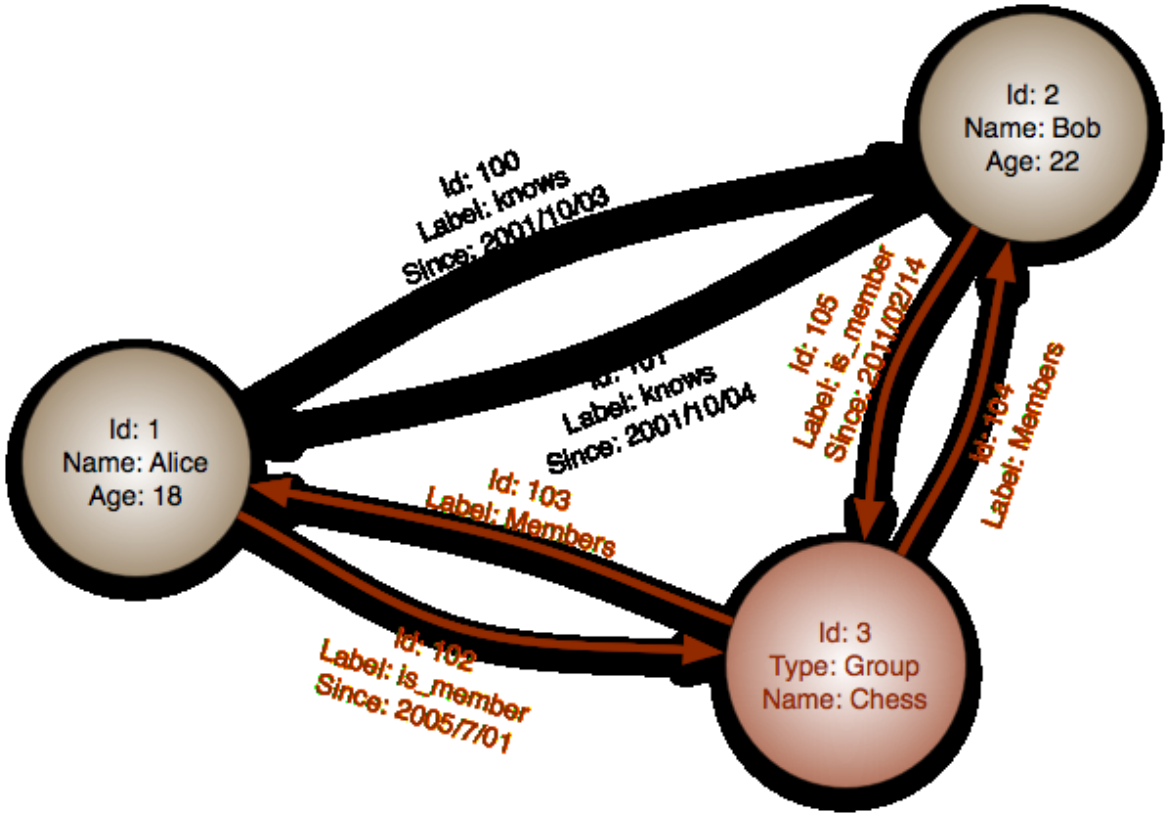
Graph database

A **graph database** is a database that uses graph structures with nodes, edges, and properties to represent and store data. A graph database is any storage system that provides index-free adjacency. This means that every element contains a direct pointer to its adjacent elements and no index lookups are necessary. General graph databases that can store any graph are distinct from specialized graph databases such as triplestores and network databases.

Structure

Graph databases are based on graph theory. Graph databases employ nodes, properties, and edges.



Nodes represent entities such as people, businesses, accounts, or any other item you might want to keep track of.

Properties are pertinent information that relate to nodes. For instance, if "Wikipedia" were one of the nodes, one might have it tied to properties such as "website", "reference material", or "word that starts with the letter 'w'", depending on which aspects of "Wikipedia" are pertinent to the particular database.

Edges are the lines that connect nodes to nodes or nodes to properties and they represent the relationship between the two. Most of the important information is really stored in the edges. Meaningful patterns emerge when one examines the connections and interconnections of nodes, properties, and edges.

Properties

Compared with relational databases, graph databases are often faster for associative data sets[*citation needed*], and map more directly to the structure of object-oriented applications. They can scale more naturally to large data sets as they do not typically require expensive join operations. As they depend less on a rigid schema, they are more suitable to manage ad hoc and changing data with evolving schemas. Conversely, relational databases are typically faster at performing the same operation on large numbers of data elements.

Graph databases are a powerful tool for graph-like queries, for example computing the shortest path between two nodes in the graph. Other graph-like queries can be performed over a graph database in a natural way (for example graph's diameter computations or community detection).

Graph database projects

The following is a list of several well-known graph database projects:[1]

Name	Version	License	Language	Description
AllegroGraph	4.11 (June 2013)	Proprietary, Clients - Eclipse Public License v1	C#, C, Common Lisp, Java, Python	A RDF and graph database.
ArangoDB [2]	2.0.0 (March 2014)	Apache 2	C, C++ & Javascript	A distributed multi-model document store and graph database. Highly scalable supporting ACID and full transaction support. Including a built-in graph explorer.
Bigdata [3]		GPL	Java	A RDF/graph database capable of clustered deployment.
Bitsy [4]	1.5.0	AGPL, Enterprise license (unlimited use, annual/perpetual)	Java	A small, embeddable, durable in-memory graph database
BrightstarDB [5]		MIT License [6]	C#	An embeddable NoSQL database for the .NET platform with code-first data model generation.
DEX/Sparksee[7]	5.0.0 (2014)	evaluation, research or development use (free) / commercial use	C++	A high-performance and scalable graph database management system from Sparsity Technologies [8], a technology transition company from DAMA-UPC [9]. Its main characteristics is its query performance for the retrieval & exploration of large networks. Sparksee 5 mobile is the first graph database for mobile devices.
Filament [10]		BSD	Java	A graph persistence framework and associated toolkits based on a navigational query style.
GraphBase [11]	1.0.03a	Proprietary	Java	A customizable, distributed, small-footprint graph store with a rich tool set from FactNexus [12].
Graphd		Proprietary		The proprietary back-end of Freebase.
Horton [13]		Proprietary	C#	A graph database from Microsoft Research Extreme Computing Group (XCG) [14] based on the cloud programming infrastructure Orleans [15].
HyperGraphDB [16]	1.2 (2012)	LGPL	Java	A graph database supporting generalized hypergraphs where edges can point to other edges.
InfiniteGraph [17]	3.0 (January 2013)	Proprietary	Java	A distributed and cloud-enabled commercial product with flexible licensing.
InfoGrid [18]	2.9.5 (2011)	AGPLv3, free for small entities[19]	Java	A graph database with web front end and configurable storage engines (MySQL, PostgreSQL, Files, Hadoop).
jCoreDB Graph [20]				An extensible database engine with a graph database subproject.

Neo4j	1.9.2 [21] (July 2013)	GPLv3 Community Edition. Commercial & AGPLv3 options for Enterprise and Advanced editions[22]	Java	A highly scalable open source graph database that supports ACID, has high-availability clustering for enterprise deployments, and comes with a web-based administration tool that includes full transaction support and visual node-link graph explorer.[23] Neo4j is accessible from most programming languages using its built-in REST web API interface. Neo4j is the most popular graph database in use today.[24]
OpenLink Virtuoso				A RDF graph database server, deployable as a local embedded instance (as used in the Nepomuk Semantic Desktop), a single-instance network server, or a shared-nothing network cluster instance.
Oracle Spatial and Graph [25]	11.2 (2012)	Proprietary	Java, PL/SQL	1) RDF Semantic Graph: comprehensive W3C RDF graph management in Oracle Database with native reasoning and triple-level label security. 2) Network Data Model property graph: for physical/logical networks with persistent storage and a Java API for in-memory graph analytics.
Oracle NoSQL Database [26]	2.0.39 (2013)	Proprietary	Java	RDF Graph for Oracle NoSQL Database is a feature of Enterprise Edition providing W3C RDF graph capabilities in NoSQL Database.
OrientDB	1.6.1 (November 2013)	Apache 2	Java	A distributed Graph Database with a hybrid model taken from Document Database.
OQGRAPH [27]		GPLv2		A graph computation engine for MySQL, MariaDB and Drizzle.
Ontotext OWLIM [28]	5.3	OWLIM Lite is free OWLIM SE and Enterprise are commercially licenced	Java	A graph database engine, based entirely on Semantic Web standards from W3C: RDF, RDFS, OWL, SPARQL. OWLIM Lite is an "in memory" engine. OWLIM SE is robust standalone database engine. OWLIM Enterprise is a clustered version which offers horizontal scalability and failover support and other enterprise features.
R2DF [29]				R2DF framework for ranked path queries over weighted RDF graphs.
ROIS [30]		Freeware	Modula-2	A programmable knowledge server that supports inheritance and transitivity. Used in OpenGALEN as a Terminology Server.
sones GraphDB		AGPLv3[31]	C#	A graph database and universal access layer (funded by Deutsche Telekom).
Sqrrl Enterprise [32]	v1.1 (2013)	Proprietary	Java	Distributed, real-time graph database featuring cell-level security and massive scalability.
Teradata Aster [33]	v6 (2013)	Proprietary	Java, SQL, Python, C++, R	A high performance, multi-purpose, highly scalable and extensible MPP database incorporating patented engines supporting native SQL, MapReduce and Graph data storage and manipulation. An extensive set of analytical function libraries and data visualization capabilities are also provided.
Titan [34]	0.4.1 (2013)	Apache 2	Java	A distributed, real-time, transactional graph database developed by Aurelius [35].
Trinity [36]			C#, C, X64 Assembly	A distributed general purpose graph engine on a memory cloud.
VelocityGraph [37]		Open source with proprietary back-end	C#	High performance, scalable & flexible graph database build with VelocityDB [38] object database.
VertexDB [39]		Revised BSD	C	A graph database server that supports automatic garbage collection.

WhiteDB [40]	0.7.0 (October 2013)	GPLv3 and a free commercial licence	C	A graph/N-tuples shared memory database library.

Graph database features

The following table compares the features of the above graph databases.

Name	Graph Model	API	Query Methods	Visualizer	Consistency	Backend	Scalability
AllegroGraph	RDF	Java, Java:Sesame, JavaJena, Python, Ruby, Perl, C#, Clojure, Lisp, Scala, REST	SPARQL 1.1, Prolog, JIG, JavaScript	Gruff - View Graphs, Visual Query Builder for SPARQL and Prolog	ACID	Native Graph Storage	1 Trillion RDF triples
ArangoDB [2]	Property Graph [41]	JavaScript, Blueprints, REST	Graph Traversals via JavaScript, Gremlin	Built-in graph explorer	MVCC/ACID	native C/C++	Replication and Sharding
Bigdata [3]							
Bitsy [4]	Property Graph	Blueprints	Gremlin, Pixy [42]		ACID with optimistic concurrency control	Human-readable JSON-encoded text files with checksums and markers for recovery	
DEX/Sparksee[43]	Labeled and directed attributed multigraph	Java, C++, .NET, Python	Native Java, C#, Python and C++ APIs, Blueprints, Gremlin	Exporting functionality to visualization formats	Consistency, durability and partial isolation and atomicity	Native graph. light and independent data structures with a small memory footprint for storage	Master/Slave replication
Filament [10]							
GraphBase Enterprise(1) [44] GraphBase Agility(2) [45]	(1) mixed, (2) Framework-managed Simple Graph	Java	Bounds Language, embedded java	GraphPad, BoundsPad, Navigator	ACID, graph-based transactions	proprietary native	(1) shared nothing distributed, (2) simple replication, 100+ Billion arcs per server
Graphd							
Horton [13]	Attributed multigraph		Horton Query Language (Regular Language Expression + SQL)			C#, .Net Framework, Asynchronous communication protocols	

HyperGraphDB [16]	Object-oriented multi-relational labeled hypergraph	Custom,Java			MVCC/STM		
InfiniteGraph [17]	Labeled and directed multi-property graph	Java, Blueprints (Read Only)	Java (with parallel, distributed queries), Gremlin (Read Only)	Graph browser for developers. Plugins to allow use of external libraries.	ACID. There is also a parallel, loosely synchronized batch loader.	Objectivity/DB on standard filesystems	Distributed & Sharded. Objectivity/DB was the first DBMS to store a Petabyte of objects.
InfoGrid [18]	Dynamically typed, object-oriented graph, multigraphs, semantic models						
jCoreDB Graph [20]							
Neo4j	Property Graph	Java, Python, JPython, Ruby, JRuby, JavaScript (Node.js), PHP, .NET, Django, Clojure, Spring, Scala, or REST (any language)	Cypher (native/preferred), Native Java APIs (special cases), Traverser API, REST, Blueprints, Gremlin	Data Browser included. Supports a variety of 3rd party tools: Gephi, Linkurio.us, Cytoscape, Tom Sawyer, Keylines, etc.	ACID	Native graph storage with native graph processing engine	Horizontal read scaling via master-slave clustering with cache sharding.
OpenLink							
Oracle Spatial and Graph [25]	RDF graph: Triple & Quad (named graphs); Network Data Model property graph	Java; Apache Jena; PL/SQL	SPARQL 1.1; SPARQL web service end point; SQL	SPARQL-compliant tools; Apache Jena-based tools; XML & JSON-based tools; SQL based tools	ACID	Efficient, compressed, partitioned graph storage; Native persisted in-database inferencing; SPARQL 1.1 & SQL integration; Triple-level label security; Semantic indexing of documents	Parallel load, query, inference; Query controls; Scales from PC to Oracle Exadata; Supports Oracle Real Application Clusters and Oracle Database 8 exabytes
Oracle NoSQL Database [26]	RDF graph: Triple default graph, Triple & Quad named graphs	Java (Apache Jena)	SPARQL 1.1; SPARQL web service end point	SPARQL-compliant tools; Apache Jena-based tools; XML & JSON-based tools	ACID; Configurable consistency & durability policies	Key/value store; W3C SPARQL 1.1 & Update; In-memory RDFS/OWL inferencing	Parallel load/query; Query controls for: parallel execution, timeout, query optimization hints

OrientDB	Property Graph	Java Traverser API, Blueprints, Rexster, Javacript[46]	Own SQL-like Query Language, Gremlin		ACID, MVCC	Custom on disc or in memory	
OQGRAPH [27]							
R2DF [29]							
ROIS [30]							
sones GraphDB							
Sqrrl Enterprise [47]	Property Graph	Thrift, Blueprint	Own SQL-like query language and Java API	Integrates with 3rd party tools	Fully Consistent and ACID (transactions limited to a single node)	Accumulo	Distributed cluster with tens of trillions of edges [48]
Titan [49]	Property Graph	Java, Blueprints, REST, RexPro binary protocol, Python, Clojure (any language)	Gremlin, SPARQL	Integrates with 3rd party tools	ACID or Eventually Consistent	Cassandra, HBase, MapR M7 Tables, Berkeley DB, Persistit, Hazelcast	Distributed cluster (120 billion+ edges) or single server.
Trinity [36]	Cell Based Graph Model [50]	C#	Trinity Query Language		Cell level Atomicity [50]	Native graph store and processing engine	billion node in-memory graph
VertexDB [39]							

Distributed Graph Processing

- Angrapa [51] - graph package in Hama [52], a bulk synchronous parallel (BSP) platform
- Apache Hama [52] - a pure BSP(Bulk Synchronous Parallel) computing framework on top of HDFS (Hadoop Distributed File System) for massive scientific computations such as matrix, graph and network algorithms.
- Bigdata [3] - a RDF/graph database capable of clustered deployment.
- Faunus [53] - a Hadoop-based graph computing framework that uses Gremlin as its query language. Faunus provides connectivity to Titan, Rexster-fronted graph databases, and to text/binary graph formats stored in HDFS. Faunus is developed by Aurelius [35].
- FlockDB - an open source distributed, fault-tolerant graph database based on MySQL and the Gizzard framework for managing Twitter-like graph data (single-hop relationships) FlockDB on GitHub [54].
- Giraph [55] - a Graph processing infrastructure that runs on Hadoop (see Pregel).
- GraphBase [56] - Enterprise Edition supports embedding of callable Java Agents within the vertices of a distributed graph.
- GoldenOrb [57] - Pregel implementation built on top of Apache Hadoop
- GraphLab [58] - A framework for machine learning and data mining in the cloud

- GraphX [59] - GraphLab built on the Spark [60] cluster computing system. Dr. Joseph Gonzalez is the project lead, the creator of GraphLab.
- HipG [61] - a library for high-level parallel processing of large-scale graphs. HipG is implemented in Java and is designed for distributed-memory machine
- InfiniteGraph [17] - a commercially available distributed graph database that supports parallel load and parallel queries.
- JPregel [62] - In-memory java based Pregel implementation
- KDT [63] - An open-source distributed graph library with a Python front-end and C++/MPI backend (Combinatorial BLAS [64]).
- OpenLink Virtuoso - the shared-nothing Cluster Edition supports distributed graph data processing.
- Oracle Spatial and Graph [25] - loading, inferencing, and querying workloads are automatically and transparently distributed across the nodes in an Oracle Real Application Cluster, Oracle Exadata Database Machine, and Oracle Database Appliance.
- Phoebus [65] - Pregel implementation written in Erlang
- Pregel [66] - Google's internal graph processing platform, released details in ACM paper.
- Powergraph [67] - Distributed graph-parallel computation on natural graphs.
- PowerLyra [68] - differentiated graph computation and partitioning on skewed graphs (dynamically applying different computation and partition strategies for different vertices).
- Sedge [69] - A framework for distributed large graph processing and graph partition management (including an open source version of Google's Pregel)
- Signal/Collect [70] - a framework for parallel graph processing written in Scala
- Sqrrl Enterprise - distributed graph processing utilizing Apache Accumulo and featuring cell-level security, massive scalability, and JSON support
- Titan [49] - A distributed, disk-based graph database developed by Aurelius [35].
- Trinity [71] - Distributed in-memory graph engine under development at Microsoft Research Labs.
- Parallel Boost Graph Library (PBGL) [72] - a C++ library for graph processing on distributed machines, part of Boost framework.
- Mizan [73] - An optimized Pregel clone that can be deployed easily on Amazon EC2, local clusters, stand-alone Linux systems and supercomputers (IBM BlueGene/P). It utilizes runtime graph repartitioning between iterations to provide dynamic load balancing for better algorithm performance.[74]

APIs and Graph Query/Programming Languages

- Bounds Language [75] - terse C-style syntax which initiates concurrent traversals in GraphBase and supports interaction between them.
- Blueprints [76] - a Java API for Property Graphs from TinkerPop [77] and supported by a few graph database vendors.
- Blueprints.NET [78] - a C#/.NET API for generic Property Graphs.
- Bulbflow [79] - a Python persistence framework for Rexster, Titan, and Neo4j Server.
- Cypher Query Language [80] - a declarative graph query language for Neo4j that enables ad hoc as well as programmatic (SQL-like) access to the graph
- Gremlin [81] - an open-source graph programming language that works over various graph database systems.
- Neo4jClient [82] - a .NET client for accessing Neo4j.
- Neography [83] - a thin Ruby wrapper that provides access to Neo4j via REST.
- Neo4jPHP [84] - a PHP library wrapping the Neo4j graph database.
- NodeNeo4j [85] - a Node.js driver for Neo4j that provides access to Neo4j via REST
- Pacer [86] - a Ruby dialect/implementation of the Gremlin graph traversal language.

- Pipes [87] - a lazy dataflow framework written in Java that forms the foundation for various property graph traversal languages.
- Pixy [42] - a declarative graph query language that works on any Blueprints-compatible graph database
- PYBlueprints [88] - a Python API for Property Graphs.
- Pygr [89] - a Python API for large-scale analysis of biological sequences and genomes, with alignments represented as graphs.
- Rexster [90] - a graph database server that provides a REST or binary protocol API (RexPro). Supports Titan, Neo4j, OrientDB, Dex, and any TinkerPop/Blueprints-enabled graph.
- SPARQL - a query language for databases, able to retrieve and manipulate data stored in Resource Description Framework format.
- SPASQL [91] - an extension of the SQL standard, allowing execution of SPARQL queries within SQL statements, typically by treating them as subquery or function clauses. This also allows SPARQL queries to be issued through "traditional" data access APIs (ODBC, JDBC, OLE DB, ADO.NET, etc.)
- Spring Data Neo4j [92] - an extension to Spring Data [93] (part of the Spring Framework), providing direct/native access to Neo4j
- Oracle SQL and PL/SQL APIs [25] - have graph extensions for Oracle Spatial and Graph.
- Styx [94] (previously named Pipes.Net) - a data flow framework for C#/.NET for processing generic graphs and Property Graphs.
- Thunderdome [95] - a Titan Rexster Object-Graph Mapper for Python

DEX (Graph database)

DEX

Developer(s)	Sparsity Technologies [1]
Initial release	2008
Stable release	v5.0 / 2013
Development status	Active
Operating system	Cross-platform
Type	Graph Database
License	Dual-licensed: personal evaluation use / commercial use
Website	Sparsity-Technologies: DEX [2]

DEX is a high-performance and scalable graph database management system written in C++.

Its development started on 2006 and its first version was available on Q3 - 2008. Fourth version is available since Q3-2010. There's a free community version, for academic or evaluation purposes, available to download (link web) limited to 1 Million nodes, no limit on edges.

DEX is a product originated by the research carried out at DAMA-UPC (Data Management group at the Polytechnic University of Catalonia). On March 2010 a spin-off called **Sparsity-Technologies** has been created at the UPC to commercialize and give services to the technologies developed at DAMA-UPC.

DEX changed name to Sparksee [3] on its 5th release on February 2014.

Graph Model [4]

DEX is based on a graph database model,[5] that is basically characterized by three properties: data structures are graphs or any other structure similar to a graph; data manipulation and queries are based on graph-oriented operations; and there are data constraints to guarantee the integrity of the data and its relationships.

A DEX graph is a Labeled Directed Attributed Multigraph. Labeled because nodes and edges in a graph belong to types. Directed because it supports directed edges as well as undirected. Attributed because both nodes and edges may have attributes and Multigraph meaning that there may be multiple edges between the same nodes even if they are from the same edge type.

One of its main characteristics is its performance storage and retrieval for large graphs (in the order of billions of nodes, edges and attributes) implemented with specialized structures.

Technical Details

- Programming Language: C++
- API: Java, .NET, C++, Python
- OS Compatibility: Windows, Linux, Mac OS, iOS, BB10
- Persistency: Disk
- Transactions: aCiD (Dex guarantees consistency and durability but only partial isolation and atomicity)
- Recovery Manager

Neo4j

Neo4j

Developer(s)	Neo Technology
Initial release	2007
Written in	Java
Operating system	Cross-platform
Type	Graph database
License	Dual-licensed: GPLv3 and AGPLv3 / commercial
Website	neo4j.org [1]

Neo4j is an open-source graph database, implemented in Java. The developers describe Neo4j as "embedded, disk-based, fully transactional Java persistence engine that stores data structured in graphs rather than in tables". Neo4j is the most popular graph database.

Neo4j version 1.0 was released in February, 2010. The community edition of the database is licensed under the free GNU General Public License (GPL) v3. The additional modules, such as online backup and high availability, are licensed under the free Affero General Public License (AGPL) v3. The database, with the additional modules, is also available under a commercial license, in a dual license model.

Neo4j version 2.0 was released in December, 2013.

Neo4j was developed by Neo Technology, Inc., based in the San Francisco Bay Area, US and Malmö, Sweden. Neo Technology board of directors consists of Rod Johnson, (founder of the Spring Framework), Magnus Christerson (Vice President of Intentional Software Corp), Nikolaj Nyholm (CEO of Polar Rose), Sami Ahvenniemi (Partner at Conor Venture Partners) and Johan Svensson (CTO of Neo Technology).

Sones GraphDB

GraphDB

Developer(s)	sones GmbH
Stable release	2.0 / May 11, 2011
Operating system	Cross-platform
Available in	English, German
Type	Database
License	Dual licensing: Community Edition is AGPLv3, Enterprise Edition is commercial & proprietary
Website	sones.de [1]

Sones GraphDB was declared bankrupt in Germany on January 1, 2012.

Sones GraphDB was developed by the company *sones* in Erfurt and Leipzig. *GraphDB* is a new type of database with its design based on weighted graphs. The open source edition has been available since July 2010.[2] The commercially available enterprise version offers a wider variety of functions.

GraphDB was entirely developed in C# and runs on Microsoft's .NET platform as well as on the open source reimplementation Mono.[3][4]

GraphDB is available as SaaS on the Microsoft cloud Azure Services Platform.[5]

The company *sones* is a member of Lisog; *GraphDB* is a component of an open source solution stack.

Functionality

Index-free adjacency

Graph databases like the sones GraphDB address the paradigm of the index-free adjacency. That means that is not necessary to manage a global index for relationships between nodes/entities. The linked objects contain direct reference to their adjacent neighboring nodes.

Handling semi-structured data

The semi-structured data approach was established in the mid-90s. This approach is based on the fact that many application areas rarely allow a structured table structure due to complex information characteristics. An example of such problem domains can be found in bioinformatics or the Semantic Web. The sones graph database is able to store and retrieve unstructured properties in any node of the graph. The idea is also to transfer unstructured data to structured data and vice versa.

Dynamic type extension

Another advantage is that structured data can be dynamically extended with high performance in nodes and edges during runtime. Additional properties can easily be entered or deleted from vertex types in a short amount of time. The number of nodes is irrelevant here.

Graph query language

The sones GraphQL is a user-friendly domain-specific language and can be thought of as an "SQL for graphs." The similarity to SQL is intentional and makes the transition much easier for developers/consultants. It enables queries to the sones graph database property hypergraph and can be dynamically extended during runtime using plugins such as functions or aggregates.

Solving the object-relational depiction problem

sones GraphDB solves this problem by using an object-oriented concept. This results in better integration into object-oriented languages, since no O/R mapper is required.

Interfaces

REST API

In addition to providing a number of interfaces (e.g., Java, C#, WebShell, WebDAV) the *sones* graph database also offers a REST API. This enables uncomplicated interaction with state-of-the-art web technologies. A REST-query is all that is required to execute CRUD operations directly on the database.

Traverser API

The Traverser API makes it possible to analyze local data. Based on a number of nodes (local), neighboring nodes can be searched recursively (breadth/depth first).

Architecture

The *sones GraphDB* has a modular structure consisting of 4 application layers. The storage engines act as the interface to different storage media. The *GraphFS* serializes and deserializes database objects (nodes and edges) and operates the available storage engines. The actual graph-oriented database logic as well as all functionalities specific to the database are implemented in the *GraphDB*. The *GraphDS* provides the interface for using the database. The interfaces between the application layers are generic, which makes it possible to update components separately.

Apache Cassandra

Apache Cassandra

Original author(s)	Avinash Lakshman, Prashant Malik
Developer(s)	Apache Software Foundation, DataStax
Initial release	2008
Stable release	2.0.6 / March 10, 2014
Development status	Active
Written in	Java
Operating system	Cross-platform
Available in	English
Type	Database
License	Apache License 2.0
Website	cassandra.apache.org [1]

Apache Cassandra is an open source distributed database management system designed to handle large amounts of data across many commodity servers, providing high availability with no single point of failure. Cassandra offers robust support for clusters spanning multiple datacenters, with asynchronous masterless replication allowing low latency operations for all clients.

Cassandra also places a high value on performance. University of Toronto researchers studying NoSQL systems concluded that "In terms of scalability, there is a clear winner throughout our experiments. Cassandra achieves the highest throughput for the maximum number of nodes in all experiments."

Cassandra's data model is a partitioned row store with tunable consistency. Rows are organized into tables; the first component of a table's primary key is the partition key; within a partition, rows are clustered by the remaining columns of the key. Other columns may be indexed separately from the primary key.

Tables may be created, dropped, and altered at runtime without blocking updates and queries.

Cassandra does not support joins or subqueries, except for batch analysis via Hadoop. Rather, Cassandra emphasizes denormalization through features like collections.

History

Apache Cassandra was developed at Facebook to power their Inbox Search feature by Avinash Lakshman (one of the authors of Amazon's Dynamo) and Prashant Malik. It was released as an open source project on Google code in July 2008. In March 2009, it became an Apache Incubator project. On February 17, 2010 it graduated to a top-level project.

Releases after graduation include

- 0.6, released Apr 12 2010, added support for integrated caching, and Apache Hadoop MapReduce[2]
- 0.7, released Jan 08 2011, added secondary indexes and online schema changes[3]
- 0.8, released Jun 2 2011, added the Cassandra Query Language (CQL), self-tuning memtables, and support for zero-downtime upgrades[4]
- 1.0, released Oct 17 2011, added integrated compression, leveled compaction, and improved read performance[5]
- 1.1, released Apr 23 2012, added self-tuning caches, row-level isolation, and support for mixed ssd/spinning disk deployments[6]
- 1.2, released Jan 2 2013, added clustering across virtual nodes, inter-node communication, atomic batches, and request tracing[7]
- 2.0, released Sep 4 2013, added lightweight transactions, triggers, improved compactions
- 2.0.4, released Dec 30 2013, added allowing specifying datacenters to participate in a repair, client encryption support to sstableloader, allow removing snapshots of no-longer-existing CFs[8]

Licensing and support

Apache Cassandra is an Apache Software Foundation project, so it has an Apache License (version 2.0).

Main features

Decentralized

> Every node in the cluster has the same role. There is **no single point of failure**. Data is distributed across the cluster (so each node contains different data), but there is no master as every node can service any request.

Supports replication and multi data center replication

> Replication strategies are configurable.[9] Cassandra is designed as a distributed system, for deployment of large numbers of nodes across multiple data centers. Key features of Cassandra's distributed architecture are specifically tailored for multiple-data center deployment, for redundancy, for failover and disaster recovery.

Scalability

> Read and write throughput both increase linearly as new machines are added, with no downtime or interruption to applications.

Fault-tolerant

> Data is automatically replicated to multiple nodes for fault-tolerance. Replication across multiple data centers is supported. Failed nodes can be replaced with no downtime.

Tunable consistency

> Writes and reads offer a tunable level of consistency, all the way from "writes never fail" to "block for all replicas to be readable", with the quorum level in the middle.

MapReduce support

> Cassandra has Hadoop integration, with MapReduce support. There is support also for Apache Pig and Apache Hive.[10]

Query language

CQL (Cassandra Query Language) was introduced, a SQL-like alternative to the traditional RPC interface. Language drivers are available for **Java** (JDBC), **Python** (DBAPI2) and **Node.JS** (Helenus).

Data model

Cassandra is essentially a hybrid between a key-value and a column-oriented (or tabular) database.

A column family resembles a table in an RDBMS. Column families contain rows and columns. Each row is uniquely identified by a row key. Each row has multiple columns, each of which has a name, value, and a timestamp. Unlike a table in an RDBMS, different rows in the same column family do not have to share the same set of columns, and a column may be added to one or multiple rows at any time.

Each key in Cassandra corresponds to a value which is an object. Each key has values as columns, and columns are grouped together into sets called column families.

Thus, each key identifies a row of a variable number of elements. These column families could be considered then as tables. A table in Cassandra is a distributed multi dimensional map indexed by a key.

Furthermore, applications can specify the sort order of columns within a Super Column or Simple Column family.

Clustering

When the cluster for Apache Cassandra is designed, an important point is to select the right partitioner. Two partitioners exist:

1. RandomPartitioner (RP): This partitioner randomly distributes the key-value pairs over the network, resulting in a good load balancing. Compared to OPP, more nodes have to be accessed to get a number of keys.
2. OrderPreservingPartitioner (OPP): This partitioner distributes the key-value pairs in a natural way so that similar keys are not far away. The advantage is that fewer nodes have to be accessed. The drawback is the uneven distribution of the key-value pairs.

Prominent users

- Apixio uses Cassandra to store its Patient Object Model and extracted features about patients and patient populations
- AppScale uses Cassandra as a back-end for Google App Engine applications
- Cisco's WebEx uses Cassandra to store user feed and activity in near real time.
- The CERN ATLAS experiment uses Cassandra to archive its online DAQ system's monitoring information
- Cloudkick uses Cassandra to store the server metrics of their users.[11]
- Constant Contact uses Cassandra in their email and social media marketing applications. Over 200 nodes are deployed.
- Digg, a large social news website, announced on Sep 9th, 2009 that it is rolling out its use of Cassandra and confirmed this on March 8, 2010. TechCrunch has since linked Cassandra to Digg v4 reliability criticisms and recent company struggles. Lead engineers at Digg later rebuked these criticisms as red herring and blamed a lack of load testing.
- Facebook used Cassandra to power Inbox Search, with over 200 nodes deployed. This was abandoned in late 2010 when they built Facebook Messaging platform on HBase.
- IBM has done research in building a scalable email system based on Cassandra.
- InWorldz has researched and developed a scalable high-performance storage system for user inventory items Cassandra.
- Netflix uses Cassandra as their back-end database for their streaming services[12]
- Formspring uses Cassandra to count responses, as well as store Social Graph data (followers, following, blockers, blocking) for 26 Million accounts with 10 million responses a day

- Mahalo.com uses Cassandra to record user activity logs and topics for their Q&A website[13]
- Ooyala Built a scalable, flexible, real-time analytics engine using Cassandra[14]
- At Openwave, Cassandra acts as a distributed database and serves as a distributed storage mechanism for Openwave's next generation messaging platform[15]
- OpenX is running over 130 nodes on Cassandra for their OpenX Enterprise product to store and replicate advertisements and targeting data for ad delivery[16]
- Plaxo has "reviewed 3 billion contacts in [their] database, compared them with publicly available data sources, and identified approximately 600 million unique people with contact info."
- PostRank uses Cassandra as their backend database
- Rackspace is known to use Cassandra internally.
- Reddit switched to Cassandra from memcacheDB on March 12, 2010 and experienced some problems in May due to insufficient nodes in their cluster.
- RockYou uses Cassandra to record every single click for 50 million Monthly Active Users in real-time for their online games
- SoundCloud uses Cassandra to store the dashboard of their users
- Talentica Software uses Cassandra as a back-end for Analytics Application with Cassandra cluster of 30 nodes and inserting around 200GB data on daily basis.[17]
- Twitter announced it is planning to use Cassandra because it can be run on large server clusters and is capable of taking in very large amounts of data at a time. Twitter continues to use it but not for Tweets themselves.
- Urban Airship uses Cassandra with the mobile service hosting for over 160 million application installs across 80 million unique devices
- @WalmartLabs[18] (previously Kosmix) uses Cassandra with SSD
- Yakaz uses Cassandra on a five-node cluster to store millions of images as well as its social data.
- ZangBeZang uses Cassandra as the datastore for its carrier grade recommendation and marketing platform.
- Zoho uses Cassandra for generating the inbox preview in their Zoho#Zoho Mail service

Ironically, Facebook moved off its pre-Apache Cassandra deployment in late 2010 when they replaced Inbox Search with the Facebook Messaging platform. In 2012, Facebook began using Apache Cassandra in its Instagram unit.

Cassandra is the most popular wide column store.

Triplestore

A **triplestore** is a purpose-built database for the storage and retrieval of triples,[1] a triple being a data entity composed of subject-predicate-object, like "Bob is 35" or "Bob knows Fred".

Much like a relational database, one stores information in a triplestore and retrieves it via a query language. Unlike a relational database, a triplestore is optimized for the storage and retrieval of triples. In addition to queries, triples can usually be imported/exported using Resource Description Framework (RDF) and other formats.

Some triplestores can store billions of triples.

Implementation

Some triplestores have been built as database engines from scratch, while others have been built on top of existing commercial relational database engines (i.e. SQL-based).[2] Like the early development of online analytical processing (OLAP) databases, this intermediate approach allowed large and powerful database engines to be constructed for little programming effort in the initial phases of triplestore development. Long-term though it seems likely that native triplestores will have the advantage for performance. A difficulty with implementing triplestores over SQL is that although *triples* may thus be *stored*, implementing efficient querying of a graph-based RDF model (i.e. mapping from SPARQL) onto SQL queries is difficult.

List of implementations

Technical overview

The following table is an overview of available triplestores, their technical implementation, support for the SPARQL World Wide Web Consortium (W3C) recommendations, and available application programming interfaces (API).

Solution Name	Native storage	Native SPARQL support	Native SPARQL/Update support	Native SPARQL Protocol Endpoint	Native APIs
4store	Triplestore	√	√	√	Command line only
AllegroGraph	Graph	√	√	√	For most modern programming languages
ARC2	3rd party	√	√	√	PHP
ARQ	3rd party	√	√		Java
BigData	Triplestore	√	√	√	Java
BrightstarDB	Graph data model in Heap file	√			.NET Framework or Web Service
Corese	3rd party	√			Java
D2R Server	3rd party	√	√	√	Java
Dydra	Graph database in the cloud SaaS	√	√	√	REST API
Hercules	Stored in web browser	√			JavaScript
IBM DB2	Object-relational				Java
Intellidimension Semantics Platform 2.0	3rd party	√			.NET Framework
Jena	Tuple store	√	√	√	Java
KAON2	3rd party	√			Java
SparkleDB	Triplestore / Quadstore	√	√	√	For most modern programming languages
MarkLogic	Triplestore / Quadstore	√		√	REST API, SPARQL Endpoint, Graph Protocol Endpoint, Java API, XQuery, SQL/ODBC
Mulgara	3rd party	√			Java or REST API
OntoBroker	Triplestore	√	√	√	Java
OntoQuad RDF Server	Triplestore / Quadstore	√	√	√	Java, SPARQL Endpoint or REST API
Ontotext OWLIM	3rd party	√	√	√	Java
Open Anzo	3rd party	√		√	Java, JavaScript, .NET Framework

OpenLink Virtuoso	Hybrid (Relational Tables and Relational Property Graphs)	√	√	√	ODBC, JDBC, ADO.NET, OLE DB, XMLA, HTTP, etc., serving most modern programming languages including C, PHP, Perl, Python, Ruby, Java, JavaScript, .NET Framework, etc.
Oracle DB Enterprise Ed.	Object-relational				For most modern programming languages
Parliament	3rd party	√	√	√	Java or C++
Pellet	3rd party	√			Java
Pointrel	Triplestore				Python
Profium Sense	In-memory triplestore	√		√	Java
RAP	In-memory triplestore or heap file	√			PHP
RDF API for PHP	3rd party	√			PHP
RDF::Query	3rd party	√	√	√	Perl
RDF-3X	Triplestore	√			Command line only
RDFBroker	3rd party				Java
Redland, Redstore	3rd party	√	√	√	C
SemWeb.NET	3rd party	√		√	.NET Framework
Sesame	3rd party	√	√	√	Java
Soprano	3rd party				C++
SPARQL Engine	3rd party	√			Java
Stardog	Triplestore	√	√	√	Java, Groovy
StrixDB	Triplestore	√	√	√	Lua
Twinql	3rd party	√			Lisp
YARS	3rd party				HTTP, JDBC

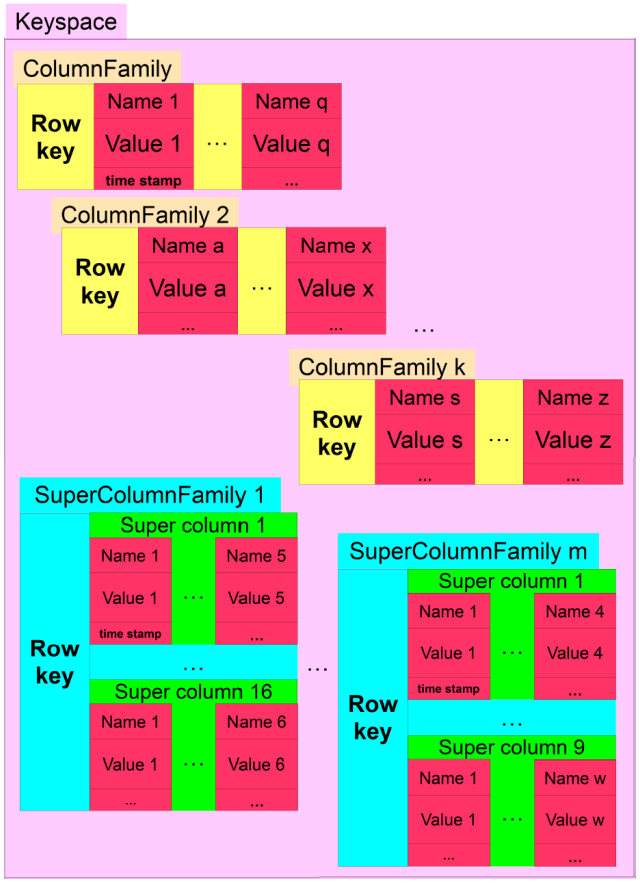
Keyspace (distributed data store)

A **key space** (or **keyspace**) in a NoSQL data store is an object that holds together all column families of a design. It is the outer most grouping of the data in the data store. It resembles to the schema concept in Relational database management systems. Generally, there is one keyspace per application.



A keyspace example with a number of column families.

Structure

A keyspace may contain column families or super columns. Each super column contains one or more column family, each column family at least one column. The keyspace is the highest abstraction in a distributed data store.

Comparison with relational database systems

The keyspace has similar importance like a schema has in a database. In contrast to the schema, however, it does not stipulate any concrete structure, like it is known in the entity-relationship model used widely in the relational data models. For instance, the contents of the keyspace can be column families, each having different number of columns, or even different columns. So, the column families that somehow relate to the row concept in relational databases do not stipulate any fixed structure. The only point that is the same with a schema is that it also contains a number of "objects", which are tables in RDBMS systems and here column families or super columns.

So, in distributed data stores, the whole burden to handle rows that may even change from data-store update to update lies on the shoulders of the programmers.

Examples

As an example, we show a number of column families in a keyspace. The `CompareWith` keyword defines how the column comparison is made. In the example, the UTF8 standard has been selected. Other ways of comparison exist, such as `AsciiType`, `BytesType`, `LongType`, `TimeUUIDType`.

```
<Keyspace Name="DeliciousClone">
  <KeysCachedFraction>0.01</KeysCachedFraction>
  <ColumnFamily CompareWith="UTF8Type" Name="Users"/>
  <ColumnFamily CompareWith="UTF8Type" Name="Bookmarks"/>
  <ColumnFamily CompareWith="UTF8Type" Name="Tags"/>
  <ColumnFamily CompareWith="UTF8Type" Name="UserTags"/>
  <ColumnFamily CompareWith="UTF8Type" CompareSubcolumnsWith="TimeUUIDType" ColumnType="Super" Name="UserBookmarks"/>
</Keyspace>
```

Another example shows a simplified Twitter clone data model:

```
<Keyspace Name="TwitterClone">
  <KeysCachedFraction>0.01</KeysCachedFraction>
  <ColumnFamily CompareWith="UTF8Type" Name="Users" />
  <ColumnFamily CompareWith="UTF8Type" Name="UserAudits" />
  <ColumnFamily CompareWith="UTF8Type" CompareSubcolumnsWith="TimeUUIDType" ColumnType="Super" Name="UserRelationships" />
  <ColumnFamily CompareWith="UTF8Type" Name="Usernames" />
  <ColumnFamily CompareWith="UTF8Type" Name="Statuses" />
  <ColumnFamily CompareWith="UTF8Type" Name="StatusAudits" />
  <ColumnFamily CompareWith="UTF8Type" CompareSubcolumnsWith="TimeUUIDType" ColumnType="Super" Name="StatusRelationships" />

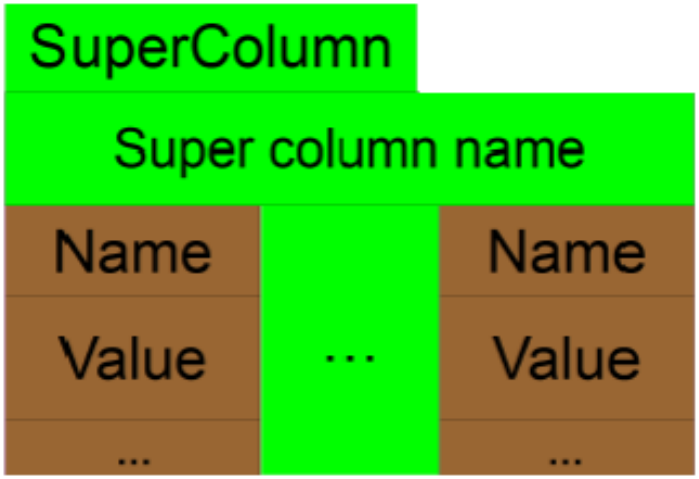
Super column

A **super column** is a tuple (a pair) with a binary super column name and a value that maps it to many columns. They consist of a key-value pairs, where the values are columns. Theoretically speaking, super columns are (sorted) associative array of columns. Similar to a regular column family where a row is a sorted map of column names and column values, a row in a super column family is a sorted map of super column names that maps to column names and column values.

A super column is part of a keyspace (data model) together with other super columns and column families, and columns.



The super column consists of a (unique) super column name, and a number of columns.

Code example

Written in the JSON-like syntax, a super column definition can be like this:

```
 {
   "mccv": {
     "Tags": {
       "cassandra": {
         "incubator": {"url":
"http://incubator.apache.org/cassandra/"},
```

```
          "jira": {"url":
"http://issues.apache.org/jira/browse/CASSANDRA"}
        },
        "thrift": {
          "jira": {"url": "http://issues.apache.org/jira/browse/THRIFT"}
        }
      }
    }
 }
```

BigTable

BigTable is a compressed, high performance, and proprietary data storage system built on Google File System, Chubby Lock Service, SSTable (log-structured storage like LevelDB) and a few other Google technologies. It is not distributed outside Google, although Google offers access to it as part of its Google App Engine.

History

BigTable development began in 2004 and is now used by a number of Google applications, such as web indexing, MapReduce, which is often used for generating and modifying data stored in BigTable,[1] Google Maps, Google Book Search, "My Search History", Google Earth, Blogger.com, Google Code hosting, Orkut, YouTube, and Gmail. Google's reasons for developing its own database include scalability and better control of performance characteristics.[2]

Google's Spanner RDBMS is layered on an implementation of BigTable with a Paxos group for two-phase commits to each tablet. Google F1 was built using Spanner to replace an implementation based on MySQL.

Design

BigTable maps two arbitrary string values (row key and column key) and timestamp (hence three-dimensional mapping) into an associated arbitrary byte array. It is not a relational database and can be better defined as a sparse, distributed multi-dimensional sorted map.[3]Wikipedia:Citing sources BigTable is designed to scale into the petabyte range across "hundreds or thousands of machines, and to make it easy to add more machines [to] the system and automatically start taking advantage of those resources without any reconfiguration".

Each table has multiple dimensions (one of which is a field for time, allowing for versioning and garbage collection). Tables are optimized for Google File System (GFS) by being split into multiple *tablets* – segments of the table are split along a row chosen such that the tablet will be ~200 megabytes in size. When sizes threaten to grow beyond a specified limit, the tablets are compressed using the algorithm BMDiff and the Zippy compression algorithm publicly known and open-sourced as Snappy, which is a less space-optimal variation of LZ77 but more efficient in terms of computing time. The locations in the GFS of tablets are recorded as database entries in multiple special tablets, which are called "META1" tablets. META1 tablets are found by querying the single "META0" tablet, which typically resides on a server of its own since it is often queried by clients as to the location of the "META1" tablet

which itself has the answer to the question of where the actual data is located. Like GFS's master server, the META0 server is not generally a bottleneck since the processor time and bandwidth necessary to discover and transmit META1 locations is minimal and clients aggressively cache locations to minimize queries.

Other similar software

- Apache Accumulo — built on top of Hadoop, ZooKeeper, and Thrift. Has cell-level access labels and a server-side programming mechanism. Written in Java.
- Apache Cassandra — brings together Dynamo's fully distributed design and BigTable's data model. Written in Java.
- Apache HBase — Provides BigTable-like support on the Hadoop Core. Written in Java.
- Hypertable — Hypertable is designed to manage the storage and processing of information on a large cluster of commodity servers. Written in C++.
- "KDI" [4], *Bluefish*, GitHub — Kosmix attempt to make a BigTable clone. Written in C++.
- LevelDB — Google's embedded key/value store that uses similar design concepts as the BigTable Tablet.

Flat file database

A **flat file database** describes any of various means to encode a database model (most commonly a table) as a single file.

A flat file can be a plain text file or a binary file. There are usually no structural relationships between the records.

Flat File Model

	Route No.	Miles	Activity
Record 1	I-95	12	Overlay
Record 2	I-495	05	Patching
Record 3	SR-301	33	Crack seal

Example of a flat file model[1]

Overview

Plain text files usually contain one record per line, There are different conventions for depicting data. In comma-separated values and delimiter-separated values files, fields can be separated by delimiters such as comma or tab characters. In other cases, each field may have a fixed length; short values may be padded with space characters. Extra formatting may be needed to avoid delimiter collision. More complex solutions are markup languages and programming languages.

Using delimiters incurs some overhead in locating them every time they are processed (unlike fixed-width formatting), which may have performance implications. However, use of character delimiters (especially commas) is also a crude form of data compression which may assist overall performance by reducing data volumes — especially for data transmission purposes. Use of character delimiters which include a length component (Declarative notation) is comparatively rare but vastly reduces the overhead associated with locating the extent of each field.

Typical examples of flat files are `/etc/passwd` and `/etc/group` on Unix-like operating systems. Another example of a flat file is a name-and-address list with the fields *Name*, *Address*, and *Phone Number*.

A list of names, addresses, and phone numbers written by hand on a sheet of paper is a flat file database. This can also be done with any typewriter or word processor. A spreadsheet or text editor program may be used to implement a flat file database, which may then be printed or used online for improved search capabilities.

History

The first uses of computing machines were implementations of simple databases. Herman Hollerith conceived the idea that census data could be represented by holes punched in paper cards and tabulated by machine. He sold his concept to the US Census Bureau; thus, the 1890 United States Census was the first computerized database—consisting, in essence, of thousands of boxes full of punched cards.

Hollerith's enterprise grew into computer giant IBM, which dominated the data processing market for most of the 20th century. IBM's fixed-length field, 80-column punch cards became the ubiquitous means of inputting electronic data until the 1970s.

In the 1980s, configurable flat-file database computer applications were popular on DOS and the Macintosh. These programs were designed to make it easy for individuals to design and use their own databases, and were almost on par with word processors and spreadsheets in popularity.[*citation needed*] Examples of flat-file database products were early versions of FileMaker and the shareware PC-File. Some of these, like dBase II, offered limited relational capabilities, allowing some data to be shared between files.

Contemporary implementations

FairCom's c-tree is an example of a modern enterprise-level solution, and spreadsheet software and text editors can be used for this purpose. WebDNA is a scripting language designed for the World Wide Web, with a hybrid flat file in-memory database system making it easy to build resilient database-driven websites. With the in-memory concept, WebDNA searches and database updates are almost realtime while the data is stored as text files within the website itself. Otherwise, flat file database is implemented in Microsoft Works and Apple Works. Over time, products like Borland's Paradox, and Microsoft's Access started offering some relational capabilities, as well as built-in programming languages. Database Management Systems (DBMS) like MySQL or Oracle generally require programmers to build applications.

Faceless flat file database engines are used internally by Mac OS X, Firefox, and other computer software to store configuration data. Programs to manage collections of books or appointments and address book are essentially single-purpose flat file database applications, allowing users to store and retrieve information from flat files using a predefined set of fields. As of 2011[2], one of the most popular flat file database engines is SQLite, which is the engine used by Firefox and Android and is part of the PHP5 standard distribution.

Data transfer operations

Flat files are used not only as data storage tools in DB and CMS systems, but also as data transfer tools to remote servers (in which case they become known as information streams).

In recent years, this latter implementation has been replaced with XML files, which not only contain but also describe the data. Those still using flat files to transfer information are mainframes employing specific procedures which are too expensive to modify.

One criticism often raised against the XML format as a way to perform mass data transfer operations is that file size is significantly larger than that of flat files, which is generally reduced to the bare minimum. The solution to this problem consists in XML file compression (a solution that applies equally well to flat files), which has nowadays gained EXI standards (i.e., Efficient XML Interchange, which is often used by mobile devices).

It is advisable that transfer data be performed via EXI rather than flat files because defining the compression method is not required, because libraries reading the file contents are readily available, and because there is no need for the two communicating systems to preliminarily establish a protocol describing data properties such as position, alignment, type, and format. However, in those circumstances where the sheer mass of data and/or the inadequacy of legacy systems becomes a problem, the only viable solution remains the use of flat files. In order to successfully handle those problems connected with data communication, format, validation, control and much else (be it a flat file or an XML file data source), it is advisable to adopt a Data Quality Firewall.

Terminology

"Flat file database" may be defined very narrowly, or more broadly. The narrower interpretation is correct in database theory; the broader covers the term as generally used.

Strictly, a flat file database should consist of nothing but data and, if records vary in length, delimiters. More broadly, the term refers to any database which exists in a single file in the form of rows and columns, with no relationships or links between records and fields except the table structure.

Terms used to describe different aspects of a database and its tools differ from one implementation to the next, but the concepts remain the same. FileMaker uses the term "Find", while MySQL uses the term "Query"; but the concept is the same. FileMaker "files", in version 7 and above, are equivalent to MySQL "databases", and so forth. To avoid confusing the reader, one consistent set of terms is used throughout this article.

However, the basic terms "record" and "field" are used in nearly every flat file database implementation.

Example database

The following example illustrates the basic elements of a flat-file database. The data arrangement consists of a series of columns and rows organized into a tabular format. This specific example uses only one table.

The columns include: *name* (a person's name, second column); *team* (the name of an athletic team supported by the person, third column); and a numeric *unique ID*, (used to uniquely identify records, first column).

Here is an example textual representation of the described data:

```
id    name    team
1     Amy     Blues
2     Bob     Reds
3     Chuck   Blues
4     Dick    Blues
5     Ethel   Reds
6     Fred    Blues
7     Gilly   Blues
8     Hank    Reds
```

This type of data representation is quite standard for a flat-file database, although there are some additional considerations that are not readily apparent from the text:

- **Data types:** each column in a database table such as the one above is ordinarily restricted to a specific data type. Such restrictions are usually established by convention, but not formally indicated unless the data is transferred to a relational database system.
- **Separated columns:** In the above example, individual columns are separated using whitespace characters. This is also called indentation or "fixed-width" data formatting. Another common convention is to separate columns using one or more delimiter characters. More complex solutions are markup and programming languages.
- **Relational algebra:** Each row or record in the above table meets the standard definition of a tuple under relational algebra (the above example depicts a series of 3-tuples). Additionally, the first row specifies the field names that are associated with the values of each row.
- **Database management system:** Since the formal operations possible with a text file are usually more limited than desired, the text in the above example would ordinarily represent an intermediary state of the data prior to being transferred into a database management system.

Terminfo

Terminfo is a library and database that enables programs to use display terminals in a device-independent manner. This library has its origins in the UNIX System III operating system. Mark Horton implemented the first terminfo library in 1981-1982 as an improvement over termcap. The improvements include

- faster access to stored terminal descriptions,
- longer, more understandable names for terminal capabilities and
- general expression evaluation for strings sent to the terminal.

Terminfo soon became the preferred form of terminal descriptions in UNIX, rather than termcap. This was imitated in **pcurses** in 1982-1984 by Pavel Curtis, and was available on other UNIX implementations, adapting or incorporating fixes from Mark Horton. For more information, refer to the posting on the `comp.sources.unix` newsgroup from December 1986.

A terminfo database can describe the capabilities of hundreds of different display terminals. This allows external programs to be able to have character-based display output, independent of the type of terminal.

Some configurations are:

- Number of lines on the screen
- Mono mode; suppress color
- Use visible bell instead of beep

Data model

Terminfo databases consist of one or more descriptions of terminals.

Indices

Each description must contain the canonical name of the terminal. It may also contain one or more aliases for the name of the terminal. The canonical name or aliases are the keys by which the library searches the terminfo database.

Data values

The description contains one or more capabilities, which have conventional names. The capabilities are typed: *boolean*, *numeric* and *string*. The terminfo library has predetermined types for each capability name. It checks the types of each capability by the syntax:

- *string* capabilities have an "=" between the capability name and its value,
- *numeric* capabilities have a "#" between the capability name and its value, and
- *boolean* capabilities have no associated value (they are always *true* if specified).

Applications which use terminfo know the types for the respective capabilities, and obtain the values of capabilities from the terminfo database using library calls that return successfully only when the capability name corresponds to one of the predefined typed capabilities.

Like termcap, some of the *string* capabilities represent escape sequences which may be sent to the host by pressing special keys on the keyboard. Other capabilities represent strings that may be sent by an application to the terminal. In the latter case, the terminfo library functions (as does a termcap library) for substituting application parameters into the string which is sent. These functions provide a stack-based expression parser, which is primarily used to help minimize the number of characters sent for control sequences which have optional parameters such as SGR (Select Graphic Rendition). In contrast, termcap libraries provide a limited set of operations which are useful for most terminals.

Hierarchy

Terminfo descriptions can be constructed by including the contents of one description in another, suppressing capabilities from the included description or overriding or adding capabilities. No matter what storage model is used, the terminfo library returns the terminal description from the requested description, using data which is compiled using a standalone tool (e.g., **tic**).

Storage model

Terminfo data is stored as a binary file, making it less simple to modify than termcap. The data can be retrieved by the terminfo library from the files where it is stored. The data itself is organized as tables for the boolean, numeric and string capabilities, respectively. This is the scheme devised by Mark Horton, and except for some differences regarding the available names is used in most terminfo implementations. X/Open does not specify the format of the compiled terminal description. In fact, it does not even mention the common **tic** or **infocmp** utilities. Because the compiled terminfo entries do not contain metadata identifying the indices within the tables to which each capability is assigned, they are not necessarily compatible between implementations. However, since most implementations use the same overall table structure (including sizes of header and data items), it is possible to automatically construct customized terminfo libraries which can read data for a given implementation. For example, ncurses can be built to match the terminfo data for several other implementations.

Directory tree

The original (and most common) implementation of the terminfo library retrieves data from a directory hierarchy. By using the first character of the name of the terminal description as one component of the pathname, and the name of the terminal description as the name of the file to retrieve, the terminfo library usually outperforms searching a large termcap file.

Hashed database

Some implementations of terminfo store the terminal description in a hashed database (e.g., something like Berkeley DB version 1.85). These store two types of records: aliases which point to the canonical entry, and the canonical entry itself, which contains the data for the terminal capabilities.

Limitations and extensions

The Open Group documents the limits for terminfo (minimum guaranteed values), which apply only to the source file.[1] Two of these are of special interest:

- 14 character maximum for terminal aliases
- 32,767 maximum for numeric quantities

The 14-character limit addresses very old filesystems which could represent filenames no longer than that. While those filesystems are generally obsolete, these limits were as documented from the late 1980s, and unreviewed since then.

The 32,767 limit is for positive values in a signed two's complement 16-bit value. A terminfo entry may use negative numbers to represent cancelled or absent values.

Unlike termcap, terminfo has both a source and compiled representation. The limits for the compiled representation are unspecified. However, most implementations note in their documentation for **tic** (terminal information compiler) that compiled entries cannot exceed 4,096 bytes in size.

Termcap

Termcap (***term****inal* ***cap****ability*) is a software library and database used on Unix-like computers. It enables programs to use display computer terminals in a device-independent manner, which greatly simplifies the process of writing portable text mode applications. Bill Joy wrote the first termcap library in 1978[1][2] for the Berkeley Unix operating system; it has since been ported to most Unix and Unix-like environments. Joy's design was reportedly influenced by the design of the terminal data store in the earlier Incompatible Timesharing System.[3]

A termcap database can describe the capabilities of hundreds of different display terminals. This allows programs to have character-based display output, independent of the type of terminal. On-screen text editors such as vi and emacs are examples of programs that may use termcap. Other programs are listed in the Termcap category.

Examples of what the database describes:

- how many columns wide the display is
- what string to send to move the cursor to an arbitrary position (including how to encode the row and column numbers)
- how to scroll the screen up one or several lines
- how much padding is needed for such a scrolling operation.

Data model

Termcap databases consist of one or more descriptions of terminals.

Indices

Each description must contain the canonical name of the terminal. It may also contain one or more aliases for the name of the terminal. The canonical name or aliases are the keys by which the library searches the termcap database.

Data values

The description contains one or more capabilities, which have conventional names. The capabilities are typed: *boolean*, *numeric* and *string*. The termcap library has no predetermined type for each capability name. It determines the types of each capability by the syntax:

- *string* capabilities have an "=" between the capability name and its value,
- *numeric* capabilities have a "#" between the capability name and its value, and
- *boolean* capabilities have no associated value (they are always *true* if specified).

Applications which use termcap do expect specific types for the commonly used capabilities, and obtain the values of capabilities from the termcap database using library calls that return successfully only when the database contents matches the assumed type.

Hierarchy

Termcap descriptions can be constructed by including the contents of one description in another, suppressing capabilities from the included description or overriding or adding capabilities. No matter what storage model is used, the termcap library constructs the terminal description from the requested description, including, suppressing or overriding at the time of the request.

Storage model

Termcap data is stored as text, making it simple to modify. The text can be retrieved by the termcap library from files or environment variables.

Environment variable

The **TERMCAP** environment variable may contain a termcap database. It is most often used to store a single termcap description, set by a terminal emulator to provide the terminal's characteristics to the shell and dependent programs.

Flat file

The original (and most common) implementation of the termcap library retrieves data from a flat text file. Searching a large termcap file, e.g., 500Kb, can be slow. To aid performance, a utility such as **reorder** is used to put the most frequently used entries near the beginning of the file.

Hashed database

Newer implementations of termcap store the terminal description in a hashed database (e.g., something like Berkeley DB version 1.85). These store two types of records: aliases which point to the canonical entry, and the canonical entry itself. The text of the termcap entry is stored literally.

Limitations and extensions

The original termcap implementation was designed to use little memory:

- the first name is two characters, to fit in 16 bits
- capability names are two characters
- descriptions are limited to 1023 characters.
- only one description can be included, and must be at the end.

Newer implementations of the termcap interface generally do not require the two-character name at the beginning of the entry.

Capability names are still two characters in all implementations.

The **tgetent** function used to read the terminal description uses a buffer whose size must be large enough for the data, and is assumed to be 1024 characters. Newer implementations of the termcap interface may relax this constraint by allowing a null pointer in place of the fixed buffer,[4] or by hiding the data which would not fit, e.g., via the **ZZ** capability in NetBSD termcap.[5] The terminfo library interface also emulates the termcap interface, and does not actually use the fixed-size buffer.

The terminfo library's emulation of termcap allows multiple descriptions to be included without restricting the position. A few other newer implementations of the termcap library may also provide this ability, though it is not well documented.[6]

MultiValue

MultiValue is a type of NoSQL and multidimensional database, typically considered synonymous with PICK, a database originally developed as the Pick operating system.

MultiValue databases include commercial products from Rocket Software, TigerLogic, jBASE, Revelation, Ladybridge, InterSystems, Northgate Information Solutions and other companies. These databases differ from a relational database in that they have features that support and encourage the use of attributes which can take a list of values, rather than all attributes being single-valued. They are often categorized with MUMPS within the category of post-relational databases, although the data model actually pre-dates the relational model. Unlike SQL-DBMS tools, most MultiValue databases can be accessed both with or without SQL.

History

Don Nelson designed the MultiValue data model in the early to mid-1960s. Dick Pick, a developer at TRW, worked on the first implementation of this model for the US Army in 1965. Pick considered the software to be in the public domain because it was written for the military. This was but the first dispute regarding MultiValue databases that was addressed by the courts.[1]

Ken Simms wrote DataBASIC, sometimes known as S-BASIC, in the mid-70's. It was based on Dartmouth BASIC, but had enhanced features for data management. Simms played a lot of Star Trek while developing the language, in order to have the language function to his satisfaction.

Three of the implementations of MultiValue: PICK version R77, Microdata Reality [2] 3.x, and Prime Information 1.0, were very similar. In spite of attempts to standardize, particularly by International Spectrum and the Spectrum Manufacturers Association, who designed a logo for all to use, there are no standards across MultiValue implementations. Subsequently, these flavors diverged, although with some cross-over. These streams of MultiValue database development could be classified as one stemming from PICK R83, one from Microdata Reality [2], and one from Prime Information. Because of the differences, some implementations have provisions for supporting several flavors of the languages. An attempt to document the similarities and differences can be found at the PRDB

Marketing groups and others in the industry over the years have classified MultiValue databases as pre-relational, post-relational, relational, and embedded, with detractors classifying it as legacy. It could now be classified as NoSQL. With a data model that aligns well with XML and that permits access with or without the use of SQL.

One reasonable hypothesis for this data model lasting more than 40 years, with new database implementations of the model even in the 21st century is that it provides database solutions in a big bang for the buck fashion. Historically,

with industry benchmarks tied to SQL transactions, this has been a difficult hypothesis to test, although there are considerable anecdotes of failed attempts to get the functionality of a MultiValue application into a relational database framework.

In spite of a history of more than 40 years of implementations, starting with TRW, many in the MultiValue industry have remained current so that various MultiValue implementations now employ object-oriented versions of Data BASIC, support AJAX frameworks, and because no one needs to use SQL (but some can) they fit under the NoSQL umbrella. In fact, MultiValue developers were the first to acquire nosql domain names, likely prior to other database products classifying their offerings as NoSQL as well. MultiValue is a seasoned data model, but with so many vendors competing in this space, it has been constantly enhanced over the years.

Data model example

In a MultiValue database system:

- a Database is called an "Account"
- a Table is called a "File"
- a Column is an "Attribute" composed of "Multivalue attribute" and "Subvalue attribute" to store multiple values in the same attribute.

Data is stored using two separate files. A "File" to store raw data and a "Dictionary" to store the format for displaying the raw data.

For example, assume there's a file (table) called "PERSON". And in this file there is a attribute called "eMailAddress". The eMailAddress field can store a variable number of email address values in the single record.

So the list [joe@example.com, jdb@example.net, joe_bacde@example.org] can be stored and accessed via a single query / disk read when accessing the associated record.

To achieve the same (1-to-many) relationship within a traditional Relational Database System one would be required to create an additional table to store the variable number of email Addresses associated to a single "PERSON" record. However, modern Relational Database Systems do support this data model too. For example, in PostgreSQL one can set up a column of type Array of baseType (baseType being any PostgreSQL data type).

MultiValue DataBASIC

Like the Java programming language, the typical DataBASIC compiler compiles to P-code and runs in a P-machine. It has as many different implementations (compilers) as there are MultiValue databases.

Like PHP programming language, the DataBASIC language does all the typecasting for the programmer.

MultiValue Query Language

Known as ENGLISH, ACCESS, AQL, UniQuery, Retrieve, CMQL, and by many other names over the years, corresponding to the different MultiValue implementations, the MultiValue query language differs from SQL in several respects. Each query is issued against a single dictionary within the schema, which could be understood as a virtual file or a portal to the database through which to view the data.

```
LIST PEOPLE LAST_NAME FIRST_NAME EMAIL_ADDRESSES WITH LAST_NAME LIKE "Van..."
```

The above statement would list all e-mail addresses for each person whose last name starts with "Van". A single entry would be output for each person, with multiple lines showing the multiple e-mail addresses (without repeating other data about the person).

OpenInsight

OpenInsight is a database application development tool from Revelation Software. It was first released in 1992; version 9.2 was released in 2010.[1]

OpenInsight is a windows-based development tool. It contains its own database which is a type of post-relational database known as a MultiValue database. OpenInsight contains tools for creating database applications that can run on Windows workstations, Windows, Linux, and Novell networks, and browser-based applications. The tools include, but are not limited to, a Table Builder, a Database Manager, editor, debugger and programming language, a forms designer for creating data entry forms, User Interface tools, reporting tools, and deployment tools.[2]

OpenInsight's programming language is called Basic+, and is an extension or dialect of the BASIC programming language. OpenInsight applications can use data from Revelation Software's built-in database, or they can use data from SQL Databases, from Rocket Software's Rocket U2 databases,[3] as well as Tiger Logic's D3 database.

Document-oriented database

A **document-oriented database** is a computer program designed for storing, retrieving, and managing document-oriented information, also known as semi-structured data. Document-oriented databases are one of the main categories of so-called NoSQL databases and the popularity of the term "document-oriented database" (or "document store") has grown[1] with the use of the term NoSQL itself. In contrast to relational databases and their notions of "Relations" (or "Tables"), these systems are designed around an abstract notion of a "Document".

Documents

The central concept of a document-oriented database is the notion of a *Document*. While each document-oriented database implementation differs on the details of this definition, in general, they all assume documents encapsulate and encode data (or information) in some standard formats or encodings. Encodings in use include XML, YAML, JSON, and BSON, as well as binary forms like PDF and Microsoft Office documents (MS Word, Excel, and so on).

Documents inside a document-oriented database are similar, in some ways, to records or rows in relational databases, but they are less rigid. They are not required to adhere to a standard schema, nor will they have all the same sections, slots, parts, or keys. For example, the following is a document:

```
{
   FirstName: "Bob",
   Address: "5 Oak St.",
   Hobby: "sailing"
}
```

A second document might be:

```
{
  FirstName: "Jonathan",
  Address: "15 Wanamassa Point Road",
  Children: [
        {Name: "Michael", Age: 10},
        {Name: "Jennifer", Age: 8},
        {Name: "Samantha", Age: 5},
        {Name: "Elena", Age: 2}
  ]
 }
```

These two documents share some structural elements with one another, but each also has unique elements. Unlike a relational database where every record contains the same fields, leaving unused fields empty; there are no empty 'fields' in either document (record) in the above example. This approach allows new information to be added to some records without requiring that every other record in the database share the same structure.

Keys

Documents are addressed in the database via a unique *key* that represents that document. This key is often a simple string, a URI, or a path. The key can be used to retrieve the document from the database. Typically, the database retains an index on the key to speed up document retrieval.

Retrieval

Another defining characteristic of a document-oriented database is that, beyond the simple key-document (or key-value) lookup that can be used to retrieve a document, the database offers an API or query language that allows the user to retrieve documents based on their content. For example, you may want a query that retrieves all the documents with a certain field set to a certain value. The set of query APIs or query language features available, as well as the expected performance of the queries, varies significantly from one implementation to the next.

Organization

Implementations offer a variety of ways of organizing documents, including notions of

- Collections
- Tags
- Non-visible Metadata
- Directory hierarchies
- Buckets

Implementations

Name	Publisher	License	Language	Notes	RESTful API
ArangoDB [2]	triAGENS [3]	Apache 2 License	C, C++ & Javascript	A distributed multi model, high-performance document store and graph database.	Yes [4]
BaseX	BaseX Team [5]	BSD License	Java, XQuery	Support for XML, JSON and binary formats; client-/server based architecture; concurrent structural and full-text searches and updates; REST APIs.	Yes
Cassandra	Apache Software Foundation	Apache License	Java	JSON over HTTP	Yes
Cloudant	Cloudant, Inc. [6]	Proprietary	Erlang, Java, Scala, and C	Distributed database service based on BigCouch, the company's open source fork of the Apache-backed CouchDB project.	Yes
Clusterpoint	Clusterpoint Ltd. [7]	Free community license / Commercial[8]	C++	Schema-free, document-oriented database management system platform with server based data storage, full text search engine functionality, information ranking for search relevance and clustering.	Yes
Couchbase Server	Couchbase, Inc.	Apache License	Erlang and C	Distributed NoSQL Document Database.	Yes [9]
CouchDB	Apache Software Foundation	Apache License	Erlang	JSON over REST/HTTP with Multi-Version Concurrency Control and limited ACID properties. Uses map and reduce for views and queries.[10]	Yes [11]

eXist	eXist, [12]	GPL	XQuery, Java	XML over REST/HTTP, WebDAV, Lucene Fulltext search, validation, versioning, clustering, triggers, URL rewriting, collections, ACLS, XQuery Update	Yes [13]
FleetDB	FleetDB [14]	MIT License	Clojure	A JSON-based [15] schema-free database optimized for agile development.	(unknown)
Jackrabbit	Apache Software Foundation	Apache License	Java		(unknown)
Informix	IBM	Proprietary	Various (Compatible with MongoDB API)	RDBMS with JSON, replication, sharding and ACID compliance	(unknown)
Inquire	Infodata Systems, Inc.	Proprietary	unknown	In the mid-80's this was the dominant document-oriented commercial database, widely successful. The company seems to have gone out of business in 2005.	(unknown)
Lotus Notes	IBM	Proprietary	LotusScript, Java, Lotus @Formula		(unknown)
MarkLogic	MarkLogic Corporation	Free Developer license [16] or Commercial [16]	REST, Java, XQuery, XSLT, C++	Distributed document-oriented database with Multi-Version Concurrency Control, integrated Full text search and ACID-compliant transaction semantics	Yes
MongoDB	MongoDB, Inc	GNU AGPL v3.0[17]	C++	Document database with replication and sharding	Optional [18]
MUMPS Database[19]		Proprietary and Affero GPL[20]	MUMPS	Commonly used in health applications.	(unknown)
OrientDB	Orient Technologies [21]	Apache License	Java	JSON over HTTP	Yes
RavenDB	Hibernating Rhinos LTD [22]	Proprietary and modified Affero GPL[23]	C#, JavaScript		Yes
Redis		BSD License	ANSI C	Key-value store supporting lists and sets with binary-safe protocol	(unknown)
RethinkDB		GNU APGL for the DBMS, Apache 2 License for the client drivers	C++		(unknown)
Rocket U2	Rocket Software	Proprietary		UniData, UniVerse	Yes (Beta)
Sqrrl Enterprise [32]	sqrrl	Proprietary	Java	Distributed, real-time database featuring cell-level security and massive scalability.	Yes

XML database implementations

Most XML databases are document-oriented databases.

MongoDB

MongoDB

Developer(s)	MongoDB Inc.
Initial release	2009
Stable release	2.4.9 / 10 January 2014
Preview release	2.5.4 / 18 November 2013
Development status	Active
Written in	C++
Operating system	Cross-platform
Available in	English
Type	Document-oriented database
License	GNU AGPL v3.0 (drivers: Apache license)
Website	www.mongodb.org [1]

MongoDB (from "hu**mongo**us") is a cross-platform document-oriented database system. Classified as a NoSQL database, MongoDB eschews the traditional table-based relational database structure in favor of JSON-like documents with dynamic schemas (MongoDB calls the format BSON), making the integration of data in certain types of applications easier and faster. Released under a combination of the GNU Affero General Public License and the Apache License, MongoDB is free and open source software.

First developed by the software company 10gen (now MongoDB Inc.) in October 2007 as a component of a planned platform as a service product, the company shifted to an open source development model in 2009, with 10gen offering commercial support and other services. Since then, MongoDB has been adopted as backend software by a number of major websites and services, including Craigslist, eBay, Foursquare, SourceForge, and The New York Times, among others. MongoDB is the most popular NoSQL database system.

History

Development of MongoDB began in 2007, when the company (then named 10gen) was building a platform as a service similar to Windows Azure or Google App Engine.[2] In 2009, MongoDB was open sourced as a stand-alone product[3] with an AGPL license.

From version 1.4 (March 2010), MongoDB has been considered production ready.[4]

The latest stable version, 2.4.9, was released on January 10, 2014.

Licensing and support

MongoDB is available for free under the GNU Affero General Public License. The language drivers are available under an Apache License. In addition, MongoDB Inc. offers commercial licenses for MongoDB.[5]

Main features

The following is a brief summary of some of the main features:[6]

Ad hoc queries

MongoDB supports search by field, range queries, regular expression searches. Queries can return specific fields of documents and also include user-defined JavaScript functions.

Indexing

Any field in a MongoDB document can be indexed (indices in MongoDB are conceptually similar to those in RDBMSes). Secondary indices are also available.

Replication

MongoDB provides high availability and increased throughput with replica sets. A replica set consists of two or more copies of the data. Each replica may act in the role of primary or secondary replica at any time. The primary replica performs all writes and reads by default. Secondary replicas maintain a copy of the data on the primary using built-in replication. When a primary replica fails, the replica set automatically conducts an election process to determine which secondary should become the primary. Secondaries can also perform read operations, but the data is eventually consistent by default.

Load balancing

MongoDB scales horizontally using sharding. The user chooses a shard key, which determines how the data in a collection will be distributed. The data is split into ranges (based on the shard key) and distributed across multiple shards. (A shard is a master with one or more slaves.)

MongoDB can run over multiple servers, balancing the load and/or duplicating data to keep the system up and running in case of hardware failure. Automatic configuration is easy to deploy, and new machines can be added to a running database.

File storage

MongoDB can be used as a file system, taking advantage of load balancing and data replication features over multiple machines for storing files.

This function, called GridFS,[7] is included with MongoDB drivers and available with no difficulty for development languages (see "Language Support" for a list of supported languages). MongoDB exposes functions for file manipulation and content to developers. GridFS is used, for example, in plugins for NGINX[8] and lighttpd.[9] Instead of storing a file in a single document, GridFS divides a file into parts, or chunks, and stores each of those chunks as a separate document.[10]

In a multi-machine MongoDB system, files can be distributed and copied multiple times between machines transparently, thus effectively creating a load-balanced and fault-tolerant system.

Aggregation

MapReduce can be used for batch processing of data and aggregation operations. The aggregation framework enables users to obtain the kind of results for which the SQL GROUP BY clause is used.

Server-side JavaScript execution

JavaScript can be used in queries, aggregation functions (such as MapReduce), and sent directly to the database to be executed.

Capped collections

MongoDB supports fixed-size collections called capped collections. This type of collection maintains insertion order and, once the specified size has been reached, behaves like a circular queue.

Criticisms

MongoDB uses a readers-writer lock that allows concurrent read access to a database but exclusive write access to a single write operation.[11] Before version 2.2, this lock was implemented on a per-mongod basis. Since version 2.2, the lock has been implemented at the database level.[12] One approach to increase concurrency is to use sharding.[13] In some situations, reads and writes will yield their locks. If MongoDB predicts a page is unlikely to be in memory, operations will yield their lock while the pages load. The use of lock yielding expanded greatly in 2.2.[14]

Another criticism related to the limitations of MongoDB when used on 32-bit systems.[15] In some cases, this was due to inherent memory limitations.[16] MongoDB recommends 64-bit systems and that users provide sufficient RAM for their working set.[17] Some users encounter issues when their working set exceeds available RAM and the system encounters page faults. MongoHQ, a provider of managed MongoDB infrastructure, recommends a scaling checklist for large systems.[18]

Additionally, MongoDB provides very limited support for sorting on utf-8 encoded string data,[19] which poses a substantial problem when storing non-english text. Specifically, MongoDB currently uses the memcmp [20] function when sorting strings, which doesn't correctly handle utf-8 data under different locales.

Language support

MongoDB has official drivers for a variety of popular programming languages and development environments. Web programming language Opa also has built-in support for MongoDB, which is tightly integrated in the language and offers a type-safety layer on top of MongoDB. There are also a large number of unofficial or community-supported drivers for other programming languages and frameworks.

Management and graphical front-ends

MongoDB tools

In a MongoDB installation the following commands are available:

mongo

MongoDB offers an interactive shell called **`mongo`**,[21] which lets developers view, insert, remove, and update data in their databases, as well as get replication information, set up sharding, shut down servers, execute JavaScript, and more.

Administrative information can also be accessed through a **web interface**,[22] a simple webpage that serves information about the current server status. By default, this interface is 1000 ports above the database port (28017).

mongostat

`mongostat`[23] is a command-line tool that displays a summary list of status statistics for a currently running MongoDB instance: how many inserts, updates, removes, queries, and commands were performed, as well as what percentage of the time the database was locked and how much memory it is using. This tool is similar to the UNIX/Linux vmstat utility.

mongotop

`mongotop`[24] is a command-line tool providing a method to track the amount of time a MongoDB instance spends reading and writing data. mongotop provides statistics on the per-collection level. By default, mongotop returns values every second. This tool is similar to the UNIX/Linux top utility.

mongosniff

`mongosniff`[25] is a command-line tool providing a low-level tracing/sniffing view into database activity by monitoring (or "sniffing") network traffic going to and from MongoDB. `mongosniff` requires the Libpcap network library and is only available for Unix-like systems. A cross-platform alternative is the open source Wireshark packet analyzer which has full support for the MongoDB wire protocol.

mongoimport, mongoexport

`mongoimport`[26] is a command-line utility to import content from a JSON, CSV, or TSV export created by `mongoexport`[27] or potentially other third-party data exports.

mongodump, mongorestore

`mongodump`[28] is a command-line utility for creating a binary export of the contents of a Mongo database; `mongorestore`[29] can be used to reload a database dump.

Production deployments

Some of the prominent users of MongoDB include:[30]

- MetLife uses MongoDB for “The Wall," a customer service application providing a "360-degree view" of MetLife customers.[31]
- Craigslist stores over 2 billion records in MongoDB.[32]
- SAP uses MongoDB in the SAP PaaS.[33]
- Forbes stores articles and companies data in MongoDB.[34]
- The New York Times uses MongoDB in its form-building application for photo submissions.[35]
- Sourceforge uses MongoDB for its back-end storage pages.[36]
- Codecademy uses MongoDB as the datastore for its online learning system.[37]
- Shutterfly uses MongoDB for its photo platform. As of 2013, the photo platform stores 18 billion photos uploaded by Shutterfly's 7 million users.[38][39]
- The Guardian uses MongoDB for its identity system.[40]
- CERN uses MongoDB as the primary back-end for the *Data Aggregation System* for the Large Hadron Collider.[41]
- Foursquare deploys MongoDB on Amazon AWS to store venues and user check-ins into venues.[42]
- eBay uses MongoDB in the search suggestion and the internal Cloud Manager *State Hub*.[43]

Spatiotemporal Databases

Temporal database

A **temporal database** is a database with built-in support for handling data involving time, for example a temporal data model and a temporal version of Structured Query Language (SQL).

More specifically the temporal aspects usually include valid time and transaction time. These attributes can be combined to form bitemporal data.

- **Valid time** is the time period during which a fact is true with respect to the real world.
- **Transaction time** is the time period during which a fact stored in the database is considered to be true.
- **Bitemporal data** combines both Valid and Transaction Time.

It is possible to have timelines other than Valid Time and Transaction Time, such as Decision Time, in the database. In that case the database is called a multitemporal database as opposed to a bitemporal database. However, this approach introduces additional complexities such as dealing with the validity of (foreign) keys.

Temporal databases are in contrast to current databases, which store only facts which are believed to be true at the current time.

Features

Temporal databases support managing and accessing temporal data by providing one or more of the following features:

- A time period datatype, including the ability to represent time periods with no end (infinity or forever)
- The ability to define valid and transaction time period attributes and bitemporal relations
- System-maintained transaction time
- Temporal primary keys, including non-overlapping period constraints
- Temporal constraints, including non-overlapping uniqueness and referential integrity
- Update and deletion of temporal records with automatic splitting and coalescing of time periods
- Temporal queries at current time, time points in the past or future, or over durations
- Predicates for querying time periods, often based on Allen's interval relations

History

With the development of SQL and its attendant use in real-life applications, database users realized that when they added date columns to key fields, some issues arose. For example, if a table has a primary key and some attributes, adding a date to the primary key to track historical changes can lead to creation of more rows than intended. Deletes must also be handled differently when rows are tracked in this way. In 1992, this issue was recognized but standard database theory was not yet up to resolving this issue, and neither was the then-newly-formalized SQL-92 standard.

Richard Snodgrass proposed in 1992 that temporal extensions to SQL be developed by the temporal database community. In response to this proposal, a committee was formed to design extensions to the 1992 edition of the SQL standard (ANSI X3.135.-1992 and ISO/IEC 9075:1992); those extensions, known as TSQL2, were developed during 1993 by this committee.[1] In late 1993, Snodgrass presented this work to the group responsible for the American National Standard for Database Language SQL, ANSI Technical Committee X3H2 (now known as NCITS H2). The preliminary language specification appeared in the March 1994 ACM SIGMOD Record. Based on responses to that specification, changes were made to the language, and the definitive version of the TSQL2

Language Specification was published in September, 1994

An attempt was made to incorporate parts of TSQL2 into the new SQL standard SQL:1999, called SQL3. Parts of TSQL2 were included in a new substandard of SQL3, ISO/IEC 9075-7, called SQL/Temporal. The TSQL2 approach was heavily criticized by Chris Date and Hugh Darwen.[2] The ISO project responsible for temporal support was canceled near the end of 2001.

As of December 2011, ISO/IEC 9075, Database Language SQL:2011 Part 2: SQL/Foundation included clauses in table definitions to define "application-time period tables" (valid time tables), "system-versioned tables" (transaction time tables) and "system-versioned application-time period tables" (bitemporal tables). A substantive difference between the TSQL2 proposal and what was adopted in SQL:2011 is that there are no hidden columns in the SQL:2011 treatment, nor does it have a new data type for intervals; instead two date or timestamp columns can be bound together using a `PERIOD FOR` declaration. Another difference is replacement of the controversial (prefix) statement modifiers from TSQL2 with a set of temporal predicates.

Example

For illustration, consider the following short biography of a fictional man, John Doe:

> John Doe was born on April 3, 1975 in the Kids Hospital of Medicine County, as son of Jack Doe and Jane Doe who lived in Smallville. Jack Doe proudly registered the birth of his first-born on April 4, 1975 at the Smallville City Hall. John grew up as a joyful boy, turned out to be a brilliant student and graduated with honors in 1993. After graduation he went to live on his own in Bigtown. Although he moved out on August 26, 1994, he forgot to register the change of address officially. It was only at the turn of the seasons that his mother reminded him that he had to register, which he did a few days later on December 27, 1994. Although John had a promising future, his story ends tragically. John Doe was accidentally hit by a truck on April 1, 2001. The coroner reported his date of death on the very same day.

Using a current database

To store the life of John Doe in a current (non-temporal) database we use a table *Person (Name, Address)*. (In order to simplify *Name* is defined as the primary key of *Person*.)

John's father officially reported his birth on April 4, 1975. On this date a Smallville official inserted the following entry in the database: `Person(John Doe, Smallville)`. Note that the date itself is not stored in the database.

After graduation John moves out, but forgets to register his new address. John's entry in the database is not changed until December 27, 1994, when he finally reports it. A Bigtown official updates his address in the database. The *Person* table now contains `Person(John Doe, Bigtown)`. Note that the information of John living in Smallville has been overwritten, so it is no longer possible to retrieve that information from the database. An official accessing the database on December 28, 1994 would be told that John lives in Bigtown. More technically: if a database administrator ran the query `SELECT ADDRESS FROM PERSON WHERE NAME='John Doe'` on December 26, 1994, the result would be `Smallville`. Running the same query 2 days later would result in `Bigtown`.

Until his death the database would state that he lived in Bigtown. On April 1, 2001 the coroner deletes the John Doe entry from the database. After this, running the above query would return no result at all.

Date	Real world event	Database Action	What the database shows
April 3, 1975	John is born	Nothing	There is no person called John Doe
April 4, 1975	John's father officially reports John's birth	Inserted:Person(John Doe, Smallville)	John Doe lives in Smallville
August 26, 1994	After graduation, John moves to Bigtown, but forgets to register his new address	Nothing	John Doe lives in Smallville
December 26, 1994	Nothing	Nothing	John Doe lives in Smallville
December 27, 1994	John registers his new address	Updated:Person(John Doe, Bigtown)	John Doe lives in Bigtown
April 1, 2001	John dies	Deleted:Person(John Doe)	There is no person called John Doe

Using Valid time

Valid time is the time for which a fact is true in the real world. A valid time period may be in the past, span the current time, or occur in the future.

For the example above, to record valid time the *Person* table has two fields added, *Valid-From* and *Valid-To*. These specify the period when a person's address is valid in the real world. On April 4, 1975 John's father registered his son's birth. An official then inserts a new entry into the database stating that John lives in Smallville from April 3. Note that although the data was inserted on the 4th, the database states that the information is valid since the 3rd. The official does not yet know if or when John will move to another place, so the *Valid-To* field is set to infinity (∞). The entry in the database is:

```
Person(John Doe, Smallville, 3-Apr-1975, ∞).
```

On December 27, 1994 John reports his new address in Bigtown where he has been living since August 26, 1994. A new database entry is made to record this fact:

```
Person(John Doe, Bigtown, 26-Aug-1994, ∞).
```

The original entry `Person (John Doe, Smallville, 3-Apr-1975, ∞)` is not deleted, but has the *Valid-To* attribute updated to reflect that it is now known that John stopped living in Smallville on August 26, 1994. The database now contains two entries for John Doe

```
Person(John Doe, Smallville, 3-Apr-1975, 26-Aug-1994).
Person(John Doe, Bigtown, 26-Aug-1994, ∞).
```

When John dies his current entry in the database is updated stating that John does not live in Bigtown any longer. The database now looks like this

```
Person(John Doe, Smallville, 3-Apr-1975, 26-Aug-1994).
Person(John Doe, Bigtown, 26-Aug-1994, 1-Apr-2001).
```

Using Transaction time

Transaction time records the time period during which a database entry is accepted as correct. This enables queries that show the state of the database at a given time. Transaction time periods can only occur in the past or up to the current time. In a transaction time table, records are never deleted. Only new records can be inserted, and existing ones updated by setting their transaction end time to show that they are no longer current.

To enable transaction time in the example above, two more fields are added to the Person table: *Transaction-From* and *Transaction-To*. *Transaction-From* is the time a transaction was made, and *Transaction-To* is the time that the transaction was superseded (which may be infinity if it has not yet been superseded). This makes the table into a bitemporal table.

What happens if the person's address as stored in the database is incorrect? Suppose an official accidentally entered the wrong address or date? Or, suppose the person lied about their address for some reason. Upon discovery of the error, the officials update the database to correct the information recorded.

For example, from 1-Jun-1995 to 3-Sep-2000 John Doe moved to Beachy. But to avoid paying Beachy's exorbitant residence tax, he never reported it to the authorities. Later during a tax investigation it is discovered on 2-Feb-2001 that he was in fact in Beachy during those dates. To record this fact the existing entry about John living in Bigtown must be split into two separate records, and a new record inserted recording his residence in Beachy. The database would then appear as follows:

```
Person(John Doe, Smallville, 3-Apr-1975, 26-Aug-1994).
Person(John Doe, Bigtown, 26-Aug-1994, 1-Jun-1995).
Person(John Doe, Beachy, 1-Jun-1995, 3-Sep-2000).
Person(John Doe, Bigtown, 3-Sep-2000, 1-Apr-2001).
```

However, this leaves no record that the database ever claimed that he lived in Bigtown during 1-Jun-1995 to 3-Sep-2000. This might be important to know for auditing reasons, or to use as evidence in the official's tax investigation. Transaction time allows capturing this changing knowledge in the database, since entries are never directly modified or deleted. Instead, each entry records when it was entered and when it was superseded (or logically deleted). The database contents then look like this:

```
Person(John Doe, Smallville, 3-Apr-1975,  ∞,           4-Apr-1975,  27-Dec-1994).
Person(John Doe, Smallville, 3-Apr-1975,  26-Aug-1994, 27-Dec-1994, ∞     ).
Person(John Doe, Bigtown,    26-Aug-1994, ∞,           27-Dec-1994, 2-Feb-2001 ).
Person(John Doe, Bigtown,    26-Aug-1994, 1-Jun-1995,  2-Feb-2001,  ∞     ).
Person(John Doe, Beachy,     1-Jun-1995,  3-Sep-2000,  2-Feb-2001,  ∞     ).
Person(John Doe, Bigtown,    3-Sep-2000,  ∞,           2-Feb-2001,  1-Apr-2001 ).
Person(John Doe, Bigtown,    3-Sep-2000,  1-Apr-2001,  1-Apr-2001,  ∞     ).
```

The database records not only what happened in the real world, but also what was officially recorded at different times.

Bitemporal relations

A bitemporal relation contains both valid and transaction time. This provides both **historical** and **rollback** information. Historical information (e.g.: "Where did John live in 1992?") is provided by the valid time. Rollback (e.g.: "In 1992, where did the database believe John lived?") is provided by the transaction time. The answers to these example questions may not be the same - the database may have been altered since 1992, causing the queries to produce different results.

The valid time and transaction time do not have to be the same for a single fact. For example, consider a temporal database storing data about the 18th century. The valid time of these facts is somewhere between 1701 and 1800.

The transaction time records when the facts are inserted into the database (for example, January 21, 1998).

Schema Evolution

A challenging issue is the support of temporal queries in a transaction time database under evolving schema. In order to achieve perfect archival quality it is of key importance to store the data under the schema version under which they firstly appeared. However even the most simple temporal query rewriting the history of an attribute value would be required to be manually rewritten under each of the schema versions, potentially hundreds as in the case of MediaWiki [1] This process would be particularly taxing for users. A proposed solution is to provide automatic query rewriting, although this is not part of SQL or similar standards.

Implementations in databases

The following implementations provide temporal features in a relational database management system (RDBMS).

- Oracle Workspace Manager [3] is a feature of Oracle Database which enables application developers and DBAs to manage current, proposed and historical versions of data in the same database.
- TimeDB [4] is a free temporal relational DBMS by TimeConsult. It runs as a frontend to Oracle that accepts TSQL2 statements and generates SQL92 statements.
- PostgreSQL [5] has an open-source contributed package that can be installed in the database to manage temporal data. The function reference is here [6].
- Teradata version 13.10 [7] and Teradata version 14 has temporal features based on TSQL2[8] built into the database.
- Anchor Modeling [9] emulates temporal features and automates the implementation in databases that lack support.
- IBM DB2 version 10 added a feature called "time travel query"[] which is based on the temporal capabilities of the SQL:2011 standard.[]

RRDtool

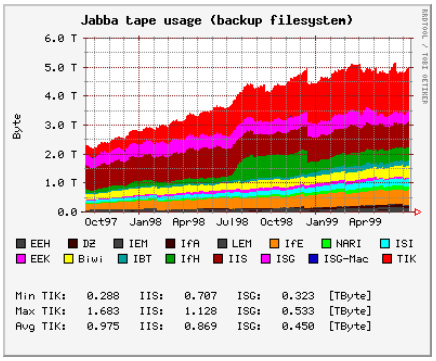
RRDtool

Original author(s)	Tobi Oetiker
Stable release	1.4.8 / May 23, 2013
Written in	C
License	GNU General Public License
Website	oss.oetiker.ch/rrdtool/ [1]

RRDtool (acronym for **r**ound-**r**obin **d**atabase **tool**) aims to handle time-series data like network bandwidth, temperatures, CPU load, etc. The data are stored in a round-robin database (circular buffer), thus the system storage footprint remains constant over time.

It also includes tools to extract **RRD** data in a graphical format, for which it was originally intended.

Bindings exist for Perl, Python, Ruby, Tcl, PHP and Lua. And there is an independent full Java implementation, rrd4j.



RRDtool has a graph function, which presents data from an RRD in a customizable graphical format

General data storage

RRDtool assumes time-variable data in intervals of a certain length. This interval, usually named **step**, is specified upon creation of an RRD file and cannot be changed afterwards. Because data may not always be available at just the right time, RRDtool will automatically interpolate any submitted data to fit its internal time-steps.

The value for a specific step, that has been interpolated, is named a primary data point (**PDP**). Multiple PDPs may be consolidated according to a consolidation function (**CF**) to form a consolidated data point (**CDP**). Typical consolidation functions are average, minimum, maximum.

After the data have been consolidated, the resulting CDP is stored in a round-robin archive (**RRA**). A round-robin archive stores a fixed number of CDPs and specifies how many PDPs should be consolidated into one CDP and which CF to use. The total time covered by an RRA can be calculated as follows:

```
time covered = (#CDPs stored) * (#PDPs per CDP) * steps
```

After this time the archive will "wrap around": the next insertion will overwrite the oldest entry. This behavior is sometimes referred to as "round-robin" and is the reason for the program's name.

To cover several timespans and/or use several consolidation functions, an RRD file may contain multiple RRAs. The data retrieval function of RRDtool automatically selects the archive with the highest resolution that still covers the requested timespan. This mechanism is also used by RRDtool's graphing subsystem.

Release history

Colour	Meaning
Red	Release no longer supported
Green	Release still supported
Blue	Future release

RRDTool is sponsored since 1.2, each release comes with a list of sponsors.

The following table contains the **release history of RRDtool**, showing its major releases.

Version number	Date	Links	Notable changes
1.0	July 16, 1999	Full release notes [2], Announce [3]	First release. Basically MRTG "done right".
1.1	April 25, 2005	Full release notes [4], Announce [5]	libart; output EPS, PDF & SVG; VDEF; trends; percentiles; updatev; Holt-Winters Forecasting; COMPUTE; .rrd format change.
1.3	June 11, 2008	Full release notes [6], Announce [7]	Safer & faster file access; cairo/pango; anti-aliasing; TEXTALIGN; dashed lines; new HWPREDICT; libxml; i18n; XML dump;
1.4	October 27, 2009	Full release notes [8], Announce [9]	Caching daemon; VDEF PERCENTNAN; CDEF PREDICT & PREDICTSIGMA; libDBI; graph legends positioning; Lua bindings; 3D border width; and more ...

Other tools that use RRDtool as a DBMS and/or graphing subsystem

- BackupPC
- Cacti
- Cherokee
- collectd
- Ganglia – system monitor clusters and grids
- Lighttpd
- Monitorix
- MRTG
- Munin
- N2rrd
- Nagios
- Nmon
- NMIS[10]
- ntop
- Observium
- OpenNMS
- ServersCheck
- SNM [11] - System and Network Monitor
- Zenoss

Spatial database

A **spatial database** is a database that is optimized to store and query data that represents objects defined in a geometric space. Most spatial databases allow representing simple geometric objects such as points, lines and polygons. Some spatial databases handle more complex structures such as 3D objects, topological coverages, linear networks, and TINs. While typical databases are designed to manage various numeric and character types of data, additional functionality needs to be added for databases to process spatial data types efficiently. These are typically called *geometry* or *feature*. The Open Geospatial Consortium created the Simple Features specification and sets standards for adding spatial functionality to database systems.[1]

Features of spatial databases

Database systems use indexes to quickly look up values and the way that most databases index data is not optimal for spatial queries. Instead, spatial databases use a spatial index to speed up database operations.

In addition to typical SQL queries such as SELECT statements, spatial databases can perform a wide variety of spatial operations. The following operations and many more are specified by the Open Geospatial Consortium standard:

- Spatial Measurements: Computes line length, polygon area, the distance between geometries, etc.
- Spatial Functions: Modify existing features to create new ones, for example by providing a buffer around them, intersecting features, etc.
- Spatial Predicates: Allows true/false queries about spatial relationships between geometries. Examples include "do two polygons overlap" or 'is there a residence located within a mile of the area we are planning to build the landfill?' (see DE-9IM)
- Geometry Constructors: Creates new geometries, usually by specifying the vertices (points or nodes) which define the shape.

- Observer Functions: Queries which return specific information about a feature such as the location of the center of a circle

Some databases support only simplified or modified sets of these operations, especially in cases of NoSQL systems like MongoDB and CouchDB.

Spatial index

Spatial indices are used by spatial databases (databases which store information related to objects in space) to optimize spatial queries. Conventional index types do not efficiently handle spatial queries such as how far two points differ, or whether points fall within a spatial area of interest. Common spatial index methods include:

- Grid (spatial index)
- Z-order (curve)
- Quadtree
- Octree
- UB-tree
- R-tree: Typically the preferred method for indexing spatial data.[*citation needed*] Objects (shapes, lines and points) are grouped using the minimum bounding rectangle (MBR). Objects are added to an MBR within the index that will lead to the smallest increase in its size.
- R+ tree
- R* tree
- Hilbert R-tree
- X-tree
- kd-tree
- m-tree - an m-tree index can be used for the efficient resolution of similarity queries on complex objects as compared using an arbitrary metric.

Spatial database systems

- All OpenGIS Specifications compliant products[2]
- Open source spatial databases and APIs, some of which are OpenGIS compliant[3]
- Boeing's Spatial Query Server spatially enables Sybase ASE.
- Smallworld VMDS, the native GE Smallworld GIS database
- SpatiaLite extends Sqlite with spatial datatypes, functions, and utilities.
- IBM DB2 Spatial Extender can be used to enable any edition of DB2, including the free DB2 Express-C, with support for spatial types
- Oracle Spatial
- Microsoft SQL Server has support for spatial types since version 2008
- PostgreSQL DBMS (database management system) uses the spatial extension PostGIS to implement the standardized datatype *geometry* and corresponding functions.
- Linter SQL Server supports spatial types and spatial functions according to the OpenGIS specifications.
- MySQL DBMS implements the datatype *geometry* plus some spatial functions that have been implemented according to the OpenGIS specifications.[4] However, in MySQL version 5.5 and earlier, functions that test spatial relationships are limited to working with minimum bounding rectangles rather than the actual geometries. MySQL versions earlier than 5.0.16 only supported spatial data in MyISAM tables. As of MySQL 5.0.16, InnoDB, NDB, BDB, and ARCHIVE also support spatial features.
- Neo4j - Graph database that can build 1D and 2D indexes as Btree, Quadtree and Hilbert curve directly in the graph

- AllegroGraph - a Graph database provides a novel mechanism for efficient storage and retrieval of two-dimensional geospatial coordinates for Resource Description Framework data. It includes an extension syntax for SPARQL queries
- MongoDB and RavenDB [5] support geospatial indexes in 2D
- Esri has a number of both single-user and multiuser geodatabases.
- SpaceBase [6] is a real-time spatial database.[7]
- CouchDB a document based database system that can be spatially enabled by a plugin called Geocouch
- CartoDB [8] is a cloud based geospatial database on top of PostgreSQL with PostGIS.
- StormDB [9] is an upcoming cloud based database on top of PostgreSQL with geospatial capabilities.
- SpatialDB [10] by MineRP is the world's first open standards (OGC) spatial database with spatial type extensions for the Mining Industry.[11]
- H2 supports geometry types[12] and spatial indices[13] as of version 1.3.173 (2013-07-28). An extension called H2GIS [14] available on Maven Central gives full OGC Simple Features support.

Spatial query

A **spatial query** is a special type of database query supported by geodatabases and spatial databases. The queries differ from SQL queries in several important ways. Two of the most important are that they allow for the use of geometry data types such as points, lines and polygons and that these queries consider the spatial relationship between these geometries.

Types of queries

The function names for queries differ across geodatabases. The following list contains commonly used functions built into PostGIS, a free geodatabase which is a PostgreSQL extension (the term 'geometry' refers to a point, line, box or other two or three dimensional shape):

Function prototype: *functionName (parameter(s)) : return type*

- Distance(geometry, geometry) : number
- Equals(geometry, geometry) : boolean
- Disjoint(geometry, geometry) : boolean
- Intersects(geometry, geometry) : boolean
- Touches(geometry, geometry) : boolean
- Crosses(geometry, geometry) : boolean
- Overlaps(geometry, geometry) : boolean
- Contains(geometry, geometry) : boolean
- Length(geometry) : number
- Area(geometry) : number
- Centroid(geometry) : geometry

Spatiotemporal database

A **spatiotemporal database** is a database that manages both space and time information. Common examples include:

- Tracking of moving objects, which typically can occupy only a single position at a given time.
- A database of wireless communication networks, which may exist only for a short timespan within a geographic region.
- An index of species in a given geographic region, where over time additional species may be introduced or existing species migrate or die out.
- Historical tracking of plate tectonic activity.

At first glance, spatiotemporal databases are an extension of spatial databases. A spatiotemporal database embodies spatial, temporal, and spatiotemporal database concepts, and captures spatial and temporal aspects of data and deals with

- geometry changing over time[1] and/or
- location of objects moving over invariant geometry (known variously as *moving objects databases* or real-time locating systems)

However, although there exist numerous relational databases with spatial extensions, the spatiotemporal databases are not based on the relational model for practical reasons, chiefly among them that the data is multi-dimensional and capturing complex structures and behaviours. As of 2008, there are no RDBMS products with spatiotemporal extensions. There are some products such as the open-source TerraLib which use a middleware approach storing their data in a relational database. Unlike in the pure spatial domain, there are however no official or *de facto* standards for spatio-temporal data models and their querying. In general, the theory of this area is also less well-developed. Another approach is the constraint database system such as MPLQ (Management of Linear Programming Queries).[2]

Object-based spatial database

An **object-based spatial database** is a spatial database that stores the location as objects. The object-based spatial model treats the world as surface littered with recognizable objects (e.g. cities, rivers), which exist independent of their locations.

Objects can be simple as polygons and lines, or be more complex to represent cities.

While a field-based data model sees the world as a continuous surface over which features (e.g. elevation) vary, using an object-based spatial database, it is easier to store additional attributes with the objects, such as direction, speed, etc. Using these attributes can make it easier to answer queries like "find all tanks whose speed is 10 km and oriented to north". Or "find all enemy tanks in a certain region".

Storing attributes with objects can provide better result presentation and improved manipulation capabilities in a more efficient way. In a field-based data model, this information is usually stored at different layers and it is harder to extract different information from various layers. This data model can be applied above the ER as in GERM model and GISER.

S.Shekhar introduces direction as a spatial object and presents a solution to object-direction-based queries.

Data model representation

The most common representations for the data model follow.

PostGIS

An open-source software program that adds support for geographic objects to the PostgreSQL object-relational database. PostGIS follows the Simple Features for SQL specification from the Open Geospatial Consortium.

OMT-G

Provides a UML representation for geographic applications, it can represent the concept of field, object and provides a way to differentiate between spatial relation and simple association.

GraphDB

Represents a framework of objects as classes that are partitioned into three kinds of classes: simple classes, link classes, and path classes. Objects of a simple class are on the one hand just like objects in other models. They have an object type and an object identity and can have attributes whose values are either of a data type (e.g. integer, string) or of an object type (that is, an attribute may contain a reference to another object). So the structure of an object is basically that of a tuple or record. On the other hand, objects of a simple class are nodes of the database graph – the whole database can also be viewed as a single graph. Objects of a link class are like objects of a simple class but additionally contain two distinguished references to source and target objects (belonging to simple classes), which makes them edges of the database graph. Finally, an object of a path class is like an object of a simple class, but contains additionally a list of references to node and edge objects which form a path over the database graph.

GEIS

Represent a data model to store geographic information on top of EER model, GEIS define the input data model and provide the following for data model Geometry. In the GISER model, geometry is an entity that is related to a spatial object by the relationship determines shape of. Additional entities represent the primitives such as points, lines, and polygons as proposed in related models. Topology. Topology is a property belonging to a spatial object and that property remains unaltered even when the object deforms. An example is a road network. The two nodes in the

network thus remain connected even if the path between the nodes is changed by road construction. In order to represent the topology, the basic primitives such as networks (i.e., graphs) and partitions are provided. Additional primitives can be added on lines of the Worboy model, This system support representation for stored data.

Oracle spatial

Oracle spatial is a component of enterprise Oracle 10g and provides support to stores object such as road on top of the current implentend construction but it used network data model to store geographic data as nodes and links (a graph representation) with each node or links it has a set of attributes. For example a route object can be added to the database.

GRASS GIS

It supports raster and some set of vector representation.

Tuple-versioning

Tuple-versioning (also called **point-in-time**) is a mechanism used in a relational database management system to store past states of a relation. Normally, only the current state is captured.

Using tuple-versioning techniques, typically two values for time are stored along with each tuple: a start time and an end time. These two values indicate the validity of the rest of the values in the tuple.

Typically when tuple-versioning techniques are used, the current tuple has a valid start time, but a null value for end time. Therefore, it is easy and efficient to obtain the current values for all tuples by querying for the null end time.

A single query that searches for tuples with start time less than, and end time greater than, a given time (where null end time is treated as a value greater than the given time) will give as a result the valid tuples at the given time.

For example, if a person's job changes from Engineer to Manager, there would be two tuples in an Employee table, one with the value Engineer for job and the other with the value Manager for job. The end time for the Engineer tuple would be equal to the start time for the Manager tuple.

The pattern known as log trigger uses this technique to automatically store historical information of a table in a database.

Valid time

Valid time (VT), a concept originated by Richard T. Snodgrass and his doctoral student, is used in temporal databases.[1] It denotes the time period during which a database fact was, is, or will be valid in the modeled reality. As of December 2011, ISO/IEC 9075, Database Language SQL:2011 Part 2: SQL/Foundation included clauses in table definitions to define "application-time period tables" (that is, valid-time tables).

In a database table valid time is often represented by two extra table-columns *StartVT* and *EndVT*. The time interval is closed at its lower bound and open at its upper bound.

Example:

Date	What happened in the real world	Database Action	What the database shows
April 3, 1975	John is born	Nothing	There is no person called John Doe
April 4, 1975	John's father officially reports John's birth	Inserted:Person(John Doe, Smallville)	John Doe lives in Smallville
August 26, 1994	After graduation, John moves to Bigtown, but forgets to register his new address	Nothing	John Doe lives in Smallville
December 26, 1994	Nothing	Nothing	John Doe lives in Smallville
December 27, 1994	John registers his new address	Updated:Person(John Doe, Bigtown)	John Doe lives in Bigtown
April 1, 2001	John dies	Deleted:Person(John Doe)	There is no person called John Doe

Valid time is the time for which a fact is true in the real world. In the example above, the Person table gets two extra fields, Valid-From and Valid-To, specifying when a person's address was valid in the real world. On April 4, 1975 John's father proudly registered his son's birth. An official will then insert a new entry to the database stating that John lives in Smallville from April, 3rd. Notice that although the data was inserted on the 4th, the database states that the information is valid since the 3rd. The official does not yet know if or when John will ever move to a better place so in the database the Valid-To is filled with infinity (∞). Resulting in this entry in the database:

```
Person(John Doe, Smallville, 3-Apr-1975, ∞).
```

December 27, 1994 John reports his new address in Bigtown where he has been living since August 26, 1994. The Bigtown official does not change the address of the current entry of John Doe in the database. He adds a new one:

```
Person (John Doe, Big Town, 26-Aug-1994, ∞).
```

The original entry Person (John Doe, Smallville, 3-Apr-1975, ∞) is then updated (not removed!). Since it is now known that John stopped living in Smallville on August 26, 1994 the Valid-To entry can be filled in. The database now contains two entries for John Doe

```
Person(John Doe, Smallville, 3-Apr-1975, 26-Aug-1994).
```

```
Person(John Doe, Bigtown, 26-Aug-1994, ∞).
```

When John dies the database is once more updated. The current entry will be updated stating that John does not live in the Bigtown any longer. No new entry is being added because officials never report heaven as a new address. The database now looks like this

```
Person(John Doe, Smallville, 3-Apr-1975, 26-Aug-1994).
```

Person(John Doe, Bigtown, 26-Aug-1994, 1-Apr-2001).

Transaction time

Transaction time (TT), a concept originated by Richard T. Snodgrass and his doctoral student, is used in temporal databases. It denotes the time period during which a fact stored in the database is considered to be true; example. As of December 2011, ISO/IEC 9075, Database Language SQL:2011 Part 2: SQL/Foundation included clauses in table definitions to define "system-versioned tables" (that is, transaction-time tables).

In a database table transaction time is often represented by two extra table-columns *StartTT* and *EndTT*. The time interval is closed at its lower bound and open at its upper bound.

When the ending transaction time is unknown, it may be considered as "Until Closed". Academic researchers and some RDBMS have represented "Until Closed" with the largest timestamp supported or the keyword "forever". This convention is not technically precise.

Geospatial metadata

Geospatial metadata (also **geographic metadata**, or simply **metadata** when used in a geographic context) is a type of metadata that is applicable to objects that have an explicit or implicit geographic extent, in other words, are associated with some position on the surface of the Globe. Such objects may be stored in a geographic information system (GIS) or may simply be documents, datasets, images or other objects, services, or related items that exist in some other native environment but whose features may be appropriate to describe in a (geographic) metadata catalogue (may also be known as a data directory, data inventory, etc.).

Definition

ISO 19115 "**Geographic Information - Metadata**"[1] from ISO/TC 211, the current "best practice" standard for geospatial metadata, does not in fact provide a definition of geospatial (or geographic) metadata; however, uses the following wording in its "scope" section:

"*This International Standard provides information about the identification, the extent, the quality, the spatial and temporal schema, spatial reference, and distribution of digital geographic data.*"

A little further, it is stated: "*Though this International Standard is applicable to digital data, its principles can be extended to many other forms of geographic data such as maps, charts, and textual documents as well as non-geographic data.*"

The U.S. FGDC (Federal Geographic Data Committee) describes (geospatial) metadata as follows:

"*A metadata record is a file of information, usually presented as an XML document, which captures the basic characteristics of a data or information resource. It represents the who, what, when, where, why and how of the resource. Geospatial metadata are used to document geographic digital resources such as Geographic Information System (GIS) files, geospatial databases, and earth imagery. A geospatial metadata record includes core library catalog elements such as Title, Abstract, and Publication Data; geographic elements such as Geographic Extent and*

Projection Information; and database elements such as Attribute Label Definitions and Attribute Domain Values."[2]

History

The growing appreciation of the value of geospatial metadata through the 1980s and 1990s led to the development of a number of initiatives to collect metadata according to a variety of formats either within agencies, communities of practice, or countries/groups of countries. For example, NASA's "DIF" metadata format was developed during an Earth Science and Applications Data Systems Workshop in 1987,[3] and formally approved for adoption in 1988. Similarly, the U.S. FGDC developed its geospatial metadata standard over the period 1992-1994.[4] The Spatial Information Council of Australia and New Zealand (ANZLIC), a combined body representing spatial data interests in Australia and New Zealand, released version 1 of its "metadata guidelines" in 1996.[5] ISO/TC 211 undertook the task of harmonizing the range of formal and *de facto* standards over the approximate period 1999-2002, resulting in the release of ISO 19115 "**Geographic Information - Metadata**" in 2003. As of 2011[6] individual countries, communities of practice, agencies, etc. have started re-casting their previously-used metadata standards as "profiles" or recommended subsets of ISO 19115, optionally with the inclusion of additional metadata elements as formal extensions to the ISO standard. The growth in popularity of Internet technologies and data formats, such as Extensible Markup Language (XML), during the 1990s led to the development of mechanisms for exchanging geographic metadata on the Web. In 2004, the Open Geospatial Consortium released the current version (3.1) of Geography Markup Language (GML), an XML grammar for expressing geospatial features and corresponding metadata. With the growth of the Semantic Web in the 2000s, the geospatial community has begun to develop ontologies for representing semantic geospatial metadata. Some examples include the Hydrology and Administrative ontologies [7] developed by the Ordnance Survey in the United Kingdom.

ISO 19115: Geographic information - Metadata

ISO 19115 is a standard of the International Organization for Standardization (ISO).[8] The standard is part of the ISO geographic information suite of standards (19100 series). ISO 19115 and its parts defines how to describe geographical information and associated services, including contents, spatial-temporal purchases, data quality, access and rights to use.

The objective of this International Standard is to provide a clear procedure for the description of digital geographic datasets so that users will be able to determine whether the data in a holding will be of use to them and how to access the data. By establishing a common set of metadata terminology, definitions and extension procedures, this standard will promote the proper use and effective retrieval of geographic data.

ISO 19139 Geographic information Metadata XML schema implementation

ISO 19139[9] provides the XML implementation schema for ISO 19115 specifying the metadata record format and may be used to describe, validate, and exchange geospatial metadata prepared in XML.[10]

The standard is part of the ISO geographic information suite of standards (19100 series), and provides a spatial metadata XML (spatial metadata eXtensible Mark-up Language (smXML)) encoding, an XML schema implementation derived from ISO 19115, Geographic information – Metadata. The metadata includes information about the identification, constraint, extent, quality, spatial and temporal reference, distribution, lineage, and maintenance of the digital geographic dataset.

Metadata directories

Also known as metadata catalogues or data directories.

(need discussion of, and subsections on GCMD, FGDC metadata gateway, ASDD, European and Canadian initiatives, etc. etc.)

- GCMD [11] - Global Change Master Directory's goal is to enable users to locate and obtain access to Earth science data sets and services relevant to global change and Earth science research. The GCMD database holds more than 20,000 descriptions of Earth science data sets and services covering all aspects of Earth and environmental sciences.
- ECHO [12] - The EOS Clearing House (ECHO) is a spatial and temporal metadata registry, service registry, and order broker. It allows users to more efficiently search and access data and services through the Reverb Client [13] or Application Programmer Interfaces (APIs). ECHO stores metadata from a variety of science disciplines and domains, totalling over 3400 Earth science data sets and over 118 million granule records.
- GoGeo [14] - GoGeo is a service run by EDINA (University of Edinburgh) and is supported by Jisc. GoGeo allows users to conduct geographically targeted searches to discover geospatial datasets. GoGeo searches many data portals from the HE and FE community and beyond. GoGeo also allows users to create standards compliant metadata through its Geodoc metadata editor.

Geospatial metadata tools

There are many commercial GIS or geospatial products that support metadata viewing and editing on GIS resources. For example, ESRI's ArcGIS Desktop, SOCET GXP, Autodesk's AutoCAD Map 3D 2008 and Intergraph's GeoMedia support geospatial metadata extensively.

GeoNetwork opensource [15] is a comprehensive Free and Open Source Software solution to manage and publish geospatial metadata and services based on international metadata and catalog standards. The software is part of the Open Source Geospatial Foundation's software stack.

GeoCat Bridge [16] allows to edit, validate and directly publish metadata from ArcGIS Desktop to GeoNetwork [15] (and generic CSW catalogs) and publishes data as map services on GeoServer [17]. Several metadata profiles are supported.

Time series database

A **time series database server (TSDS)** is a software system that is optimized for handling time series data, arrays of numbers indexed by time (a datetime or a datetime range). In some fields these *time series* are called profiles, curves, or traces. A time series of stock prices might be called a price curve. A time series of energy consumption might be called a load profile. A log of temperature values over time might be called a temperature trace. Despite the disparate names, many of the same mathematical operations, queries, or database transactions are useful for analysing all of them. And the implementation of a database that can correctly, reliably, and efficiently implement these operations must be specialized for time-series data. Despite this specialized treatment, TSDSs are nonetheless subject to Brewer's Theorem[1] which states that CAP (Consistency, Availability, Partitionability) is a spectrum of capabilities and not a single achievable requirement, at least for large transaction bandwidth and large data sets.[2]

TSDSs are databases that are optimized for time series data. Software with complex logic or business rules and high transaction volume for time series data are not practical with the alternative to TSDS, relational database management systems. Flat file databases are not a viable option either, if the data and transaction volume reaches a maximum threshold determined by the capacity of individual servers (processing power and storage capacity). Queries for historical data, replete with time ranges and roll ups and arbitrary time zone conversions are difficult in a relational database. Compositions of those rules are even more difficult. This is a problem compounded by the free nature of relational systems themselves. Many relational systems are often not modelled correctly with respect to time series data. TSDS on the other hand impose a model and this allows them to provide more features for doing so.

Ideally, these repositories are often natively implemented using specialized database algorithms. However, it is possible to store time series as binary large objects (BLOBs) in a *relational database* or by using a *VLDB* approach coupled with a pure *star schema*. Efficiency is often improved if time is treated as a discrete quantity rather than as a continuous mathematical dimension. Database joins across multiple time series data sets is only practical when the time tag associated with each data entry spans the same set of discrete times for all data sets across which the join is performed.[3]

Overview

The TSDS allows users to create, enumerate, update and destroy various time series and organize them in some fashion. These series may be organized hierarchically and optionally have companion metadata available with them. The server often supports a number of basic calculations that work on a series as a whole, such as multiplying, adding, or otherwise combining various time series into a new time series. They can also filter on arbitrary patterns defined by the day of the week, low value filters, high value filters, or even have the values of one series filter another. Some TSDSs also build in a wealth of statistical functions.

For example, consider the following hypothetical "time series" or "profile" expression:

```
select nymex/gold_price * nymex/gold_volume
```

To analyze this, the TSDS would join the two series nymex/gold_price and nymex/gold_volume based on the overlapping areas of time for each, multiply the values where they intersect, and then output a single composite time series.

Obviously, more complex expressions are allowed. TSDSs often allow users to manage a repository of filters or masks that specify in some way a pattern based on the day of a week and a set of holidays. In this way, one can readily assemble time series data. Assuming such a filter exists, one might hypothetically write

```
select onpeak( cellphoneusage )
```

which would extract out the time series of cellphoneusage that only intersects that of 'onpeak'. Some systems might generalize the filter to be a time series itself.

This syntactical simplicity drives the appeal of the TSDS. For example, a simple utility bill might be implemented using a query such as:

```
select max( onpeak( powerusagekw ) ) * demand_charge;

select sum( onpeak( powerusagekwh ) ) * energy_charge;
```

TSDS also generally have conversions to and from specific time zones implemented at the server level.

Example

A workable implementation of a time series database can be easily deployed in a conventional SQL-based relational database provided that the database software supports both binary large objects (BLOBs) and user-defined functions. SQL statements that operate on one or more time series quantities on the same row of a table or join can easily be written, as the user-defined time series functions operate comfortably inside of a SELECT statement. However, time series functionality such as a SUM function operating in the context of a GROUP BY clause cannot be easily achieved.

Specialized database systems designed for TSDS are often dubbed *NoSQL*, because of their break from SQL, the language of relational database management system queries. Some example database software packages optimized for dealing with large volumes of time series data include:

- Apache Accumulo
- Apache Cassandra
- CouchDB
- Couchbase Server
- FAME
- HBase (Hadoop)
- InfluxDB [4]

- IBM Informix
- OpenTSDB [5]
- SiteWhere [6]
- Riak
- Redis
- tsdb[7]
- TempoDB [8]
- Treasure Data [9]

Operational historian

Operational Historian refers to a database software application that logs or historizes time-based process data. Historian software is used to record trends and historical information about industrial processes for future reference. It captures plant management information about production status, performance monitoring, quality assurance, tracking and genealogy, and product delivery with enhanced data capture, data compression, and data presentation capabilities.

Operational Historians are like Enterprise Historians but differ in that they are used by engineers on the plant floor rather than by business processes. They are typically cheaper, lighter weight, and easier to use and reconfigure than enterprise historians. Having an operational historian enables "at the source" analysis of the historical data that is not typically possible with enterprise historians.

Typically, these applications offer two layers of data access: through a dedicated SDK (sometimes in two different flavours: full administration API and high-speed read/write API), as well as user front-end tools (for instance, administration panels, engineering consoles or portal-like web clients).

Due to the fact that these applications are designed to fulfil specific operation time requirements, their marketing materials often indicate that these are real-time database systems.[1] However, since such performance measurements are often executed for atomic operations (especially write operations), not necessarily whole transactions, not all of the operational historians must be in fact real-time databases.

Usual challenges the operational historians must address are as follows:

- data collection from real-time external systems,
- storage and archiving of very large volumes of data,
- tag organisation (typically time series, where a single sample contains the information about the time stamp, the value and the sample quality),
- basic data limit monitoring (alarms) and user prompts (messages),
- performance of read/write operations.

Data Access

As opposed to enterprise historians, the data access layer in the operational historians is designed to offer sophisticated data fetching modes without complex information analysis facilities. The following settings are typically available for data access operations:

- Data scope (single point, history based on time range, history based on sample count),
- Request modes (raw data, last-known value, aggregation, interpolation),
- Sampling (single point, all points without sampling, all points with interval sampling),
- Data omission (based on the sample quality, based on the sample value, based on the count).

Even though the operational historians are rarely relational database management systems, they often offer SQL-based interface to query the database. In most of such implementations, the dialect does not follow SQL standard in order to provide syntax for specifying data access operations parameters.

Implementations

Such systems are available from e.g.:

Special Databases

Real-time database

A **real-time database** is a database system which uses real-time processing to handle workloads whose state is constantly changing.[1] This differs from traditional databases containing persistent data, mostly unaffected by time. For example, a stock market changes very rapidly and is dynamic. The graphs of the different markets appear to be very unstable and yet a database has to keep track of current values for all of the markets of the New York Stock Exchange.[2] Real-time processing means that a transaction is processed fast enough for the result to come back and be acted on right away.[3] Real-time databases are useful for accounting, banking, law, medical records, multi-media, process control, reservation systems, and scientific data analysis.[4]

Overview

Real-time databases are traditional databases that use an extension to give the additional power to yield reliable responses. They use timing constraints that represent a certain range of values for which the data are valid. This range is called temporal validity. A conventional database cannot work under these circumstances because the inconsistencies between the real world objects and the data that represents them are too severe for simple modifications. An effective system needs to be able to handle time-sensitive queries, return only temporally valid data, and support priority scheduling. To enter the data in the records, often a sensor or an input device monitors the state of the physical system and updates the database with new information to reflect the physical system more accurately. [5] When designing a real-time database system, one should consider how to represent valid time, how facts are associated with real-time system. Also, consider how to represent attribute values in the database so that process transactions and data consistency have no violations.

When designing a system, it is important to consider what the system should do when deadlines are not met. For example, an air-traffic control system constantly monitors hundreds of aircraft and makes decisions about incoming flight paths and determines the order in which aircraft should land based on data such as fuel, altitude, and speed. If any of this information is late, the result could be devastating. To address issues of obsolete data, the timestamp can support transactions by providing clear time references.

Preserving data consistency

Although the real-time database system may seem like a simple system, problems arise during overload when two or more database transactions require access to the same portion of the database. A transaction is usually the result of an execution of a program that accesses or changes the contents of a database. [6] A transaction is different from a stream because a stream only allows read-only operations, and transactions can do both read and write operations. This means in a stream, multiple users can read from the same piece of data, but they cannot both modify it. [7] A database must let only one transaction operate at a time to preserve data consistency. For example, if two students demand to take the remaining spot for a section of a class and they hit submit at the same time, only one student should be able to register for it. [8]

Real-time databases can process these requests utilizing scheduling algorithms for concurrency control, prioritizing both students' requests in some way. Throughout this article, we assume that the system has a single processor, a disk based database, and a main memory pool.[9]

In real-time databases, deadlines are formed and different kinds of systems respond differently to data that does not meet its deadline. In a real-time system, each transaction uses a timestamp to schedule the transactions. [10] A priority mapper unit assigns a level of importance to each transaction upon its arrival in the database system that is dependent on how the system views times and other priorities. The timestamp method on relies on the arrival time in the system. Researchers indicate that for most studies, transactions are sporadic with unpredictable arrival times. For example, the system gives an earlier request deadline to a higher priority and a later deadline to a lower priority.[11] Below is a comparison of different scheduling algorithms.

Earliest Deadline

PT = DT — The value of a transaction is not important. An example is a group of people calling to order a product.

Highest Value

PT = 1/VT — The deadline is not important. Some transactions should get to CPU based on criticalness, not fairness. This is an example of least slack that can wait the least amount of time. If the telephone switchboards were overloaded, people who call 911 should get priority.[12]

Value inflated deadline

PT = DT/VT — Gives equal weight to deadline and values based on scheduling. An example is registering for classes where the student selects a block of classes that he wishes to take and presses submit. In this scenario, higher priorities often take up precedence. A school registration system probably uses this technique when the server receives two registration transactions. If one student had 22 credits and the other had 100 credits, the person with 100 credits would take priority (Value based scheduling).

Timing constraints and deadlines

A system that correctly perceives the serialization and timing constraints associated with transactions with soft or firm deadlines, takes advantage of absolute consistency.[13] Another way of making sure that data is absolute is using relative constraints. Relative constraints ensure transactions enter into the system at the same time as the rest of the group that the data transaction is associated with. Using the mechanisms of absolute and relative constraints greatly ensures the accuracy of data.

An additional way of dealing with conflict resolution in a real-time database system besides deadlines is a wait policy method. This process helps ensure the latest information in time critical systems. The policy avoids conflict by asking all non-requesting blocks to wait until the most essential block of data is processed.[14] While studies in labs have found that data-deadline based policies do not improve performance significantly, the forced wait policy can improve performance by 50 percent.[15] The forced wait policy may involve waiting for higher priority transactions to process in order to prevent deadlock. Another example of when data can be delayed is when a block of data is about to expire. The forced wait policy delays processing until the data is updated using new input data. The latter method helps increase the accuracy of the system and can cut down on the number of necessary processes that are aborted. [16] Generally relying on wait policies is a not optimal.[17]

It is necessary to discuss the formation of deadlines. Deadlines are the constraints for soon-to-be replaced data accessed by the transaction. Deadlines can be either observant or predictive.[18] In an observant deadline system, all unfinished transactions are examined and the processor determines whether any had met its deadline.[19] Problems arise in this method because of variations caused by seek time variations, buffer management and page faults (An Overview of Real-Time Database Systems). A more stable way of organizing deadlines is the predictive method. It builds a candidate schedule and determines if a transaction would miss its deadline under the schedule.[20]

The type of response to a missed deadline depends on whether the deadline is hard, soft, or firm. Hard deadlines require that each data packet reach its destination before the packet has expired and if not, the process could be lost, causing a possible problem. Problems like these are not very common because omnipotence of the system is required

before assigning deadlines to determine worst case. This is very hard to do and if something unexpected happens to the system such as a minute hardware glitch, it could throw the data off. For soft or firm deadlines, missing a deadline can lead to a degraded performance but not a catastrophe.[21] A soft deadline meets as many deadlines as possible. However, no guarantee exists that the system can meet all deadlines. Should a transaction miss its deadline, the system has more flexibility and the transaction may increase in importance. Below is a description of these responses:

Hard deadline: If not meeting deadlines creates problems, a hard deadline is best. It is periodic, meaning that it enters the database on a regular rhythmic pattern. An example is data gathered by a sensor. These are often used in life critical systems.[22]

Firm deadline: Firm deadlines appear to be similar to hard deadlines yet they differ from hard deadlines because firm deadlines measure how important it is to complete the transaction at some point after the transaction arrives. Sometimes completing a transaction after its deadline has expired may be harmful or not helpful, and both the firm and hard deadlines consider this. An example of a firm deadline is an autopilot system.[23]

Soft deadline: If meeting time constrains is desirable but missing deadlines do not cause serious damage, a soft deadline may be best. It operates on an aperiodic or irregular schedule. In fact, the arrival of each time for each task is unknown. An example is an operator switchboard for a telephone.[24]

Hard deadline processes abort transactions that have passed the deadline, improving the system by cleaning out clutter that needs to be processed. Processes can clear out not only the transactions with expired deadlines but also transactions with the longest deadlines, assuming that once they reach the processor they would be obsolete. This means other transactions should be of higher priority. In addition, a system can remove the least critical transactions. When I was pre-selecting classes on during a high traffic period, a field in the database can become so busy with registration requests that it was unavailable for a while and the result of my transaction was a display of the SQL query sent and a message that said that the data is currently unavailable. This error is caused by the checker, a mechanism that checks the condition of the rules, and the rule that occurred before it. [25]

The goal of scheduling periods and deadlines is to update transactions guaranteed to complete before their deadline in such a way that the workload is minimal. With large real-time databases, buffering functions can help improve performance tremendously. A buffer is part of the database that is stored in main memory to reduce transaction response time. In order to reduce disk input and output transactions, a certain number of buffers should be allocated. [26] Sometimes multiversions are stored in buffers when the data block the transaction needs is currently in use. Later, the database has the data appended to it. Different strategies allocate buffers and must balance between taking an excessive amount of memory and having everything in one buffer that it has to search for. The goal is to eliminate search time and distribute the resources between buffer frames in order to access data quickly. A buffer manager is capable of allocating more memory, if necessary, to improve response time. The buffer manager can even determine whether a transaction that it has should advance. Buffering can improve speed in real-time systems.[27]

Examples

Following is a list of real time database applications and architecture schemes produced and used by both universities and corporations. [28]

Eaglespeed-RTDB

Clustra

Timesten

Empress

eXtremeDB

SolidDB

RODAIN (Real-Time Object-Oriented Database Architecture for Intelligent Networks)

M2RTSS

RT-CARAT
REACH (Real-time Active and Heterogeneous Mediator System Project)
STRIP (Stanford Real-time Information Processor)

Future database systems

Traditional databases are persistent but are incapable of dealing with dynamic data that constantly changes. Therefore, another system is needed. Real-time databases may be modified to improve accuracy and efficiency and to avoid conflict, by providing deadlines and wait periods to insure temporal consistency. Real-time database systems offer a way of monitoring a physical system and representing it in data streams to a database. A data stream, like memory, fades over time. In order to guarantee that the freshest and most accurate information is recorded there are a number of ways of checking transactions to make sure they are executed in the proper order. An online auction house provides an example of a rapidly changing database.

Now database systems are faster than they were in the past. In the future, we can look forward to even faster database systems. Although we have faster systems now, an effort to reduce misses and tardy times will still be beneficial. The ability to process results in a timely and predictable manner will always be more important than fast processing. Fast processing that is misapplied is not helpful for real-time database systems. Transactions that run faster still sometimes block in such a way that they have to be aborted and restarted. In fact, faster processing hurts some real-time applications because increased speed brings more complexity and more of a chance for problems caused by a variance of speed. Faster processing makes it harder to determine which deadlines have been met successfully. [29] With future database systems running even faster than ever, there is a need to do more studies so we can continue to have efficient systems. [30]

The amount of research studying real-time database systems will increase because of commercial applications such as web based auction houses like e-bay. More developing countries are expanding their phone systems, and the number of people with cell phones in the United States as well as other places in the world continues to grow. Also likely to spur real-time research is the exponentially increasing speed of the microprocessor. This also enables new technologies such as web-video conferencing and instant messenger conversations in sound and high-resolution video, which are reliant on real-time database systems. Studies of temporal consistency result in new protocols and timing constraints with the goal of handling real-time transactions more effectively.[31]

In-memory database

An **in-memory database** (**IMDB**; also **main memory database system** or **MMDB** or **memory resident database**) is a database management system that primarily relies on main memory for computer data storage. It is contrasted with database management systems that employ a disk storage mechanism. Main memory databases are faster than disk-optimized databases since the internal optimization algorithms are simpler and execute fewer CPU instructions. Accessing data in memory eliminates seek time when querying the data, which provides faster and more predictable performance than disk.

In applications where response time is critical, such as telecommunications network equipment and mobile advertising networks, main memory databases are often used. IMDBs have gained a lot of traction, especially in the data analytics space, starting mid-2000s mainly due to cheaper RAM.

With the introduction of NVDIMM technology, in-memory databases will now be able to run at full speed and maintain data in the event of power failure.[1][2][3]

Storage memory

Another variation is to have large amounts of nonvolatile memory in the server. For example Flash memory chips as addressable memory rather than structured as disk arrays. A database in this form of memory combines very fast access speed with persistence over reboots and power losses.[4]

Products

Name	Developer	License	Description/Notes
ActiveSpaces	TIBCO Software	Proprietary with developer download	For Java/.Net./C, distributed, hybrid, event enabled, NewSQL
ALTIBASE HDB	Altibase Corporation	Proprietary	"Hybrid DBMS" that combines an in-memory database with a conventional disk-resident database
BigMemory	Terracotta, Inc. (Software AG)	Proprietary (free editions)	
Datablitz (formerly Dali)	Bell Labs (Alcatel-Lucent)	Proprietary	Dali prototype was developed for in-house Bell Labs needs
DB2 BLU	IBM	Proprietary	IBM DB2 for Linux, UNIX and Windows supports Dynamic In-memory (in-memory columnar processing) Parallel Vector Processing, Actionable Compression, and Data Skipping technologies, collectively called IBM BLU Acceleration by IBM. Released in June 2013.
Ehcache	Terracotta, Inc. (Software AG)	Open source (Apache License)	For Java, distributed
EXASolution	EXASOL	Proprietary	Relational (SQL over ODBC, JDBC, or ADO.NET), multi-dimensional (MDX over ODBO or XMLA); EXASOL leads the well-respected international TPC-H benchmark,[5] since 2008, in the datavolume-based categories 100GB, 300GB, 1TB, 3TB, and 10TB; EXASolution architecture: shared-nothing, column-store, in-memory database
eXtremeDB	McObject	Proprietary	Cross-platform, including Linux, Windows, RTOS and server platforms. Interfaces include type-safe, native C/C++; native Java & .NET; SQL/ODBC/JDBC. Specialized editions for clustering, high availability, 64-bit support, hybrid (in-memory and persistent) storage, and more. eXtremeDB Financial Edition implements columnar data handling, vector-based statistical function library, integrated performance monitoring.

H2 (DBMS)	H2	Mozilla Public License or Eclipse Public License	For Java
Hazelcast	Hazelcast Team	Open source (Apache License 2.0)	For Java, NoSQL, distributed
Kognitio Analytical Platform	Kognitio, Limited	Proprietary	Development of an in-memory database, specialized for analytical workloads was started at White Cross Systems, Limited in 1988. The first beta release of that system was in 1989. It was based on the INMOS Transputer. The first full production release was offered in 1992. White Cross merged in 2005 with Kognitio, Limited in the United Kingdom and is currently marketing version 8 of the same code base as the "Kognitio Analytical Platform".
MemSQL	MemSQL, Inc.	Proprietary	SQL relational
Microsoft COM+ IMDB	Microsoft Corporation	Proprietary	Defunct
Microsoft SQL Server	Microsoft	Proprietary	SQL Server 2012 contains an in-memory technology called xVelocity column store indexes targeted for data warehouse workload. The recently announced SQL Server 2014 will contain a in-memory technology with the code name Hekaton targeted for OLTP type workloads.
Oracle Coherence	Oracle Corporation	Proprietary with developer download	For Java, relational, distributed
Oracle Exalytics	Oracle Corporation	Proprietary	Appliance
Polyhedra	ENEA AB (previously Perihelion Software)	Proprietary, with a free to use edition (Polyhedra Lite)	Relational (SQL, ODBC, JDBC) in-memory database system originally developed for use in SCADA and embedded systems, but used in a variety of other applications including financial systems. Supports data durability via snapshots and journal logging, and high availability via a hot-standby. First release was in 1993; 8.7 released in March 2013. Polyhedra Lite was released under a free-to-use license in 2012.
SAP HANA	SAP AG	Proprietary	SAP HANA, short for 'High Performance Analytic Appliance' is an in-memory, column-oriented, relational database management system written in C, C++
solidDB	IBM	Proprietary	Relational
SQLFire	VMware	Proprietary	Relational, distributed, NewSQL
TimesTen	Oracle Corporation	Proprietary	Standalone database or in-memory cache for Oracle Database
UnQLite Embedded Database	Symisc Systems	BSD, SPL	UnQLite has support for in-memory databases as well on-disk databases using the same API with pluggable run-time interchangeable storage engines (B+tree, Hash, etc.)
VoltDB	VoltDB Inc.	Open source (GPL) / Proprietary	Relational; implements H-Store design
WebDNA	WebDNA Software Corporation	Freeware	Robust hybrid in-memory database system and scripting language designed for the World Wide Web. Resilience is provided by both in-memory and on-disk tables in a single database.
Xeround	Xeround Inc.	Proprietary/Not for sale, service only	Cloud database

Many DBMS support in-memory-only storage engines, including:

- MySQL
- Adaptive Server Enterprise
- Raima

Probabilistic database

Most real databases contain data whose correctness is uncertain. In order to work with such data, there is a need to quantify the integrity of the data. This is achieved by using probabilistic databases.

A **probabilistic database** is an uncertain database in which the possible worlds have associated probabilities. Probabilistic database management systems are currently an active area of research. "While there are currently no commercial probabilistic database systems, several research prototypes exist..."[1]

Probabilistic databases distinguish between the logical data model and the physical representation of the data much like relational databases do in the ANSI-SPARC Architecture. In probabilistic databases this is even more crucial since such databases have to represent very large numbers of possible worlds, often exponential in the size of one world (a classical database), succinctly.[2][3]

Terminology

In a probabilistic database, each data item - relation, tuple and value that an attribute can take - is associated with a probability $\in (0,1]$, with 0 representing that the data is certainly incorrect, and 1 representing that it is certainly correct.

Possible Worlds

A probabilistic database could exist in multiple states. For example, if we are uncertain about the existence of a tuple in the database, then the database could be in two different states with respect to that tuple - the first state contains the tuple, while the second one does not. Similarly, if an attribute can take one of the values x, y or z, then the database can be in three different states with respect to that attribute.

Each of these *states* is called a possible world.

Consider the following database:

An Incomplete Database

A	B
a1	b1
a2	b2
a3	{b3,b3′,b3″}

(Here *{b3,b3′,b3″}* denotes that the attribute can take any of the values *b3*,*b3′* or *b3″*)

- Let us assume that we are uncertain about the first tuple, certain about the second tuple and uncertain about the value of attribute **B** in the third tuple.

Then the actual state of the database may or may not contain the first tuple (depending on whether it is correct or not). Similarly, the value of the attribute **B** may be *b3*,*b3′* or *b3″*.

Consequently, the possible worlds corresponding to the database are as follows:

World 1

A	B
a1	b1
a2	b2
a3	b3

World 2

A	B
a1	b1
a2	b2
a3	b3′

World 3

A	B
a1	b1
a2	b2
a3	b3″

World 4

A	B
a2	b2
a3	b3

World 5

A	B
a2	b2
a3	b3′

World 6

A	B
a2	b2
a3	b3″

Types of Uncertainties

There are essentially two kinds of uncertainties that could exist in a probabilistic database, as described in the table below:

Types of Uncertainties

Tuple-level uncertainty	Attribute-level uncertainty
Here, we are not sure if a tuple is correct or not, that is, whether it should exist in the database or not.	Here, we are not sure about the values that an attribute of a tuple can take, that is, it could take one of the several possible values.
Corresponding to each uncertain tuple, there are two possible worlds: one which includes the tuple while the other which does not.	Corresponding to each uncertain attribute which can take one of the values $a_1,...,a_n$, there are n possible worlds.
Tuple-level uncertainty can be seen as a boolean random variable associated with each uncertain tuple.	Attribute-level uncertainty can be seen as a random variable associated with each uncertain attribute which can take values $a_1,...,a_n$.

By assigning values to random variables associated with the data items, we can represent different possible worlds.

Deductive database

A **Deductive database** is a database system that can make deductions (i.e., conclude additional facts) based on rules and facts stored in the (deductive) database. Datalog is the language typically used to specify facts, rules and queries in deductive databases. Deductive databases have grown out of the desire to combine logic programming with relational databases to construct systems that support a powerful formalism and are still fast and able to deal with very large datasets. Deductive databases are more expressive than relational databases but less expressive than logic programming systems. In recent years, deductive databases such as Datalog have found new application in data integration, information extraction, networking, program analysis, security, and cloud computing.[1]

Deductive databases and logic programming

Deductive databases reuse a large number of concepts from logic programming; rules and facts specified in the deductive database language Datalog look very similar to those in Prolog. However important differences between deductive databases and logic programming:

- Order sensitivity and procedurality: In Prolog, program execution depends on the order of rules in the program and on the order of parts of rules; these properties are used by programmers to build efficient programs. In database languages (like SQL or Datalog), however, program execution is independent of the order of rules and facts.
- Special predicates: In Prolog, programmers can directly influence the procedural evaluation of the program with special predicates such as the cut, this has no correspondence in deductive databases.
- Function symbols: Logic Programming languages allow function symbols to build up complex symbols. This is not allowed in deductive databases.
- Tuple-oriented processing: Deductive databases use set-oriented processing while logic programming languages concentrate on one tuple at a time.

Deductive language

A **deductive language** is a computer programming language in which the program is a collection of predicates ('facts') and rules that connect them. Such a language is used to create knowledge based systems or expert systems which can deduce answers to problems set them by applying the rules to the facts they have been given. An example of a deductive language is Prolog, or it's database-query cousin, Datalog.

Mobile database

--*mobile Devices database Management commonly called as Mobile Database*' is either a stationary database that can be connected to by a mobile computing device - such as smart phones or PDAs - over a mobile network, or a database which is actually carried by the mobile device. This could be a list of contacts, price information, distance travelled, or any other information.[1]

Many applications require the ability to download information from an information repository and operate on this information even when out of range or disconnected. An example of this is your contacts and calendar on the phone. In this scenario, a user would require access to update information from files in the home directories on a server or customer records from a database. This type of access and work load generated by such users is different from the traditional workloads seen in client–server systems of today.[*citation needed*]

Mobile databases are not just update of company contacts and calendars, but used in a number of industries.

Considerations

- Mobile users must be able to work without a network connection due to poor or even non-existent connections. A cache could be maintained to hold recently accessed data and transactions so that they are not lost due to connection failure. Users might not require access to truly live data, only recently modified data, and uploading of changing might be deferred until reconnected.
- Bandwidth must be conserved (a common requirement on wireless networks that charge per megabyte or data transferred).
- Mobile computing devices tend to have slower CPUs and limited battery life.
- Users with multiple devices (e.g. smartphone and tablet) need to synchronize their devices to a centralized data store. This may require application-specific automation features.[2]

This is in database theory known as "replication", and good mobile database system should provide tools for automatic replication that takes into account that others may have modified the same data as you while you were away, and not just the last update is kept, but also supports "merge" of variants.

- Users may change location geographically and on the network. Usually dealing with this is left to the operating system, which is responsible for maintaining the wireless network connection.

Products

Commercially available mobile databases include those shown on this comparison chart.

Name	Developer	Type	Description
SQL Anywhere	Sybase iAnywhere	Relational	Embedded/portable database, can synchronize with stationary database
DB2 Everyplace	IBM	Relational	Portable, can synchronize with stationary database
IBM Mobile Database	IBM	Relational	Portable/embedded small-footprint version of solidDB server
SQL Server Compact	Microsoft	Relational	Small-footprint embedded/portable database for Microsoft Windows mobile devices and desktops, supports synchronization with Microsoft SQL Server
SQL Server Express	Microsoft	Relational	Embedded database, free download
Oracle Database Lite	Oracle Corporation		Portable, can synchronize with stationary database
SQLite	D. Richard Hipp	C programming library	Public domain
SQLBase	Gupta Technologies LLC of Redwood Shores, California		
Sparksee 5 mobile [3]	Sparsity Technologies [4]	Graph database	Small-footprint embedded/portable database for Android, iOS and BB10. It allows traversals of nodes, minimum distance computations, community search, etc.

SQL Anywhere hasWikipedia:Manual of Style/Dates and numbers#Chronological items about 68% of the mobile database market.[*citation needed*]

Well Known Databases

Standard data model

A **standard data model** or industry standard data model (ISDM) is a data model that is widely applied in some industry, and shared amongst competitors to some degree. They are often defined by standards bodies, database vendors or operating system vendors.

When in use, they enable easier and faster information sharing because heterogeneous organizations have a standard vocabulary and pre-negotiated semantics, format, and quality standards for exchanged data. The standardization has an impact on software architecture as solutions that vary from the standard may cause data sharing issues and problems if data is out of compliance with the standard.

The more effective standard models have developed in the banking, insurance, pharmaceutical and automotive industries, to reflect the stringent standards applied to customer information gathering, customer privacy, consumer safety, or just in time manufacturing.

Typically these use the popular relational model of database management, but some use the hierarchical model, especially those used in manufacturing or mandated by governments, e.g., the DIN codes specified by Germany. While the format of the standard may have implementation trade-offs, the underlying goal of these standards is to make sharing of data easier.

The most complex data models known are in military use, and consortia such as NATO tend to require strict standards of their members' equipment and supply databases. However, they typically do not share these with non-NATO competitors, and so calling these 'standard' in the same sense as commercial software is probably not very appropriate.

An emerging area of standard data model is in the identity card arena, where a vast number of security engineering solutions for public spaces, e.g., airports, other public transport, hospitals, are expected soon to rely on a standard data model for identifying the card holder/user of the facility. This may contain biometric information or other data that would be standardized across an entire trade bloc, e.g., the European Union or the North American Free Trade Agreement (NAFTA). This raises many privacy and carceral state concerns. These are discussed more deeply in an article on standard user models.

Example Standard Data Models

- ISO 10303 CAE Data Exchange Standard - includes its own data modelling language, EXPRESS
- ISO 15926 Process Plants including Oil and Gas facilities Life-Cycle data
- IDEAS Group Foundation Ontology agreed by defence departments of Australia, Canada, France, Sweden, UK and USA

Suppliers and Parts database

The Suppliers and Parts database is an example relational database that is referred to extensively in the literature[*citation needed*] and described in detail in C. J. Date's "Introduction" 8ed. It is a simple database comprising three tables: Supplier, Part and Shipment, and is often used as a minimal exemplar of the interrelationships found in a database.

1. The Supplier relation[1] holds information about suppliers. The SID attribute identifies the supplier, while the other attributes each hold one piece of information about the supplier.
2. The Part relation holds information about parts. Likewise, the PID attribute identifies the part, while the other attributes hold information about the part.
3. The Shipment relation holds information about shipments. The SID and PID attributes identify the supplier of the shipment and the part shipped, respectively. The remaining attribute indicates how many parts where shipped.
    - Referential constraints known as Foreign keys ensure that these attributes can only hold values that are also found in the corresponding attributes in the Supplier and Parts relations.
    - It is assumed that only one shipment exists for each supplier/part pairing, which isn't realistic for real world scenarios. This is intentionally oversimplified for pedagogical purposes, as is the entire database.

SQL

The following SQL schema is one possible expression of the Suppliers-and-Parts database.

```
CREATE TABLE Supplier (
  SID     int          primary key,
  SName   varchar(10)  NOT NULL,
  Status  int          NOT NULL,
  City    varchar(10)  NOT NULL
)

CREATE TABLE Part (
  PID     int          primary key,
  PName   varchar(10)  NOT NULL,
  Color   int          NOT NULL,
  Weight  real         NOT NULL,
  City    varchar(10)  NOT NULL
)

CREATE TABLE Shipment (
  SID     int          NOT NULL FOREIGN KEY REFERENCES Supplier(SID),
  PID     int          NOT NULL FOREIGN KEY REFERENCES Part(PID),
  Qty     int          NOT NULL,
  PRIMARY KEY (SID, PID)
)
```

Notes:

1. The ID attributes are simple integers, but they could be (among other things) UUIDs or a system-defined identifier type that holds system-generated values.
2. The choice of VARCHAR(10) is arbitrary and would be too small for real-world use.
3. The application of the NOT NULL constraint to all attributes is a design decision based on the view that NULLs are to be avoided. It is not, strictly speaking, a requirement of the schema.

References

[1] Relations and SQL tables are roughly synonymous.

Internet Movie Database

Internet Movie Database (IMDb)

Web address	imdb.com [1]
Commercial?	Yes
Type of site	Online database for movies, television, and video games
Registration	Registration is optional for members to participate in discussions, comments, ratings, and voting.
Available language(s)	English
Owner	Amazon.com
Created by	Col Needham (CEO)
Launched	October 17, 1990
Alexa rank	▼ 44 (March 2014[2])
Current status	Active

Internet Movie Database (abbreviated **IMDb**) is an online database of information related to films, television programs and video games, taking in actors, production crew, fictional characters, biographies, plot summaries and trivia. Actors and crew can post their own résumé and upload photos of themselves for a yearly fee. U.S. users can also view over 6,000 movies and television shows from CBS, Sony and various independent film makers.

Launched in 1990 by professional computer programmer Col Needham, the company was incorporated in the UK as Internet Movie Database Ltd in 1996, with revenue generated through advertising, licensing and partnerships. In 1998, it became a subsidiary of Amazon.com, who were then able to use it as an advertising resource for selling DVDs and videotapes.

As of February 27, 2014, IMDb had 2,798,497 titles (includes episodes) and 5,749,077 personalities in its database, as well as 51 million registered users [*citation needed*] and is an Alexa Top 50 site.

The site enables any user to submit new material and request edits to existing entries. Although all data is checked before going live, the system has been open to abuse, and occasional errors are acknowledged. Users are also invited to rate any film on a scale of 1 to 10, and the totals are converted into a weighted mean-rating that is displayed beside each title, with online filters employed to deter ballot-stuffing. The site also features Message Boards, which stimulate regular debates among authenticated users.

History

History before website

IMDb originated with a Usenet posting by British film fan and professional computer programmer Col Needham entitled "Those Eyes", about actresses with beautiful eyes. Others with similar interests soon responded with additions or different lists of their own. Needham subsequently started a (male) "Actors List", while Dave Knight began a "Directors List", and Andy Krieg took over "THE LIST" from Hank Driskill, which would later be renamed the "Actress List". Both lists had been restricted to people who were alive and working, but soon retired people were

added so Needham started what was then (but did not remain) a separate "Dead Actors/Actresses List". The goal of the participants now was to make the lists as inclusive as possible. By late 1990, the lists included almost 10,000 movies and television series correlated with actors and actresses appearing therein. On October 17, 1990, Needham developed and posted a collection of Unix shell scripts which could be used to search the four lists, and thus the database that would become the IMDb was born. At the time, it was known as the "rec.arts.movies movie database", but by 1993 had been moved out of the Usenet group as an independent website underwritten and controlled by Needham and personal followers. Other website users were invited to contribute data which they may have collected and verified, on a volunteer basis, which greatly increased the amount and types of data to be stored. Entire new sections were added. As the site grew hugely, full production crews, uncredited performers and other demographic data were added. Needham's group allowed some advertising to support ongoing operations of the site, including the hiring of full-time paid data managers. All the primary staff came (and still come) from the burgeoning computer industry and/or training schools and did not have extensive expertise in the visual media.[*citation needed*] In 1998, unable to secure sufficient funding from limited advertising, contributions and unable to raise support from the visual media industries or academia, Needham sold the IMDb to Amazon.com, on condition that its operation would remain in the hands of Needham and his small cadre of managers, who soon were able to move into full-time paid staff positions.

On the web

The database had been expanded to include additional categories of filmmakers and other demographic material, as well as trivia, biographies, and plot summaries. The movie ratings had been properly integrated with the list data and a centralized email interface for querying the database had been created by Alan Jay. Later in the yearWikipedia:Manual of Style/Dates and numbers#Chronological items it moved onto the World Wide Web (a network in its infancy at that time) under the name of *Cardiff Internet Movie Database*. The database resided on the servers of the computer science department of Cardiff University in Wales. Rob Hartill was the original web interface author. In 1994 the email interface was revised to accept the submission of all information meaning that people no longer had to email the specific list maintainer with their updates. However, the structure remained that information received on a single film was divided among multiple section managers, the sections being defined and determined by categories of film personnel and the individual filmographies contained therein. Over the next few years, the database was run on a network of mirrors across the world with donated bandwidth.[*citation needed*]

The website is Perl-based.[3] As of May 2011, the site has been filtered in China for more than one year, although many users address it through proxy server or by VPN.

On October 17, 2010, IMDb launched original video (www.imdb.com/20) in celebration of its 20th anniversary.

As an independent company

In 1996 IMDb was incorporated in the United Kingdom, becoming the Internet Movie Database Ltd. Founder Col Needham became the primary owner as well as the figurehead. General revenue for site operations was generated through advertising, licensing and partnerships.

As Amazon.com subsidiary

In 1998, Jeff Bezos, founder, owner and CEO of Amazon.com, struck a deal with Col Needham and other principal shareholders to buy IMDb outright and attach it to Amazon as a subsidiary, private company. This gave IMDb the ability to pay the shareholders salaries for their work, while Amazon.com would be able to use the IMDb as an advertising resource for selling DVDs and videotapes.

IMDb continued to expand its functionality. On January 15, 2002, it added a subscription service known as IMDbPro, aimed at entertainment professionals. IMDbPro was announced and launched at the 2002 Sundance Film Festival. It provides a variety of services including film production and box office details, as well as a company

directory.

As an additional incentive for users, as of 2003, users identified as one of "the top 100 contributors" of hard data received complimentary free access to IMDbPro for the following calendar year; for 2006 this was increased to the top 150 contributors, and for 2010 to the top 250. In 2008 IMDb launched their first official foreign language version with the German IMDb.de. Also in 2008, IMDb acquired two other companies, Withoutabox and Box Office Mojo.

Television episodes

On January 26, 2006, "Full Episode Support" came online, allowing the database to support separate cast and crew listings for each episode of every television series. This was described by Col Needham as "the largest change we've ever made to our data model",[*citation needed*] and increased the number of titles in the database from 485,000 to nearly 755,000.[*citation needed*]

Characters' filmography

On October 2, 2007,[*citation needed*] the characters' filmography was added. Character entries are created from character listings in the main filmography database, and as such do not need any additional verification by IMDb staff. They have already been verified when they are added to the main filmography.

Instant viewing

On September 15, 2008, a feature was added that enables instant viewing of over 6,000 movies and television shows from CBS, Sony and a number of independent film makers, with direct links from their profiles. Due to licensing restrictions, this feature is only available to viewers in the United States.

Content and format

Data provided by subjects

In 2006, IMDb introduced its "Résumé subscription service", where actors and crew can post their own résumé and upload photos of themselves[4] for a yearly fee.[5] The base annual charge for including a photo with an account was $39.95 until 2010, when it was increased to $54.95. IMDb résumé pages are kept on a sub-page of the regular entry about that person, with a regular entry automatically created for each résumé subscriber who does not already have one.[6]

As of 2012, Resume Services is now included as part of an IMDbPro subscription, and is no longer offered as a separate subscription service.

Copyright, vandalism, and error issues

All volunteers who contribute content to the database technically retain copyright on their contributions but the compilation of the content becomes the exclusive property of IMDb with the full right to copy, modify, and sublicense it and they are verified before posting.[7] Credit is not given on specific title or filmography pages to the contributor(s) who have provided information. Conversely, a credited text entry, such as a plot summary, may be "corrected" for content, grammar, sentence structure, perceived omission or error, by other contributors without having to add their names as co-authors. Due to the process of having the submitted data or text reviewed by a section manager, IMDb is different from database projects like Wikipedia, Discogs, or OpenStreetMap in that contributors cannot add, delete, or modify the data or text on impulse, and the manipulation of data is controlled by IMDb technology and salaried staff.[8] Nevertheless, although it is generally assumed to be reliable,[9] IMDb has been subject to deliberate additions of false information, as acknowledged by a spokesperson in 2012: "We make it easy for users and professionals to update much of our content, which is why we have an 'edit page.' The data that is

submitted goes through a series of consistency checks before it goes live. Given the sheer volume of the information, occasional mistakes are inevitable, and, when reported, they are promptly fixed. We always welcome corrections."

The Java Movie Database (JMDB) is reportedly creating an IMDb_Error.log file that lists all the errors found while processing the IMDb plain text files. A Wiki alternative to IMDb is Open Media Database [10] whose content is also contributed by users but licensed under CC-by and the GFDL. Since 2007, IMDb has been experimenting with wiki-programmed sections for complete film synopses, parental guides, and FAQs about titles as determined by (and answered by) individual contributors.

Data format and access

IMDb does not provide an API for automated queries. However most of the data can be downloaded as compressed plain text files and the information can be extracted using the command-line interface tools provided. Beside that there is the Java-based graphical user interface (GUI) application available which is able to process the compressed plain text files and allow to search and display the information. This GUI application supports different languages but the movie related data is of course English as made available by IMDb. A Python package called IMDbPY can also be used to process the compressed plain text files into a number of different SQL databases, enabling easier access to the entire dataset for searching or data mining.

Film titles

The IMDb has sites in English as well as versions translated completely or in part into other languages (Finnish, French, German, Hungarian, Italian, Polish, Portuguese and Romanian). The non-English language sites display film titles in the specified language. While originally the IMDb's English-language sites displayed titles according to their original country-of-origin language, in 2010 the IMDb began allowing individual users in the UK and USA to choose primary title display by either the original-language titles, or the US or UK release title (normally, in English).

Ancillary features

User ratings of films

As one adjunct to data, the IMDb offers a rating scale that allows users to rate films on a scale of one to ten. The rating system is recognized as being severely flawed for several reasons.

IMDb indicates that submitted ratings are filtered and weighted in various ways in order to produce a weighted mean that is displayed for each film, series, and so on. It states that filters are used to avoid ballot stuffing; the method is not described in detail to avoid attempts to circumvent it. In fact, it sometimes produces an extreme difference between the weighted average and the arithmetic mean. For example, *Jonas Brothers: The 3D Concert Experience* is considered to be the worst film with a weighted average of 2.1 as of 2014, but has a rather ordinary arithmetic mean of 3.9.[11][12]

Film rankings (IMDb Top 250)

The IMDb Top 250[13] is intended to be a listing of the top 'rated' 250 films, based on ratings by the registered users of the website using the methods described. Only non-documentary theatrical releases running at least forty-five minutes with over 25,000 ratings are considered; all other products are ineligible. Also, the 'top 250' rating is based on only the ratings of "regular voters". The exact number of votes a registered user would have to make to be considered to be a user who votes regularly has been kept secret. IMDb has stated that to maintain the effectiveness of the top 250 list they *"deliberately do not disclose the criteria used for a person to be counted as a regular voter"*.[14] In addition to other weightings, the top 250 films are also based on a weighted rating formula referred to in actuarial science as a *credibility formula*.[15] This label arises because a statistic is taken to be more credible the

greater the number of individual pieces of information; in this case from eligible users who submit ratings. IMDb uses the following formula to calculate the weighted rating:

$$W = \frac{Rv + Cm}{v + m}$$

where:

W = weighted rating

R = average for the movie as a number from 0 to 10 (mean) = (Rating)

v = number of votes for the movie = (votes)

m = minimum votes required to be listed in the Top 250 (currently 25,000)

C = the mean vote across the whole report (currently 7.0)

The W in this formula is equivalent to a Bayesian posterior mean (See Bayesian statistics).

The IMDb also has a Bottom 100 feature which is assembled through a similar process although only 1500 votes must be received to qualify for the list.

The top 250 list comprises a wide range of films, including major releases, cult films, independent films, critically acclaimed films, silent films and non-English language films.

Fan activity

One of the most used features of the Internet Movie Database is the message boards that coincide with every title (excepting, as of 2013, TV episodes[16]) and name entry, along with over 140 main boards. This section is one of the more recent features of IMDb, having its beginnings in 2001. In order to post on the message boards a user needs to "authenticate" their account via cell phone, credit card, or by having been a recent customer of the parent company Amazon.com. Message boards have expanded in recent years. The Soapbox started in 1999 is a general message board meant for debates on any subject. The Politics board started in 2007 is a message board to discuss politics, news events and current affairs as well as history and economics. Both these message boards have become the most popular message boards in IMDb, more popular on a long term basis than any individual movie message board.

Litigation

In 2011, in the case of *Hoang v. Amazon.com*, IMDb was sued by an anonymous actress for more than US$1 million due to IMDb revealing her age (40, at the time). The actress claimed that revealing her age could cause her to lose acting opportunities. Judge Marsha J. Pechman, a U.S. district judge in Seattle, dismissed the lawsuit, saying the actress had no grounds to proceed with an anonymous complaint. She re-filed and so revealed that the complainant is a Huong Hoang of Texas, who uses the stage name Junie Hoang. In 2013, Pechman dismissed all causes of action except for a breach of contract claim against IMDb; a jury then sided with IMDb on that claim.

Also in 2011, in the case of United Video Properties Inc., et al. v. Amazon.Com Inc. et al., IMDb and Amazon were sued by Rovi Corporation and others for patent infringement over their various program listing offerings. The patent claims were ultimately construed in a way favorable to IMDb and Rovi/United Video Properties lost the case, though it is currently on appeal.

YAGO (ontology)

YAGO

Developer(s)	Max-Planck-Institute Saarbrücken
Initial release	2008
Stable release	YAGO2s / 16 October 2012
Type	Semantic Web, Linked Data
License	Creative Commons CC-BY 3.0
Website	www.mpi-inf.mpg.de/yago-naga/yago/ [1]

YAGO is a knowledge base developed at the Max Planck Institute for Computer Science in Saarbrücken. It is automatically extracted from Wikipedia and other sources.

As of 2012, YAGO2s has knowledge of more than 10 million entities and contains more than 120 million facts about these entities. The information in YAGO is extracted from Wikipedia (e.g., categories, redirects, infoboxes), WordNet (e.g., synsets. hyponymy) and GeoNames.[2] The accuracy of YAGO was manually evaluated to be above 95% on a sample of facts. To integrate it to the linked data cloud, YAGO has been linked to the DBpedia ontology and to the SUMO ontology.

YAGO2s is provided in Turtle and tsv formats. Dumps of the whole database are available, as well as thematic and specialized dumps. It can also be queried through various online browsers [3] and through a SPARQL endpoint hosted by OpenLink Software. YAGO has been used in the Watson artificial intelligence system.[4]

World Wide Molecular Matrix

The **World Wide Molecular Matrix** (WWMM) is an electronic repository for unpublished chemical data. First proposed in 2002 by Peter Murray-Rust and his colleagues in the chemistry department at the University of Cambridge in the United Kingdom, WWMM provides a free, easily searchable database for information about thousands of complicated molecules, data that would otherwise remain inaccessible to scientists.

Murray-Rust, a chemical informatics specialist, has estimated that 80% of the results produced by chemists around the world is never published in scientific journals. Most of this data is not ground-breaking, yet it could conceivably be of use to scientists doing related projects—if they could access it. The WWMM was proposed as a solution to this problem. It would house the results of experiments on over 100,000 molecules in physical chemistry, organic chemistry, biochemistry and medicinal chemistry.

In other scientific fields, the need for a similar depository to house inaccessible information could be more acute. In a presentation at the "CERN Workshop on Innovations in Scholarly Communications (OAI4)", Murray-Rust said that chemistry actually leads other fields in published data. He estimated that as much as 99% of the data in some scientific fields never reaches publication.[*citation needed*]

Although scientific in nature, the WWMM is part of the broader open archives and open source movements, pushes to make more and more information freely available to any user via the Internet or World Wide Web. In his CERN presentation, Murray-Rust stated that the WWMM was a "response to the expense of [scientific] journals," and he asked the rhetorical question, "Can we win the war to make data open, or will it be absorbed into the publishing and pseudo-publishing world?" Murray-Rust and his colleagues are also responsible for the development of the Chemical Mark-up Language (CML), a variant of XML intended for chemists.

Voter database

A **voter database** is a database containing information on voters for the purpose of assisting a political party or an individual politician, in their Get out the vote (GOTV) efforts and other areas of the campaign.

In most countries, the election agency makes the electoral roll available to all campaigns soon after the election campaign has begun. Campaigns can then merge this information with the other data they have collected on voters over the years to create their database. Often basic information such as phone numbers and postal codes are not included on the voters list, and the campaign will have to procure this data as well.

The United States has no state or federal election agency, and thus no central lists. In 2002, the United States Congress passed the Help America Vote Act (HAVA). HAVA required that each state compile an official state voter database by January 2006. Most states complied with HAVA by gathering the voter files available from each individual county. States decided what information to include, what restrictions to place on the use of their voter database, and how much the database would cost. In the United States, several companies have merged state voter information with commercially obtained data to create comprehensive voter databases that include a plethora of personal details on each voter. These companies often provide United States Voter Files to statutorily permitted or otherwise non-restricted users.

Uses

The voter database is central to many parts of a campaign:

- Fundraising: The database can determine who should receive fundraising direct mail or telephone calls. These letters and calls can be tailored to reflect the issues and concerns of each potential donor. Past donor history, support for related advocacy groups, magazine subscriptions, and consumer behaviour can all be used to find likely donors and maximize the returns of any fundraising efforts.
- Recruitment: As with fundraising, databases, especially those with detailed past election behaviour, are essential to recruiting volunteers and also finding locations for lawn signs.
- Issue tracking: A campaign can track how a certain issues are perceived across geographic and demographic lines and can show how to adjust the campaign's message for different audiences. By databasing all incoming telephone calls and e-mails as well as entering petitions and supporter lists from advocacy groups and NGOs (Non-Government Organizations) one can closely track how issues are followed by the electorate.
- Get out the vote: One of the most important parts of a modern campaign is the campaign to ensure one's own supporters go to the polls on election day, and databases are central to this. A successful voter identification campaign requires connecting with a significant portion of the electorate and recording how they are going to vote in a database. On election day this information needs to be given out with accurate contact information for each voter so that they can be pulled to the polls.

Voter information

Personal data frequently included in a voter database:

- Name
- Physical address
- Mailing address
- Phone number
- Party membership or affiliation
- Voting history (including federal, sub-national, primary, municipal, or special election voting history)
- Absentee or military voter designations
- Source of voter registration, i.e., DMV/MVA, Public Assistance Office, etc.

- Ethnicity or emerges race hypothesis
- Gender
- Birth date or age range

Data that may be added via commercial routes:

- "Extreme voters" status (voters who vote very frequently)
- Homeownership
- Hunting or fishing license holders
- Boat owners
- Concealed Weapon Permit Holders
- Occupation such as physical therapist, teacher, etc.
- Charitable or political contributions
- Magazine subscription status

Voter database management software

The use of voter databases has been established in political campaigns from local school board to national elections:

In the United States

In the 2004 presidential election in the United States, the Republican Party used the Voter Vault platform and the Democratic Party used DataMart. Currently, the Republicans use GOP Data Center and the Democrats use Votebuilder from the Voter Activation Network (VAN). There are non partisan firms that offer registered voter data in the United Sates too: eMerges.com [1] and Labels and Lists [2].

In the United Kingdom

In 2005, the British Conservative Party used the Voter Vault software to assist them in the 2005 General Election.

Currently,Wikipedia:Manual of Style/Dates and numbers#Chronological items the British Conservative Party uses MERLIN (Managing Elector Relationships through Local Information Networks) which is a national database accessible by every local Conservative Association in the country. This was commissioned in 2005,[3] and went live in 2008.[4]

Britain's Labour Party has used a variety of voter databases through the past two decades. Its most recent incarnation is the Labour Contact Creator system, an online tool accessible from anywhere with an internet connection. Party members and activists are provided with a username and password and voter contact details, preferences, interests, past voting behaviour, and demographic/socio-economic information are available. The system allows voters to be selected on the basis of a MOSAIC grouping, which attempts to determine the sort of interests and activities a voter or a household might display. Maps of where key voters live and information can be cross-referenced so users can find where target voters live, how often they are contacted, how they prefer to be contacted, and what responses have been provided upon making contact.

The Contact Creator system is also linked with the Labour Party's other new media tools, Print Creator and Email Creator. Print Creator allows key voters identified through Contact Creator to be targeted with direct mails and leaflets about Labour Party activity. Email Creator allows the user to collect a list of email addresses on the Contact Creator system, e-mail thousands of voters, and monitor the response rate from targets.

The Labour Party also operates 'Membersnet', which allows party members to update their registration details, inform other members and Party HQ of rival campaign activities, create events and invite others to attend, email members, create blogs, and share best practice campaign material.

The Labour Party introduced a new system to Membersnet and Contact Creator in 2013,[5] focusing on a new user-friendly interface, which allows Party Members anywhere in the UK to contact target voters and identify their

voting preferences. They will then be able to enter the information gained directly into the Contact Creator system.

In late 2011 Liberal Democrats began to adopt the use of a variant of NGP VAN's Voter Activation Network (VAN) software named "Connect".[6] This firm also supplies "Votebuilder" and VAN to the Democrats in the USA and to the Liberal Party of Canada as "Liberal List".

In Canada

In Canada, the Conservative Party of Canada uses the in-house developed C-VOTE database, and used to use Constituent Information Management System (CIMS) [7], originally developed by the same company which produced Trackright, which the Progressive Conservative Party of Ontario, uses to manage voter information. It is similar to the Voter Vault software. The New Democratic Party uses their own custom database system called NDP Vote. The Liberal Party has recently introduced "Liberalist [8]" based on the US's Democrats' Voter Activation Network (VAN) Previously the Liberals used a system called ManagElect[9][10] .

Availability

The availability of voter files sometimes creates a need for voter list management software as opposed to, for example, using Excel spreadsheets. Political campaigns generally have three options:

- Write-their-own software: A political campaign may choose to build their own database management system to handle their voter registration files. This may be accomplished in a spreadsheet program like Microsoft Excel. This method can be time-consuming and require a certain level of technology know-how, but may be the only option for certain campaigns.
- Desktop-based software: A variety of companies provide voter list management software for a desktop or laptop computer. Generally, this type of software is distributed on a per-computer basis and can therefore be expensive for larger campaigns. However, desktop-based software is easier to use than create-your-own and can provide many integrated, helpful solutions for political campaigns such as walking list generation, computer-based phone banking, and more.
- Internet-based software: Many companies provide online voter list management software. Internet-based software has many of the same benefits of desktop-based software, and has the additional advantage of being accessible from any computer (Windows, Mac, or Linux) with an Internet connection. Internet-based software helps campaigns eliminate the need for large campaign offices with central computer and phone banks.

VIOLIN vaccine database

The **Vaccine Investigation and OnLine Information Network** (**VIOLIN**) is the largest web-based vaccine database and analysis system. VIOLIN currently contains over 2,700 vaccines or vaccine candidates for over 170 pathogens. The vaccine information in the database is collected by manual curation from over 1,600 peer-reviewed papers. Different from most existing vaccine databases, VIOLIN focuses on vaccine research data. Different types of information is curated, including vaccine name, license status, antigens used, vaccine adjuvants, vaccine vectors, vaccination procedure, host immune response, challenge procedure, vaccine efficacy, adverse events, etc. All vaccine information in the VIOLIN vaccine database is supported by quoted references. The data generated by a curator is published only after a careful review and approval by a vaccine domain expert.

In addition, VIOLIN includes many vaccine analysis programs. For example, VIOLIN includes Vaxign (http://www. violinet. org/ vaxign), the first web-based vaccine design program based on the strategy of reverse vaccinology. Vaxign has been tested in different pathogen models, including uropathogenic E. coli and Brucella spp.

VIOLIN also maintains the official web page for the development of community-based Vaccine Ontology (VO) (http://www. violinet. org/ vaccineontology). VO is a formal biomedical ontology in the domain of vaccine and vaccination. VO is targeted for vaccine data standardization and integration, and supporting automated reasoning. VO has been shown to enhance vaccine literature mining.

Census of Governments

The **Census of Governments** is a census performed by the United States Census Bureau. It is mandated by 13 U.S.C. § 161 [1]. The Census of Governments occurs twice-per-decade, in years ending with 2 and 7. The survey identifies the scope of American government at the federal, state, and municipal level by measuring public finance, public employment, classifies municipal government structures and activities, and identifies municipal authorities and Special-purpose districts. The Census of Governments in its current form started in year 1957.

Management information base

A **management information base** (**MIB**) is a database used for managing the entities in a communications network. Most often associated with the Simple Network Management Protocol (SNMP), the term is also used more generically in contexts such as in OSI/ISO Network management model. While intended to refer to the complete collection of management information available on an entity, it is often used to refer to a particular subset, more correctly referred to as MIB-module.

Objects in the MIB are defined using a subset of Abstract Syntax Notation One (ASN.1) called "Structure of Management Information Version 2 (SMIv2)" RFC 2578.The software that performs the parsing is a MIB compiler.

The database is hierarchical (tree-structured) and each entry is addressed through an object identifier (OID). Internet documentation RFCs discuss MIBs, notably RFC 1155, "Structure and Identification of Management Information for TCP/IP based internets", and its two companions, RFC 1213, "Management Information Base for Network Management of TCP/IP-based internets", and RFC 1157, "A Simple Network Management Protocol".

Abstract Syntax Notation One (ASN.1)

In telecommunications and computer networking, Abstract Syntax Notation One (ASN.1) is a standard and flexible notation that describes data structures for representing, encoding, transmitting, and decoding data. It provides a set of formal rules for describing the structure of objects that are independent of machine-specific encoding techniques and is a precise, formal notation that removes ambiguities.

ASN.1 is a joint ISO and ITU-T standard, originally defined in 1984 as part of CCITT X.409:1984. ASN.1 moved to its own standard, X.208, in 1988 due to wide applicability. The substantially revised 1995 version is covered by the X.680 series.

An adapted subset of ASN.1, Structure of Management Information (SMI), is specified in SNMP to define sets of related MIB objects; these sets are termed MIB modules.

MIB hierarchy

The MIB hierarchy can be depicted as a tree with a nameless root, the levels of which are assigned by different organizations. The top-level MIB OIDs belong to different standards organizations, while lower-level object IDs are allocated by associated organizations. This model permits management across all layers of the OSI reference model, extending into applications such as databases, email, and the Java reference model, as MIBs can be defined for all such area-specific information and operations.

A managed object (sometimes called a MIB object, an object, or a MIB) is one of any number of specific characteristics of a managed device. Managed objects are made up of one or more object instances (identified by their OIDs), which are essentially variables.

Two types of managed objects exist:

- Scalar objects define a single object instance.
- Tabular objects define multiple related object instances that are grouped in MIB tables.

An example of a managed object is `atInput`, which is a scalar object that contains a single object instance, the integer value that indicates the total number of input AppleTalk packets on a router interface.

An object identifier (or object ID or OID) uniquely identifies a managed object in the MIB hierarchy.

SNMPv1 and SMI-specific data types

The first version of the SMI (SMIv1) specifies the use of a number of SMI-specific data types, which are divided into two categories:

- Simple data types
- Application-wide data types

Simple data types

Three simple data types are defined in the SNMPv1 SMI:

- The integer data type is a signed integer in the range of -2^{31} to $2^{31}-1$.
- Octet strings are ordered sequences of 0 to 65,535 octets.
- Object IDs come from the set of all object identifiers allocated according to the rules specified in ASN.1.

Application-wide data types

The following application-wide data types exist in the SNMPv1 SMI:

- *Network addresses* represent addresses from a particular protocol family. SMIv1 supports only 32-bit (IPv4) addresses (SMIv2 uses Octet Strings to represent addresses generically, and thus are usable in SMIv1 too. SMIv1 had an explicit IPv4 address datatype.)
- *Counters* are non-negative integers that increase until they reach a maximum value and then roll over to zero. SNMPv1 specifies a counter size of 32 bits.
- *Gauges* are non-negative integers that can increase or decrease between specified minimum and maximum values. Whenever the system property represented by the gauge is outside of that range, the value of the gauge itself will vary no further than the respective maximum or minimum, as specified in RFC 2578.
- *Time ticks* represent time since some event, measured in hundredths of a second.
- *Opaques* represent an arbitrary encoding that is used to pass arbitrary information strings that do not conform to the strict data typing used by the SMI.
- *Integers* represent signed integer-valued information. This data type redefines the integer data type, which has arbitrary precision in ASN.1 but bounded precision in the SMI.
- *Unsigned integers* represent unsigned integer-valued information, which is useful when values are always non-negative. This data type redefines the integer data type, which has arbitrary precision in ASN.1 but bounded

precision in the SMI.

SNMPv1 MIB tables

The SNMPv1 SMI defines highly structured tables that are used to group the instances of a tabular object (that is, an object that contains multiple variables). Tables are composed of zero or more rows, which are indexed in a way that allows SNMP to retrieve or alter an entire row with a single `Get`, `GetNext`, or `Set` command.

SMIv2 and structure of management information

The second version of the SMI (SMIv2) is described in RFC 2578 and RFC 2579. It enhances and adds to the SMIv1-specific data types, such as including bit strings, network addresses, and counters. Bit strings are defined only in SMIv2 and comprise zero or more named bits that specify a value. Network addresses represent an address from a particular protocol family. Counters are non-negative integers that increase until they reach a maximum value and then return to zero. In SMIv1, a 32-bit counter size is specified. In SMIv2, 32-bit and 64-bit counters are defined.

SMIv2 also specifies information modules, which specify a group of related definitions. Three types of SMI information modules exist: MIB modules, compliance statements, and capability statements.

- MIB modules contain definitions of interrelated managed objects.
- Compliance statements provide a systematic way to describe a group of managed objects that must be implemented for conformance to a standard.
- Capability statements are used to indicate the precise level of support that an agent claims with respect to a MIB group. An NMS can adjust its behavior toward agents according to the capabilities statements associated with each agent.

Updating MIB Modules

MIB modules are occasionally updated to add new functionality, remove ambiguities and to fix defects. These changes are made in conformance to section 10 of RFC 2578 and section 5 of RFC 2579. An example of a MIB module that has been updated many times is the important set of objects that was originally defined in RFC 1213, also known as "MIB-II". This MIB module has since been split up and can be found in MIB modules such as RFC 4293 "Management Information Base for the Internet Protocol (IP)", RFC 4022 "Management Information Base for the Transmission Control Protocol (TCP)", RFC 4113 "Management Information Base for the User Datagram Protocol (UDP)", RFC 2863 "The Interfaces Group MIB" and RFC 3418 "Management Information Base (MIB) for the Simple Network Management Protocol (SNMP)".

MIBs index

There are a large number of MIBs defined by both standards organizations like the IETF, private enterprises and other entities.

IETF maintained

There are 318 RFCs in the first 5000 RFCs from the IETF that contain MIBs. This list is merely a fraction of the MIBs that have been written:

- **SNMP - SMI**: RFC 1155 — Defines the Structure of Management Information (SMI)
- **MIB-I**: RFC 1156 — Historically used with CMOT, not to be used with SNMP
- **SNMPv2-SMI**: RFC 2578 — Structure of Management Information Version 2 (SMIv2)
- **MIB-II**: RFC 1213 — Management Information Base for Network Management of TCP/IP-based internets

- **SNMPv2-MIB**: RFC 3418 — Management Information Base (MIB) for the Simple Network Management Protocol (SNMP)
- **TCP-MIB**: RFC 4022 — Management Information Base for the Transmission Control Protocol (TCP)
- **UDP-MIB**: RFC 4113 — Management Information Base for the User Datagram Protocol (UDP)
- **IP-MIB**: RFC 4293 — Management Information Base for the Internet Protocol (IP)
- **IF-MIB**: RFC 2863 — The Interfaces Group MIB
- **ENTITY-MIB**: RFC 4133 — Entity MIB (Version 3)
- **ENTITY-STATE-MIB**: RFC 4268 — Entity State MIB
- **ALARM-MIB**: RFC 3877 — Alarm Management Information Base (MIB)
- Fibre Channel
  - **FC-MGMT-MIB**: RFC 4044 Fibre Channel Management MIB
  - **FIBRE-CHANNEL-FE-MIB**: RFC 2837 Definitions of Managed Objects for the Fabric Element in Fibre Channel Standard
- **HPR-IP-MIB**: RFC 2584 — Definitions of Managed Objects for APPN/HPR in IP Networks

IEEE maintained

The IETF and IEEE have agreed to move MIBs relating to IEEE work (for example Ethernet and bridging) to their respective IEEE workgroup. This is in process and a few items are complete.

- Network bridge
  - IEEE 802.1ap-2008 consolidated the IEEE and IETF RFCs related to bridging networks into eight related MIBs.

MIB Browsers

- SnmpB: A graphical open source MIB browser (http://sourceforge.net/projects/snmpb/) for Windows, MacOSX and Linux.
- mbrowse: A graphical SNMP MIB browser for Linux (http://sourceforge.net/projects/mbrowse/), based upon GTK+ and Net-SNMP.
- BlackOwl MIB Browser: A graphical MIB browser for Windows and Linux (http://sourceforge.net/projects/blackowl/) which can extract MIBs from RFCs and display graphs.
- SMI-Mib Browser: A graphical MIB browser (http://sourceforge.net/projects/mibview/) — as of 2010-05-18, this project is no longer under active development.
- MBJ: A graphical MIB browser, written in Java (http://sourceforge.net/projects/mbj/)
- JMibBrowser: A graphical MIB browser, written in Java (http://sourceforge.net/projects/jmibbrowser/). It can send SNMP requests and dynamically load MIB data.
- qtmib: An open source graphical MIB browser (http://qtmib.sourceforge.net/) written in C++. It is build as a front-end for Net-SNMP.
- NetDecision MIB Browser: A graphical MIB browser, written in C++ (http://www.netmechanica.com/products/?prod_id=1009). It can send SNMP requests and dynamically load MIB files.

Planetary Data System

The **Planetary Data System** (PDS) is a distributed data system that NASA uses to archive data collected by Solar System robotic missions and ground-based support data associated with those missions. PDS is managed by NASA Headquarters' Planetary Sciences Division. The PDS is an active archive that makes available well documented, peer reviewed data to the research community. The archive and data within are held to high quality standards established by the PDS. The PDS is divided into a number of science discipline "nodes" which are individually curated by planetary scientists. The Solar System Exploration Data Services Office at the Goddard Space Flight Center handles PDS Project Management.

PDS archiving philosophy

The main objective of the PDS is to maintain a planetary data archive that will withstand the test of time such that future generations of scientists can access, understand and use preexisting planetary data. The PDS tries to ensure compatibility of the archive by adhering to strict standards of storage media, archiving formats, and required documentation.

Storage media

One critical component of the PDS archive is the storage media. The data must be stored effectively and efficiently with no degradation of the data over the archive's lifespan. Therefore, the physical media must have large capacity and must remain readable over many years. PDS is migrating toward electronic storage as its "standard" media.

Archiving formats

The format of the data is also important. In general, transparent, non-proprietary formats are best. When a proprietary format is submitted to the archive (such as a Microsoft Word document) an accompanying plain text file is also required. It is assumed that the scientists of the future will at least be able to make sense of regular ASCII bytes even if the proprietary software and support ceases to exist. PDS allows figures and illustrations to be included in the archive as individual images. PDS adheres to many other standards including, but not limited to, special directory and file naming conventions and label requirements. Each file in the PDS archive is accompanied by a

searchable label (attached or detached) that describes the file content.

Archiving documents

The archive must be complete and be able to stand alone. There is no guarantee that the people who originally worked with and submitted the data to the archive will be available in the future to field questions regarding the data, its calibration or the mission. Therefore, the archive must include good descriptive documentation of how the spacecraft and its instruments worked, how the data were collected and calibrated, and what the data mean. The quality of the documentation is examined during a mission independent PDS peer review.

Nodes

The PDS [1] is composed of 8 nodes, 6 science discipline nodes and 2 support nodes. In addition, there are several subnodes and data nodes whose exact status tends to change over time.

Science Discipline Nodes

- Atmospheres Node [2] - handles non-imaging atmospheric data (New Mexico State University)
- Geosciences Node [3] - handles data of the surfaces and interiors of terrestrial planetary bodies (Washington University)
- Imaging Node [4] - archives many of the larger planetary image data collections (Astrogeology Research Program of the United States Geological Survey, and Jet Propulsion Laboratory)
- Planetary Plasma Interaction (PPI) Node [5] - handles data consisting of the interaction between the solar wind and planetary winds with planetary magnetospheres, ionospheres and surfaces (University of California, Los Angeles)
- Planetary Rings Node [6] - handles planetary ring system data (SETI Institute)
- Small Bodies Node (SBN) [7] - handles asteroid, comet and planetary dust data (University of Maryland, College Park)
  - Comet Subnode (University of Maryland, College Park)
  - Asteroid/Interplanetary Dust Subnode (Planetary Science Institute)

Support Nodes

- Engineering Node [8] - provides systems engineering support to the PDS (Jet Propulsion Laboratory)
- Navigation and Ancillary Information Facility (NAIF) Node [9] - maintains the SPICE information system (Jet Propulsion Laboratory)

National Data Repository

A **National Data Repository** (**NDR**) is a data bank that seeks to preserve and promote a country's natural resources data, particularly data related to the petroleum exploration and production (E&P) sector.

A National Data Repository is normally established by an entity that governs, controls and supports the exchange, capture, transference and distribution of E&P information, with the final target to provide the State with the tools and information to assure the growth, govern-ability, control, independence and sovereignty of the industry.

The two fundamental reasons for a country to establish an NDR are to **preserve** data generated inside the country by the industry, and to **promote** investments in the country by utilizing data to reduce the exploration, production, and transportation business risks.

Countries take different approaches towards preserving and promoting their natural resources data. The approach varies according to a country's natural resources policies, level of openness, and its attitude towards foreign investment.

Data types

NDRs store a vast array of data related to a country's natural resources. This includes wells, well log data, well reports, core samples, seismic surveys, post-stack seismic, field data/tapes, seismic (acquisition/processing) reports, production data, geological maps and reports, license data and geological models.

Funding models

Some NDRs are financed entirely by a country's government. Others are industry-funded. Still some are hybrid systems, funded in part by industry and government. NDRs typically charge fees for data requests and for data loading. The cost differs significantly between countries. In some cases an annual membership is charged to oil companies to store and access the data in the NDR.

Standards body

Energistics is the global energy standards resource center for the upstream oil and gas industry.

Energistics National Data Repository Work Group: The standards body is Energistics.[1]

Energistics-standards-directory

Global regulators of upstream oil and natural gas information, including seismic, drilling, production and reservoir data, formed the National Data Repository (NDR) Work Group in 2008 to collaborate on the development of data management standards and to assist emerging nations with hydrocarbon reserves to better collect, maintain and deliver oil and gas data to the public and to the industry.

Ten countries, led by the Netherlands, Norway and the United Kingdom, formed NDR to share best practices and to formalize the development and deployment of data management standards for regulatory agencies. The other countries involved in the NDR Work Group's formation are Australia, Canada, India, Kenya, New Zealand, South Africa and the United States.

Annual NDR Conference: Approximately every 18 months Energistics organizes a National Data Repository Conference. The purpose is to provide government and regulatory agencies from around the world an opportunity to attend a series of workshops dedicated to developing data exchange standards, improving communications with the oil and gas industry and learning data management techniques for natural resources information.[2]

NDRs around the world

Country	Name	Agency	Scope	Status	Purposes	Data types/volumes	Standards used	Funding	Website					
Algeria	BDN	ALNAFT	Onshore and Offshore Algeria	Ongoing project - agency created by new law in 2005	Custodian of all E&P data of the country	Cultural, Seismic, Wells, Logs, Production, Facilities, Economical and Fiscality, Interpretation, Physical assets index	SEGY, UKOOA, LAS, DLIS	Government funding/Agency revenue						
Colombia	EPIS	Agencia Nacional de Hidrocarburos (ANH)	Onshore and offshore Colombia	Created originally for Ecopetrol and transferred to ANH when it was established in 2003. New system launched December 2009	Promote and preserve all the technical E&P information assets of the country	wells, surveys, licenses, seismic sections, well reports, maps	REST Web services	Government funding	http://www.epis.com.co					
Canada	CNSOPB	Nova Scotia Offshore Petroleum Board – Geoscience Research Centre- Digital Data Management Centre (DMC)	Offshore Nova Scotia, Canada	Operational since 2007	To provide an effective & efficient system for the management of digital petroleum data, assist explorers in easily obtaining access to large volumes of data via the web, Data Preservation and Data Distribution	Wells, well log curves, well reports, cores and samples, field data/tapes, seismic (acquisition/processing) reports, production data, interpretative maps and reports	LAS, DLIS, SEGY	Funded 50/50 by the Federal and Provincial Governments with some funds from industry through cost recovery	http://www.cnsopb.ns.ca/ [4]					
Australia	PIMS	Geoscience Australia		Active	Various online and web based systems exist for E &P, geosciences	Wells, well log curves, well reports, cores and samples, field data/tapes, seismic (acquisition/processing) reports, production data, interpretative maps and reports			[5] [6] [7] https://vdr.ga.gov.au/					
Western Australia	WAPIMS	Government of Western Australia		Active	WAPIMS is a petroleum, geothermal and minerals exploration database	Contains data on titles, wells, geophysical surveys and other petroleum exploration and production data submitted to DMP by the petroleum industry.			http://dmp.wa.gov.au [8]					
New South Wales		Government of New South Wales		Active	Various online geoscience databases to assist New South Wales including DIGS				[9] [10]					

Northern Territory		Government of Northern Territory		Active	Various online geoscience databases to assist Northern Territories		Wells, well log curves, well reports, cores and samples, field data/tapes, seismic (acquisition/processing) reports, production data, interpretative maps and reports		[11] [12] [13] [14]				
Queensland		Government of Queensland		Active	Various online geoscience databases to assist Queensland including Q-DEX		Wells, well log curves, well reports, cores and samples, field data/tapes, seismic (acquisition/processing) reports, production data, interpretative maps and reports		[15] [16] [17]				
South Australia	PIRSA	Government of South Australia		Active	Various online geoscience databases to assist South Australia such as PEP-SA		Wells, well log curves, well reports, cores and samples, field data/tapes, seismic (acquisition/processing) reports, production data, interpretative maps and reports		[18] [19] [20]				
Tasmania					Various online geoscience databases to assist Tasmania		Active		[21] [22]	China	CNPC	Chinese National Petroleum Corporation	Various oil companies in China with CNPC the largest and parent of Petrochina	http://www.cnpc.com.cn/en/ [23] http://www.cnooc.com.cn/ [24]
Russia		Sakhalin, DIGC RDC		Various oil companies in Russia the largest being Rosneft which is state owned					http://www.rosneft.com http://www.lukoil.com http://www.tnk-bp.com/en/ http://www.surgutneftegas.ru/ http://www.gazprom-neft.com/ [25]					

Indonesia	Indonesia's National Data Centre (NDC) for petroleum, energy and minerals data	Agency for Research and Development in the Ministry of Energy and Mineral Resources of the Republic of Indonesia	Onshore & Offshore	In 1997 Indonesia established Migas Data Management (MDM) operated by PT. Patra Nusa Data (PND)	PND manages and promotes petroleum investment opportunities by compiling and value adding available petroleum data and information.				http://www.patranusa.com/				
New Zealand	New Zealand Online Exploration Database	New Zealand Petroleum & Minerals, Ministry of Business Innovation & Employment	New Zealand onshore and offshore out to the outer continental shelf.	Opened to public in April 2007.	Data preservation, Investment facilitation, aid in monitoring regulatory compliance, maximise the return to the nation by informing public policy and business strategy.	Wells, well log curves, petroleum reports (includes wells and surveys), mineral reports, coal reports, cores and samples, seismic surveys, post-stack seismic, field data/tapes, seismic acquisition/processing reports, geophysical and geochemical data acquired in mineral and coal exploration (incorporated as enclosures to reports), VSP (incorporated as enclosures to reports), Seismic survey observer logs. GIS data and projects (minerals and coal). Estimated total NDR Size: 2.5 TB loaded, 3.0 TB staged for loading, 40 TB field data offline.	Closely follow Australian digital reporting standards. No naming standards for wells and surveys.	50% Government funding, 50% third party permit (license) fees paid by exploration companies.	https://data.nzpam.govt.nz				
Jordan	NRA	Jordan Natural Resources Authority (NRA)	Onshore	Active	Online data room allows users to browse and select large data set quickly in a controlled and secure environment	Reserves land records, field data, maps, engineering, seismic data, geological studies and well files.			http://www.nra.gov.jo/				
Angola		Sonangol	Offshore Angola	Active	Promotion, Organisation & Management of all Exploration & Production (E&P) Data of Angola	Wells, surveys, licenses, seismic sections, well reports, maps		Norad/OfD and NPD assistance	http://www.sonangol.co.ao				

France	BEPH		French Territory		Interactive maps of French territory of oil data are available to Internet users which includes: Permits for petroleum exploration, seismic exploration, oil drilling (data, documents available)	Wells, Surveys, Licenses, Seismic Sections, Well Reports, Maps			http://www.beph.net/					
São Tomé and Príncipe	ANP-STP	National Petroleum Agency of São Tomé & Principe (ANP-STP)	Offshore					Norad/OfD and NPD assistance	http://www.anp-stp.gov.st/pt/					
Tanzania	TPDC	Tanzania Petroleum Development Corp		Began in the early 1990s with Norwegian assistance	An E & P data archive centre	Geophysical survey data, Geological studies, Well drilling and completion reports, Cores and drill steam data		Norad/OfD and NPD assistance	http://www.tpdc-tz.com					
Oman	OGDR	Department of Petroleum Concession, Ministry of Oil and Gas		Department of Petroleum Concession is running an effort to establish Oman Oil&Gas Data Repository (OGDR) project.					[26]					
Netherlands	DINO	The Geological Survey of the Netherlands, a division of TNO	The Netherlands including offshore waters	Started in 2004. Currently BRO is being planned to succeed DINO.	To archive subsurface data of the Netherlands in one repository and provide easy access to the data to encourage multiple use of data.		WMS web services. DINO uses own naming conventions	100% Government funding	[27]					

India	DGH	Directorate General of Hydrocarbons (DGH)		Active - scheduled operation by April 2015	Establishing national data archival, improving data quality and access for quality exploration covering large area under exploration and providing basis for long term energy policy formulation as well as support OALP	Wells, Well Logs, Cores, Scanned core images, Seismic, Reports, production, Technical Reports		Government of India	[28]				
Sri Lanka	PRDS	Ministry of Petroleum and Petroleum Resources Development		Active since 2009	The PRDS developed a website to disseminate petroleum data and information to public and to investors to assist promotion of offshore areas to attract investors for petroleum exploration	Wells, surveys, licenses, seismic sections, well reports, maps. Data historic and current, archived on different media (paper, mylar, magnetic tape)			[29]				
Argentina	ENARSA	Energia Argentina SA		Established in 2006					http://www.enarsa.com.ar [30]				
Peru	PeruPetro			Active					http://www.perupetro.com.pe				
Kazakhstan		Ministry of Energy and Mineral Resources of the Republic of Kazakhstan (MEMR)		Active					http://www.petrodata.kz				
Pakistan	PPEPDR	Directorate General Petroleum Concessions (DGPC)		Active since 2001		Repository contains more than 10 terabytes of secure petrotechnical data			http://www.ppepdr.net/				

Nigeria	Department of Petroleum Resources			Active since December 2003.	Preserve, maintain the integrity and promote the National E&P data assets with improved quality, efficiency and accessibility in the most rapid, secure and reliable manner		International and PetroBank data management standards	Funded by Establishment Costs - one-off funding by Government and Running Costs - Subscription & Transaction Fees by Operators	http://ndr.dprnigeria.com/					
Turkey	PetroBank MDS	Turkish Petroleum Corporation (TPAO). It is NOC of Turkey.	36˚-42˚ northern parallel and the 26-45˚ eastern meridian.	Operational since 2007	Data assets preservation, easy access to assets, assets access controlling and auditing, consolidation of assets, national archive, central management of all assets, standardization of assets according to international standards and naming conventions, working with the most convenient assets.	Wells, Well log curves, well reports, cores and samples, seismic surveys, post-stack seismic, field data/tapes and seismic acquisition/processing reports.	International and PetroBank data management standards	Funded fully by the Turkish Petroleum Corporation. Service usage is free of charge.	http://www.tpao.gov.tr					

Norway	DISKOS-Norwegian National Data Repository	Norwegian Petroleum Directorate (NPD) and DISKOS Group of oil companies	Norwegian continental shelf	Started in 1995	To ensure compliance with NPD reporting regulations for digital E&P data. To reduce data redundancy. To ensure that data is made generally available to the oil and gas industry and to society as a whole Long term preservation of data.	Wells, Well Log Curves, Seismic Surveys, field, pre-stack & post-stack seismic, seismic reports, production data (monthly allocated).Size of NDR estimated at 310 Terabytes.	SEG-D for seismic field data, SEG-Y for pre-stack and post-stack seismic data (currently only limited amounts of field and pre-stack data) All relevant well data standards such as LIS, DLIS, LAS, SPLA, SCAL etc. PDF and TIF are also used.	Costs are shared equally between all participating oil companies (58) in the Diskos consortium, including the NPD. In addition reporting companies pay to submit and download data. All Norwegian universities have free access to public data in Diskos. Non-oil companies can apply for Associated Membership, there are currently 15 such members.	http://www.diskos.com http://www.npd.no					
United Kingdom	CDA	CDA Common Data Access Ltd	UK Offshore Waters	Well DataStore went live in 1995. DEAL started operations in 2000. The Seismic datastore went live in 2009. Estimated NDR size: 6 Terabytes	Save costs for licenses,Improve access to data,Comply with regulations	Well log curves, Well reports, Post-stack seismic, Seismic reports, VSP, deviation and test data. Estimated NDR size: 6 Terabytes	CDA has adopted DECC's naming standards for wells and surveys and continues to work closely with DECC and industry to identify a range of standards (see the CDA and DECC websites for more on this)	Owned by the UK oil and gas industry	[31] [32] [33] http://www.cdal.com [34]					
United Kingdom	UKOGL	UK Onshore Geophysical Library	UK onshore	In operation since 1994. Managed and operated by Lynx Information Systems Ltd on behalf of UKOGL.	Custodian of all UK onshore seismic data	Seismic, well tops, logs, cultural. Current archive size approx 6TB	SEGY, UKOOA, LAS, DLIS	Self-funded through data sales	http://www.ukogl.org.uk [35]					
Brazil	ANP	Agência Nacional do Petróleo (ANP)		BDEP formed in May 2000		Stores seismic, well log, post stack and pre-stack seismic data and potential field data(Grav/Mag)	ANP standards in place	Funded by Members	http://www.bdep.gov.br					

Mexico	Ditep	Pemex		Established in 2002		Promotes and preserve all the technical E&P information assets of the country			[36]				
Israel		The Ministry of National Infrastructures		Exploratory					[37]				
Cyprus	MCIT	Ministry of Commerce, Industry and Tourism-Energy Service	Offshore	Promotional	Responsible for granting licences for prospecting, exploration and exploitation of hydrocarbons				[38]				
South Africa		Petroleum Agency of South Africa		Active	Seismic data, Well data, Samples, reports and diagrams		Standards: Formats – SEGD, SEGY, LIS, LAS, PDF and TIFF, Media – 3480, 3590, DLT, 8mm Exabyte, DAT	From 2010 funded by Government	[39]				
Kenya	National Data Center (NDC)	National Oil Corporation of Kenya	Offshore and Onshore	Began in 2007, system implemented in 2010.	Digital data preservation, National archive, to implement integrated data management systems, provide easy access to quality-controlled data for internal and external customers, attract oil and gas exploration investment and to reduce data management costs.	Wells, well log curves, well reports, post-stack seismic, field data/tapes, seismic acquisition/processing reports, interpretive maps and reports.	Seismic data- SEGY. 3590 or 3592 data cartridges.	100% Government Funded	http://www.nockenya.co.ke/				
United States	BOEMRE	Bureau of Ocean Energy, Management, Regulation and Enforcement (BOEMRE)	Gulf of Mexico	Has replaced the former Minerals Management Service (MMS)					[40]				
United States	NGRDS	National Geoscience Data Repository System (NGDRS)			NGRDS is a system of geoscience data repositories, providing information about their respective holdings accessible through a web-based supercatalog.		geologic, geophysical, and engineering data, maps, well logs, and samples	DOE has provided funds for the NGDRS since 1993	[41] http://www.energy.gov/ [42] List of Repositories in US listed also as directory [43]				

Cambodia	CNPA	Cambodia National Petroleum Authority	Onshore & Offshore		Promotion and preservation of technical E&P information assets of the country			Norad/OfD and NPD assistance	http://www.cnpa-cambodia.com/				
Afghanistan	MOM	Ministry of Mines of the Islamic Republic of Afghanistan (MoM)	Onshore		Promotion and preservation of technical E&P information assets of the country			Norad/OfD and NPD assistance	http://www.mom.gov.af [44]				
Bangladesh	MOEMR	Hydrocarbon Unit, Ministry of Power, Energy and Mineral Resources (MOEMR)	Onshore & Offshore	Active and ongoing via HCU unit since 2005	A mini-data bank has established in the HCU to handle Production data, Resource data by using Database & GIS Software 2005 and promotion of technical E&P information assets of the country		Funded assistance	Norad/OfD and NPD assistance	http://www.hcu.org.bd/ http://www.petrobangla.org.bd http://www.bapex.com.bd				
Ethiopia	MOME	Ministry of Mines and Energy Ethiopia		Active and ongoing	Promotion of technical E&P information assets of the country				[45]				
Cameroon	SNH	SNH Cameroon		Active & Ongoing	Preservation and promotion of technical E&P information assets of the country				http://www.snh.cm				
Malaysia	PIRI	Petronas		Yet to establish full NDR	Promotion and preservation of technical E&P information assets of the country				http://www.petronas.com.my				
Spain	ATH				Online GIS databases to geophyscial information SIGEOF and ATH (Archivo de Hydrocarbures)				[46] [47] [48]				

Morocco	ONHYM	Office National des Hydrocarbures et des Mines			Promotion and preservation of technical E&P information assets of the country				http://www.onhym.com				
Madagascar	OMNIS				Promotion and preservation of technical E&P information assets of the country			Norad OfD and NPD assistance					
Sudan								Norad OfD and NPD assistance					
Morocco	ONHYM	Office National des Hydrocarbures et des Mines			Promotion and preservation of technical E&P information assets of the country				http://www.onhym.com				
Nicaragua	MEM			Active & ongoing				Norad OfD and NPD assistance	http://www.ine.gob.ni http://www.mem.gob.ni				
Iraq	MoO	Ministry of Oil Republic of Iraq		Active and Ongoing since 2005	MoO establishing a centralized data base and NDR for Iraqi petroleum data and to ensure that data & information from petroleum activities is made available and attract more investors by promoting the petroleum activities	Well logs, Maps, Magnetic tapes, Core & cutting samples, Other geological and geophysical information		Norad/OfD and NPD assistance	http://www.oil.gov.iq				
Latvia	LEGMC	Latvian Environment, Geology and Meteorology Centre	Offshore & Onshore		An E & P data archive centre which provides data available for purchase	Geological (well and seismic data, maps, reports etc.)			[49]				
Albania	AKBN	National Agency of Natural Resources			Generates and promotes exploration opportunities in Albania, maintains archive of E & P data.				[50]				

Uganda	PEPD	Petroleum Exploration & Production Dept (PEPD)	Onshore			Technical E & P data archive and information		Norad/Ofd assistance	[51] [52]				
Zambia		Ministry of Mines and Minerals Development, Geological Survey Department (GSD)	Onshore	Active and ongoing		Technical E & P data archive and information - Technical Records Unit		Norad/Ofd & NPD assistance	[53]				
Ivory Coast	MME	Ministry of Mines & Energy	Onshore & Offshore					Norad/Ofd and NPD assistance	http://www.cotedivoirepr.ci/ [54]				
Romania		National Agency for Mineral Resources			Promotion and preservation of technical E&P information assets of the country				http://www.namr.ro/main_en.htm				
Fiji	SOPAC	Mineral Resources Dept Fiji		Created as SOPAC Petroleum Data Bank a cooperative effort with Geoscience Australia	SOPAC acts as custodian and primary point for E & P data & information preserved on behalf of Pacific Island member nations	Well logs, Maps, Magnetic tapes, Core & cutting samples, Other geological and geophysical information		In part externally managed	http://www.mrd.gov.fj/gfiji/ [55] [56] [57]				
Papua New Guinea	SOPAC	Department of Petroleum and Energy		Created as SOPAC Petroleum Data Bank a cooperative effort with Geoscience Australia	SOPAC acts as custodian and primary point for E & P data & information preserved on behalf of Pacific Island member nations	Well logs, Maps, Magnetic tapes, Core & cutting samples, Other geological and geophysical information		Externally managed	http://www.petroleum.gov.pg [58] [56] [59]				
Solomon Islands	SOPAC			Created as SOPAC Petroleum Data Bank a cooperative effort with Geoscience Australia	SOPAC acts as custodian and primary point for E & P data & information preserved on behalf of Pacific Island member nations	Well logs, Maps, Magnetic tapes, Core & cutting samples, Other geological and geophysical information		Externally managed	[56] [60]				

Tonga	SOPAC			Created as SOPAC Petroleum Data Bank a cooperative effort with Geoscience Australia	SOPAC acts as custodian and primary point for E & P data & information preserved on behalf of Pacific Island member nations	Well logs, Maps, Magnetic tapes, Core & cutting samples, Other geological and geophysical information		Externally managed	[56] [61]					
Vanuatu	SOPAC			Created as SOPAC Petroleum Data Bank a cooperative effort with Geoscience Australia	SOPAC acts as custodian and primary point for E & P data & information preserved on behalf of Pacific Island member nations	Well logs, Maps, Magnetic tapes, Core & cutting samples, Other geological and geophysical information		Externally managed	[56] [62]					
Guyana	GGMC	Guyana Geology and Mines Commission			Promotion and preservation of technical E&P information assets of the country				http://www.ggmc.gov.gy					
Syria	SPC	Syrian Petroleum Company							[63]					
Liberia	NOCAL	National Oil Company of Liberia			Promotion and preservation of technical E&P information assets of the country				http://www.nocal-lr.com/					
Chile	ENAP	National Oil Company of Chile			Promotion and preservation of technical E&P information assets of the country				http://www.enap.cl					
Thailand	PTTEP	PTT Exploration and Production Public Company Ltd			Promotion and preservation of technical E&P information assets of the country				http://www.pttep.com/ [64]					
Venezuela	PDVSA	Petroleos de Venezuela	Onshore & Offshore		Promotion and preservation of technical E&P information assets of the country				http://www.pdvsa.com/					

Trinidad and Tobago		Trinidad Ministry of Energy and Energy Affairs			Promotion and preservation of technical E&P information assets of the country				[65] [66]					
Mozambique	NAPD			Established in 1999 under NORAD support	To ensure that data & information from petroleum activities is made available and attract more investors by promoting the petroleum activities	Well logs, Maps, Magnetic tapes, Core & cutting samples, Other geological and geophysical information		National Budget and INP funds	http://www.inp.gov.mz					
Denmark		Danish Energy Agency			Online GIS service for wells and license data				[67]					
Dominican Republic		Directorate of Hydrocarbons							[68]					
Equatorial Guinea					Exploration databank for Equatorial Guinea				http://www.equatorialoil.com [69]					
Faroe Islands	Jardfeingi	Jardfeingi Faorese Earth and Energy Directorate			Promotion of exploration and licensing rounds				http://www.jardfeingi.fo					
Philippines	PNOC	Philippine National Oil Company			Promotion of exploration and licensing rounds				http://www.pnoc.com.ph [70]					
Greenland	NunaGIS	BMP- Bureau of Minerals and Petroleum		Online GIS with licensing round promotion for hydrocarbons.					http://www.bmp.gl http://licence-map.bmp.gl/					
Iceland	Iceland Continental Shelf Portal (ICSP)	Orkustofnunn - National Energy Authority	Offshore	The Iceland Continental Shelf Portal (ICSP)	Provides access to information about data pertaining to the Icelandic Continental Shelf, in particular initially to the northern Dreki Area to assist with licensing round promotion				http://www.os.is [71]					
Myanmar	MOGE	Myanmar Oil & Gas Enterprise							[72]					

Yemen	PEPA	Petroleum Exploration and Production Authority (PEPA)							http://www.pepa.com.ye/					
Tunisia	ETAP	Enterprise Tunisienne D'Activities Petrolieres			Promotion and preservation of technical E&P information assets of the country				http://www.etap.com.tn					
Gabon	DGH	Direction Generale des Hydrocarbures (DGH)							[73]					
Congo	SNPC	Société Nationale des pétroles du Congo												
Mali	Aurep	Autorite pour la Promotion de la Recherce des Petroliere au Mali			Databank service managing the geological and geophysical data relative to petroleum research.				http://www.aurep.org [74]					
Guatemala	MEM	Dirección General de Hidrocarbures			Online maps and images of wells, seismic, licenses, protected areas, exploration and production				[75] [76]					
Iran	NIOC	National Oil Company of Iran							http://www.nioc.ir					
Libya	NOC	NOC Libya			Virtual data room in place for promotion of exploration and exploitation of hydrocarbons									
United Arab Emirates	ADNOC	Abu Dhabi National Oil Company							http://www.adnoc.ae					
Qatar		Qatar Petroleum							http://www.qp.com.qa					
South Korea	KNOC	Korea National Petroleum Corporation							http://www.knoc.co.kr					
Seychelles	SNOC	Seychelles National Oil Company												

Saudi Arabia		Saudi Aramco							http://www.saudiaramco.com					
Belarus									[77] [78]					
Timor-Leste	LAFAEK	Autoridade Nacional do Petróleo			Online GIS with wells and licences			Norad/OfD assistance	[79]

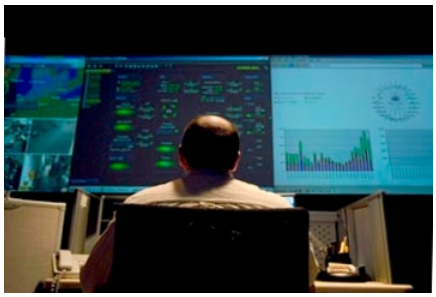
Data Centers

Data center

A **data center** is a facility used to house computer systems and associated components, such as telecommunications and storage systems. It generally includes redundant or backup power supplies, redundant data communications connections, environmental controls (e.g., air conditioning, fire suppression) and various security devices. Large data centers are industrial scale operations using as much electricity as a small town and sometimes are a significant source of air pollution in the form of diesel exhaust.



An operation engineer overseeing a network operations control room of a data center

History

Data centers have their roots in the huge computer rooms of the early ages of the computing industry. Early computer systems were complex to operate and maintain, and required a special environment in which to operate. Many cables were necessary to connect all the components, and methods to accommodate and organize these were devised, such as standard racks to mount equipment, raised floors, and cable trays (installed overhead or under the elevated floor). Also, a single mainframe required a great deal of power, and had to be cooled to avoid overheating. Security was important – computers were expensive, and were often used for military purposes. Basic design guidelines for controlling access to the computer room were therefore devised.

Indiana University Data Center. Bloomington, Indiana

During the boom of the microcomputer industry, and especially during the 1980s, computers started to be deployed everywhere, in many cases with little or no care about operating requirements. However, as information technology (IT) operations started to grow in complexity, companies grew aware of the need to control IT resources. With the advent of Linux and the subsequent proliferation of freely available Unix compatible PC operating systems during the 1990s, as well as MS-DOS finally giving way to a multi-tasking capable Windows OS, PCs started to find their places in the old computer rooms. These were called "servers" as timesharing operating systems like Unix rely heavily on the client-server model to facilitate sharing unique resources between multiple users. The availability of inexpensive networking equipment, coupled with new standards for network structured cabling, made it possible to use a hierarchical design that put the servers in a specific room inside the company. The use of the term "data center," as applied to specially designed computer rooms, started to gain popular recognition about this time.

The boom of data centers came during the dot-com bubble. Companies needed fast Internet connectivity and nonstop operation to deploy systems and establish a presence on the Internet. Installing such equipment was not viable for many smaller companies. Many companies started building very large facilities, called Internet data centers (IDCs),

which provide businesses with a range of solutions for systems deployment and operation. New technologies and practices were designed to handle the scale and the operational requirements of such large-scale operations. These practices eventually migrated toward the private data centers, and were adopted largely because of their practical results. Data centers for cloud computing are called cloud data centers (CDCs). But nowadays, the division of these terms has almost disappeared and they are being integrated into a term "data center."

With an increase in the uptake of cloud computing, business and government organizations are scrutinizing data centers to a higher degree in areas such as security, availability, environmental impact and adherence to standards. Standard Documents from accredited professional groups, such as the Telecommunications Industry Association, specify the requirements for data center design. Well-known operational metrics for data center availability can be used to evaluate the business impact of a disruption. There is still a lot of development being done in operation practice, and also in environmentally friendly data center design. Data centers are typically very expensive to build and maintain.

Requirements for modern data centers

Racks of telecommunications equipment in part of a data center

IT operations are a crucial aspect of most organizational operations around the world. One of the main concerns is **business continuity**; companies rely on their information systems to run their operations. If a system becomes unavailable, company operations may be impaired or stopped completely. It is necessary to provide a reliable infrastructure for IT operations, in order to minimize any chance of disruption. Information security is also a concern, and for this reason a data center has to offer a secure environment which minimizes the chances of a security breach. A data center must therefore keep high standards for assuring the integrity and functionality of its hosted computer environment. This is accomplished through redundancy of both fiber optic cables and power, which includes emergency backup power generation.

The Telecommunications Industry Association's TIA-942 Telecommunications Infrastructure Standard for Data Centers [1], specifies the minimum requirements for telecommunications infrastructure of data centers and computer rooms including single tenant enterprise data centers and multi-tenant Internet hosting data centers. The topology proposed in this document is intended to be applicable to any size data center.[2]

Telcordia GR-3160, *NEBS Requirements for Telecommunications Data Center Equipment and Spaces* [3], provides guidelines for data center spaces within telecommunications networks, and environmental requirements for the equipment intended for installation in those spaces. These criteria were developed jointly by Telcordia and industry representatives. They may be applied to data center spaces housing data processing or Information Technology (IT) equipment. The equipment may be used to:

- Operate and manage a carrier's telecommunication network
- Provide data center based applications directly to the carrier's customers
- Provide hosted applications for a third party to provide services to their customers
- Provide a combination of these and similar data center applications

Effective data center operation requires a balanced investment in both the facility and the housed equipment. The first step is to establish a baseline facility environment suitable for equipment installation. Standardization and modularity can yield savings and efficiencies in the design and construction of telecommunications data centers.

Standardization means integrated building and equipment engineering. Modularity has the benefits of scalability and easier growth, even when planning forecasts are less than optimal. For these reasons, telecommunications data centers should be planned in repetitive building blocks of equipment, and associated power and support

(conditioning) equipment when practical. The use of dedicated centralized systems requires more accurate forecasts of future needs to prevent expensive over construction, or perhaps worse — under construction that fails to meet future needs.

The "lights-out" data center, also known as a darkened or a dark data center, is a data center that, ideally, has all but eliminated the need for direct access by personnel, except under extraordinary circumstances. Because of the lack of need for staff to enter the data center, it can be operated without lighting. All of the devices are accessed and managed by remote systems, with automation programs used to perform unattended operations. In addition to the energy savings, reduction in staffing costs and the ability to locate the site further from population centers, implementing a lights-out data center reduces the threat of malicious attacks upon the infrastructure.

There is a trend to modernize data centers in order to take advantage of the performance and energy efficiency increases of newer IT equipment and capabilities, such as cloud computing. This process is also known as data center transformation.[4]

Organizations are experiencing rapid IT growth but their data centers are aging. Industry research company International Data Corporation (IDC) puts the average age of a data center at nine years old. Gartner, another research company says data centers older than seven years are obsolete.

In May 2011, data center research organization Uptime Institute, reported that 36 percent of the large companies it surveyed expect to exhaust IT capacity within the next 18 months.[5]

Data center transformation takes a step-by-step approach through integrated projects carried out over time. This differs from a traditional method of data center upgrades that takes a serial and siloed approach.[6] The typical projects within a data center transformation initiative include standardization/consolidation, virtualization, automation and security.

- Standardization/consolidation: The purpose of this project is to reduce the number of data centers a large organization may have. This project also helps to reduce the number of hardware, software platforms, tools and processes within a data center. Organizations replace aging data center equipment with newer ones that provide increased capacity and performance. Computing, networking and management platforms are standardized so they are easier to manage.[7]
- Virtualize: There is a trend to use IT virtualization technologies to replace or consolidate multiple data center equipment, such as servers. Virtualization helps to lower capital and operational expenses,[8] and reduce energy consumption.[9] Virtualization technologies are also used to create virtual desktops, which can then be hosted in data centers and rented out on a subscription basis. Data released by investment bank Lazard Capital Markets reports that 48 percent of enterprise operations will be virtualized by 2012. Gartner views virtualization as a catalyst for modernization.[10]
- Automating: Data center automation involves automating tasks such as provisioning, configuration, patching, release management and compliance. As enterprises suffer from few skilled IT workers, automating tasks make data centers run more efficiently.
- Securing: In modern data centers, the security of data on virtual systems is integrated with existing security of physical infrastructures.[11] The security of a modern data center must take into account physical security, network security, and data and user security.

Carrier neutrality

Today many data centers are run by Internet service providers solely for the purpose of hosting their own and third party servers.

However traditionally data centers were either built for the sole use of one large company, or as carrier hotels or Network-neutral data centers.

These facilities enable interconnection of carriers and act as regional fiber hubs serving local business in addition to hosting content servers.

Data center tiers

The Telecommunications Industry Association is a trade association accredited by ANSI (American National Standards Institute). In 2005 it published ANSI/TIA-942 [12], Telecommunications Infrastructure Standard for Data Centers, which defined four levels (called tiers) of data centers in a thorough, quantifiable manner. TIA-942 was amended in 2008 and again in 2010. *TIA-942:Data Center Standards Overview* describes the requirements for the data center infrastructure. The simplest is a Tier 1 data center, which is basically a server room, following basic guidelines for the installation of computer systems. The most stringent level is a Tier 4 data center, which is designed to host mission critical computer systems, with fully redundant subsystems and compartmentalized security zones controlled by biometric access controls methods. Another consideration is the placement of the data center in a subterranean context, for data security as well as environmental considerations such as cooling requirements.[13]

The German Datacenter star audit program uses an auditing process to certify 5 levels of "gratification" that affect Data Center criticality.

Independent from the ANSI/TIA-942 standard, the Uptime Institute, a think tank and professional-services organization based in Santa Fe, New Mexico, has defined its own four levels. The levels describe the availability of data from the hardware at a location. The higher the tier, the greater the availability. The levels are: [14] [15]

Tier Level	Requirements
1	• Single non-redundant distribution path serving the IT equipment • Non-redundant capacity components • Basic site infrastructure with expected availability of 99.671%
2	• Meets or exceeds all Tier 1 requirements • Redundant site infrastructure capacity components with expected availability of 99.741%
3	• Meets or exceeds all Tier 2 requirements • Multiple independent distribution paths serving the IT equipment • All IT equipment must be dual-powered and fully compatible with the topology of a site's architecture • Concurrently maintainable site infrastructure with expected availability of 99.982%
4	• Meets or exceeds all Tier 3 requirements • All cooling equipment is independently dual-powered, including chillers and heating, ventilating and air-conditioning (HVAC) systems • Fault-tolerant site infrastructure with electrical power storage and distribution facilities with expected availability of 99.995%

The difference between 99.671%, 99.741%, 99.982%, and 99.995%, while seemingly nominal, could be significant depending on the application.

Whilst no down-time is ideal, the tier system allows the below durations for services to be unavailable within one year (525,600 minutes):

- Tier 1 (99.671%) status would allow 1729.224 minutes
- Tier 2 (99.741%) status would allow 1361.304 minutes
- Tier 3 (99.982%) status would allow 94.608 minutes

- Tier 4 (99.995%) status would allow 26.28 minutes

Design considerations

A data center can occupy one room of a building, one or more floors, or an entire building. Most of the equipment is often in the form of servers mounted in 19 inch rack cabinets, which are usually placed in single rows forming corridors (so-called aisles) between them. This allows people access to the front and rear of each cabinet. Servers differ greatly in size from 1U servers to large freestanding storage silos which occupy many square feet of floor space. Some equipment such as mainframe computers and storage devices are often as big as the racks themselves, and are placed alongside them. Very large data centers may use shipping containers packed with 1,000 or more servers each; when repairs or upgrades are needed, whole containers are replaced (rather than repairing individual servers).

A typical server rack, commonly seen in colocation

Local building codes may govern the minimum ceiling heights.

Design programming

Design programming, also known as architectural programming, is the process of researching and making decisions to identify the scope of a design project.[16] Other than the architecture of the building itself there are three elements to design programming for data centers: facility topology design (space planning), engineering infrastructure design (mechanical systems such as cooling and electrical systems including power) and technology infrastructure design (cable plant). Each will be influenced by performance assessments and modelling to identify gaps pertaining to the owner's performance wishes of the facility over time.

Various vendors who provide data center design services define the steps of data center design slightly differently, but all address the same basic aspects as given below.

Modeling criteria

Modeling criteria are used to develop future-state scenarios for space, power, cooling, and costs.[17] The aim is to create a master plan with parameters such as number, size, location, topology, IT floor system layouts, and power and cooling technology and configurations.

Design recommendations

Design recommendations/plans generally follow the modelling criteria phase. The optimal technology infrastructure is identified and planning criteria is developed, such as critical power capacities, overall data center power requirements using an agreed upon PUE (power utilization efficiency), mechanical cooling capacities, kilowatts per cabinet, raised floor space, and the resiliency level for the facility.

Conceptual design

Conceptual designs embody the design recommendations or plans and should take into account “what-if” scenarios to ensure all operational outcomes are met in order to future-proof the facility. Conceptual floor layouts should be driven by IT performance requirements as well as lifecycle costs associated with IT demand, energy efficiency, cost efficiency and availability. Future-proofing will also include expansion capabilities, often provided in modern data centers through modularity.

Detail design

Detail design is undertaken once the appropriate conceptual design is determined, typically including a proof of concept. The detail design phase should include the development of facility schematics and construction documents as well as schematic of technology infrastructure, detailed IT infrastructure design and IT infrastructure documentation.

Mechanical engineering infrastructure design

Mechanical engineering infrastructure design addresses mechanical systems involved in maintaining the interior environment of a data center, such as heating, ventilation and air conditioning (HVAC); humidification and dehumidification equipment; pressurization; and so on.[18] This stage of the design process should be aimed at saving space and costs, while ensuring business and reliability objectives are met as well as achieving PUE and green requirements.[19] Modern designs include modularizing and scaling IT loads, and making sure capital spending on the building construction is optimized.

CRAC Air Handler

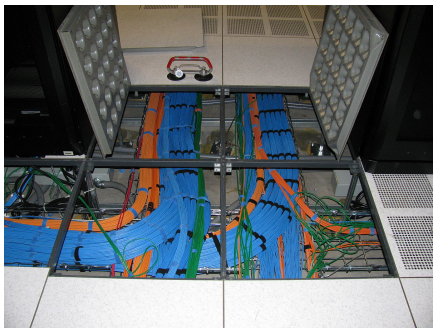
Electrical engineering infrastructure design

Electrical Engineering infrastructure design is focused on designing electrical configurations that accommodate various reliability requirements and data center sizes. Aspects may include utility service planning; distribution, switching and bypass from power sources; uninterruptable power source (UPS) systems; and more.

These designs should dovetail to energy standards and best practices while also meeting business objectives. Electrical configurations should be optimized and operationally compatible with the data center user’s capabilities. Modern electrical design is modular and scalable,[20] and is available for low and medium voltage requirements as well as DC (direct current).

Technology infrastructure design

Technology infrastructure design addresses the telecommunications cabling systems that run throughout data centers. There are cabling systems for all data center environments, including horizontal cabling, voice, modem, and facsimile telecommunications services, premises switching equipment, computer and telecommunications management connections, keyboard/video/mouse connections and data communications.[21] Wide area, local area, and storage area networks should link with other building signaling systems (e.g. fire, security, power, HVAC, EMS).



Under Floor Cable Runs

Availability expectations

The higher the availability needs of a data center, the higher the capital and operational costs of building and managing it. Business needs should dictate the level of availability required and should be evaluated based on characterization of the criticality of IT systems estimated cost analyses from modeled scenarios. In other words, how can an appropriate level of availability best be met by design criteria to avoid financial and operational risks as a result of downtime? If the estimated cost of downtime within a specified time unit exceeds the amortized capital costs and operational expenses, a higher level of availability should be factored into the data center design. If the cost of avoiding downtime greatly exceeds the cost of downtime itself, a lower level of availability should be factored into the design.[22]

Site selection

Aspects such as proximity to available power grids, telecommunications infrastructure, networking services, transportation lines and emergency services can affect costs, risk, security and other factors to be taken into consideration for data center design. Location affects data center design also because the climatic conditions dictate what cooling technologies should be deployed. In turn this impacts uptime and the costs associated with cooling.[23] For example, the topology and the cost of managing a data center in a warm, humid climate will vary greatly from managing one in a cool, dry climate.

Modularity and flexibility

Modularity and flexibility are key elements in allowing for a data center to grow and change over time. Data center modules are pre-engineered, standardized building blocks that can be easily configured and moved as needed.[24]

A modular data center may consist of data center equipment contained within shipping containers or similar portable containers.[25] But it can also be described as a design style in which components of the data center are prefabricated and standardized so that they can be constructed, moved or added to quickly as needs change.[26]

Cabinet Aisle in a Data Center

Environmental control

The physical environment of a data center is rigorously controlled. Air conditioning is used to control the temperature and humidity in the data center. ASHRAE's "Thermal Guidelines for Data Processing Environments" recommends a temperature range of 18–27 °C (64–81 °F), a dew point range of 5–15 °C (41–59 °F), and a maximum relative humidity of 60% for data center environments. The temperature in a data center will naturally rise because the electrical power used heats the air. Unless the heat is removed, the ambient temperature will rise, resulting in electronic equipment malfunction. By controlling the air temperature, the server components at the board level are kept within the manufacturer's specified temperature/humidity range. Air conditioning systems help control humidity by cooling the return space air below the dew point. Too much humidity, and water may begin to condense on internal components. In case of a dry atmosphere, ancillary humidification systems may add water vapor if the humidity is too low, which can result in static electricity discharge problems which may damage components. Subterranean data centers may keep computer equipment cool while expending less energy than conventional designs.

Modern data centers try to use economizer cooling, where they use outside air to keep the data center cool. At least one data center (located in Upstate New York) will cool servers using outside air during the winter. They do not use chillers/air conditioners, which creates potential energy savings in the millions.

Telcordia GR-2930, *NEBS: Raised Floor Generic Requirements for Network and Data Centers* [27], presents generic engineering requirements for raised floors that fall within the strict NEBS guidelines.

There are many types of commercially available floors that offer a wide range of structural strength and loading capabilities, depending on component construction and the materials used. The general types of raised floors include stringerless, stringered, and structural platforms, all of which are discussed in detail in GR-2930 and summarized below.

- ***Stringerless raised floors*** - One non-earthquake type of raised floor generally consists of an array of pedestals that provide the necessary height for routing cables and also serve to support each corner of the floor panels. With this type of floor, there may or may not be provisioning to mechanically fasten the floor panels to the pedestals. This stringerless type of system (having no mechanical attachments between the pedestal heads) provides maximum accessibility to the space under the floor. However, stringerless floors are significantly weaker than stringered raised floors in supporting lateral loads and are not recommended.
- ***Stringered raised floors*** - This type of raised floor generally consists of a vertical array of steel pedestal assemblies (each assembly is made up of a steel base plate, tubular upright, and a head) uniformly spaced on two-foot centers and mechanically fastened to the concrete floor. The steel pedestal head has a stud that is

inserted into the pedestal upright and the overall height is adjustable with a leveling nut on the welded stud of the pedestal head.

- ***Structural platforms*** - One type of structural platform consists of members constructed of steel angles or channels that are welded or bolted together to form an integrated platform for supporting equipment. This design permits equipment to be fastened directly to the platform without the need for toggle bars or supplemental bracing. Structural platforms may or may not contain panels or stringers.

Data centers typically have raised flooring made up of 60 cm (2 ft) removable square tiles. The trend is towards 80–100 cm (31–39 in) void to cater for better and uniform air distribution. These provide a plenum for air to circulate below the floor, as part of the air conditioning system, as well as providing space for power cabling.

Metal whiskers

Raised floors and other metal structures such as cable trays and ventilation ducts have caused many problems with zinc whiskers in the past, and likely are still present in many data centers. This happens when microscopic metallic filaments form on metals such as zinc or tin that protect many metal structures and electronic components from corrosion. Maintenance on a raised floor or installing of cable etc. can dislodge the whiskers, which enter the airflow and may short circuit server components or power supplies, sometimes through a high current metal vapor plasma arc. This phenomenon is not unique to data centers, and has also caused catastrophic failures of satellites and military hardware.

Electrical power

Backup power consists of one or more uninterruptible power supplies, battery banks, and/or diesel / gas turbine generators.[28]

To prevent single points of failure, all elements of the electrical systems, including backup systems, are typically fully duplicated, and critical servers are connected to both the "A-side" and "B-side" power feeds. This arrangement is often made to achieve N+1 redundancy in the systems. Static transfer switches are sometimes used to ensure instantaneous switchover from one supply to the other in the event of a power failure.

A bank of batteries in a large data center, used to provide power until diesel generators can start

Low-voltage cable routing

Data cabling is typically routed through overhead cable trays in modern data centers. But someWikipedia:Avoid weasel words are still recommending under raised floor cabling for security reasons and to consider the addition of cooling systems above the racks in case this enhancement is necessary. Smaller/less expensive data centers without raised flooring may use anti-static tiles for a flooring surface. Computer cabinets are often organized into a hot aisle arrangement to maximize airflow efficiency.

Fire protection

FM200 Fire Suppression Tanks

Data centers feature fire protection systems, including passive and active design elements, as well as implementation of fire prevention programs in operations. Smoke detectors are usually installed to provide early warning of a fire at its incipient stage. This allows investigation, interruption of power, and manual fire suppression using hand held fire extinguishers before the fire grows to a large size. An active fire protection system, such as a fire sprinkler system or a clean agent fire suppression gaseous system, is often provided to control a full scale fire if it develops. High sensitivity smoke detectors, such as Aspirating smoke detectors, activating clean agent fire suppression gaseous systems activate earlier than fire sprinklers. However, as gaseous systems have a limited fire suppression agent storage quantity, the provision of a clean agent system and a sprinkler system protects the building should the fire reignite after the gaseous agent has dispersed. Passive fire protection elements include the installation of fire walls around the data center, so a fire can be restricted to a portion of the facility for a limited time in the event of the failure of the active fire protection systems. Fire wall penetrations into the server room, such as cable penetrations, coolant line penetrations and air ducts, must be provided with fire rated penetration assemblies, such as fire stoping.

Security

Physical security also plays a large role with data centers. Physical access to the site is usually restricted to selected personnel, with controls including bollards and mantraps. Video camera surveillance and permanent security guards are almost always present if the data center is large or contains sensitive information on any of the systems within. The use of finger print recognition mantraps is starting to be commonplace.

Energy use

Google Data Center, The Dalles, Oregon

Energy use is a central issue for data centers. Power draw for data centers ranges from a few kW for a rack of servers in a closet to several tens of MW for large facilities. Some facilities have power densities more than 100 times that of a typical office building. For higher power density facilities, electricity costs are a dominant operating expense and account for over 10% of the total cost of ownership (TCO) of a data center.[29] By 2012 the cost of power for the data center is expected to exceed the cost of the original capital investment.

Greenhouse gas emissions

In 2007 the entire information and communication technologies or ICT sector was estimated to be responsible for roughly 2% of global carbon emissions with data centers accounting for 14% of the ICT footprint. The US EPA estimates that servers and data centers are responsible for up to 1.5% of the total US electricity consumption, or roughly .5% of US GHG emissions,[30] for 2007. Given a business as usual scenario greenhouse gas emissions from data centers is projected to more than double from 2007 levels by 2020.

Siting is one of the factors that affect the energy consumption and environmental effects of a datacenter. In areas where climate favors cooling and lots of renewable electricity is available the environmental effects will be more

moderate. Thus countries with favorable conditions, such as: Canada,[31] Finland,[32] Sweden[33] and Switzerland,[34] are trying to attract cloud computing data centers.

In an 18-month investigation by scholars at Rice University's Baker Institute for Public Policy in Houston and the Institute for Sustainable and Applied Infodynamics in Singapore, data center-related emissions will more than triple by 2020.

Energy efficiency

The most commonly used metric to determine the energy efficiency of a data center is power usage effectiveness, or PUE. This simple ratio is the total power entering the data center divided by the power used by the IT equipment.

$$\mathrm{PUE} = \frac{\text{Total Facility Power}}{\text{IT Equipment Power}}$$

Power used by support equipment, often referred to as overhead load, mainly consists of cooling systems, power delivery, and other facility infrastructure like lighting. The average data center in the US has a PUE of 2.0, meaning that the facility uses one watt of overhead power for every watt delivered to IT equipment. State-of-the-art data center energy efficiency is estimated to be roughly 1.2. Some large data center operators like Microsoft and Yahoo! have published projections of PUE for facilities in development; Google publishes quarterly actual efficiency performance from data centers in operation.

The U.S. Environmental Protection Agency has an Energy Star rating for standalone or large data centers. To qualify for the ecolabel, a data center must be within the top quartile of energy efficiency of all reported facilities.[35]

European Union also has a similar initiative: EU Code of Conduct for Data Centres

Energy use analysis

Often, the first step toward curbing energy use in a data center is to understand how energy is being used in the data center. Multiple types of analysis exist to measure data center energy use. Aspects measured include not just energy used by IT equipment itself, but also by the data center facility equipment, such as chillers and fans.[36]

Power and cooling analysis

Power is the largest recurring cost to the user of a data center. A power and cooling analysis, also referred to as a thermal assessment, measures the relative temperatures in specific areas as well as the capacity of the cooling systems to handle specific ambient temperatures.[37] A power and cooling analysis can help to identify hot spots, over-cooled areas that can handle greater power use density, the breakpoint of equipment loading, the effectiveness of a raised-floor strategy, and optimal equipment positioning (such as AC units) to balance temperatures across the data center. Power cooling density is a measure of how much square footage the center can cool at maximum capacity.

Energy efficiency analysis

An energy efficiency analysis measures the energy use of data center IT and facilities equipment. A typical energy efficiency analysis measures factors such as a data center's power use effectiveness (PUE) against industry standards, identifies mechanical and electrical sources of inefficiency, and identifies air-management metrics.[38]

Computational fluid dynamics (CFD) analysis

This type of analysis uses sophisticated tools and techniques to understand the unique thermal conditions present in each data center—predicting the temperature, airflow, and pressure behavior of a data center to assess performance and energy consumption, using numerical modeling.[39] By predicting the effects of these environmental conditions, CFD analysis in the data center can be used to predict the impact of high-density racks mixed with low-density

racks[40] and the onward impact on cooling resources, poor infrastructure management practices and AC failure of AC shutdown for scheduled maintenance.

Thermal zone mapping

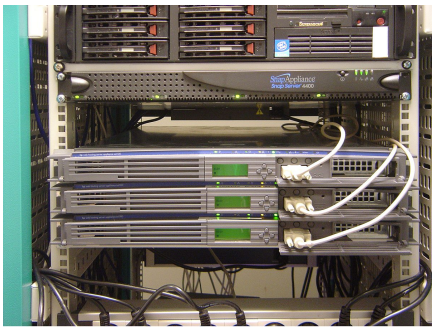
Thermal zone mapping uses sensors and computer modeling to create a three-dimensional image of the hot and cool zones in a data center.[41]

This information can help to identify optimal positioning of data center equipment. For example, critical servers might be placed in a cool zone that is serviced by redundant AC units.

Green datacenters

Datacenters use a lot of power, consumed by two main usages: the power required to run the actual equipment and then the power required to cool the equipment. The first category is addressed by designing computers and storage systems that are more and more power-efficient. And to bring down the cooling costs datacenter designers try to use natural ways to cool the equipment. Many datacenters have to be located near people-concentrations to manage the equipment, but there are also many circumstances where the datacenter can be miles away from the users and don't need a lot of local management. Examples of this are the 'mass' datacenters like Google or Facebook: these DC's are built around many standarised servers and storage-arrays and the actual users of the systems are located all around the world. After the initial build of a datacenter there is not much staff required to keep it running: especially datacenters that provide mass-storage or computing power don't need to be near population centers. Datacenters in arctic locations where outside air provides all cooling are getting more popular as cooling and electricity are the two main variable cost components.[42]

Network infrastructure



An example of "rack mounted" servers

Communications in data centers today are most often based on networks running the IP protocol suite. Data centers contain a set of routers and switches that transport traffic between the servers and to the outside world. Redundancy of the Internet connection is often provided by using two or more upstream service providers (see Multihoming).

Some of the servers at the data center are used for running the basic Internet and intranet services needed by internal users in the organization, e.g., e-mail servers, proxy servers, and DNS servers.

Network security elements are also usually deployed: firewalls, VPN gateways, intrusion detection systems, etc. Also common are monitoring systems for the network and some of the applications. Additional off site monitoring systems are also typical, in case of a failure of communications inside the data center.

Data center infrastructure management

Data center infrastructure management (DCIM) is the integration of information technology (IT) and facility management disciplines to centralize monitoring, management and intelligent capacity planning of a data center's critical systems. Achieved through the implementation of specialized software, hardware and sensors, DCIM enables common, real-time monitoring and management platform for all interdependent systems across IT and facility infrastructures.

Depending on the type of implementation, DCIM products can help data center managers identify and eliminate sources of risk to increase availability of critical IT systems. DCIM products also can be used to identify interdependencies between facility and IT infrastructures to alert the facility manager to gaps in system redundancy, and provide dynamic, holistic benchmarks on power consumption and efficiency to measure the effectiveness of "green IT" initiatives.

Measuring and understanding important data center efficiency metrics. A lot of the discussion in this area has focused on energy issues, but other metrics beyond the PUE can give a more detailed picture of the data center operations. Server, storage, and staff utilization metrics can contribute to a more complete view of an enterprise data center. In many cases, disc capacity goes unused and in many instances the organizations run their servers at 20% utilization or less. More effective automation tools can also improve the number of servers or virtual machines that a single admin can handle.

Applications

A 40-foot Portable Modular Data Center

The main purpose of a data center is running the applications that handle the core business and operational data of the organization. Such systems may be proprietary and developed internally by the organization, or bought from enterprise software vendors. Such common applications are ERP and CRM systems.

A data center may be concerned with just operations architecture or it may provide other services as well.

Often these applications will be composed of multiple hosts, each running a single component. Common components of such applications are databases, file servers, application servers, middleware, and various others.

Data centers are also used for off site backups. Companies may subscribe to backup services provided by a data center. This is often used in conjunction with backup tapes. Backups can be taken off servers locally on to tapes. However, tapes stored on site pose a security threat and are also susceptible to fire and flooding. Larger companies may also send their backups off site for added security. This can be done by backing up to a data center. Encrypted backups can be sent over the Internet to another data center where they can be stored securely.

For quick deployment or disaster recovery, several large hardware vendors have developed mobile solutions that can be installed and made operational in very short time. Companies such as Cisco Systems, Sun Microsystems (Sun Modular Datacenter),[43] Bull, IBM (Portable Modular Data Center), HP (Performance Optimized Datacenter), and Google (Google Modular Data Center) have developed systems that could be used for this purpose.

US Retail Colocation Providers

- Contains estimates from Synergy Research Group.[44]

Rank	Company Name	US Market Share
1	Equinix	18%
2	CenturyLink	8%
3	SunGard	5%
4	AT&T	5%
5	Verizon	5%
6	Telx	4%
7	CyrusOne	4%
8	Level 3 Communications	3%
9	Internap	2%

Virtual data room

A **virtual data room** (sometimes called a **VDR**) is an online repository of information that is used for the storing and distribution of documents. In many cases, a virtual data room is used to facilitate the due diligence process during an M&A transaction, loan syndication, or private equity and venture capital transactions. This due diligence process has traditionally used a physical data room to accomplish the disclosure of documents. For reasons of cost, efficiency and security, virtual data rooms have widely replaced the more traditional physical data room.

Introduction

An alternative to the physical data room involves the setting up of a virtual data room in the form of an extranet to which the bidders and their advisers are given access via the internet. An extranet is essentially an Internet site with limited controlled access, using a secure log-on supplied by the vendor, which can be disabled at any time, by the vendor, if a bidder withdraws. Much of the information released is confidential and restrictions are applied to the viewer's ability to release this to third parties (by means of forwarding, copying or printing). This can be effectively applied to protect the data using digital rights management.

In the process of mergers & acquisitions the data room is set up as part of the central repository of data relating to companies or divisions being acquired or sold. The data room enables the interested parties to view information relating to the business in a controlled environment. Confidentiality is paramount and strict controls for viewing, copying and printing are imposed. Conventionally this is achieved by establishing a supervised, physical data room in secure premises with controlled access. In most cases, with a physical data room, only one bidder team can access the room at a time. This becomes time consuming.

A virtual data room has exactly the same strengths as a conventional data room: controlling access, viewing, copying and printing as well as setting time limits on viewing and logging. It has none of the disadvantages of being in a standard, physical location, needing couriers to move documents or transporting of key staff and personnel back and forth. It is also accessible 24/7 over the allowed period. With a virtual data room, documents reach the regulators and investors in a more efficient and timely manner. Due to improvements in efficiency and speed, a virtual data room typically pays for itself in a single M&A transaction.

A virtual data room is quick to set up. Scanned data and existing electronic files can be mixed, information can be added or eliminated at any time (the changes could be logged if required) and any or all information can be restricted to any or all registered viewers at any time.

Disadvantages of a physical data room

- Time consuming
- Narrow bandwidth
- Expensive
- Cost of travel
- Paper intensive

Benefits of a virtual data room

The largest financial benefits accrue to the seller although buyers also benefit. For the former, advantages include:

- Improvement in the number of bidders.
- Increased bid throughout (and time zone access) if the virtual data room is accessible 24/7 over the allowed period. [*citation needed*]
- Increased control and understanding of bidders.
- Resulting 20%-30% higher bid values. [*citation needed*]
- Increased speed of transactions owing to improved accessibility
- Enhanced information secures more deals at higher prices. [*citation needed*]
- Conventional physical data rooms restrict the bidder or buyers' ability to get the correct people to the room simply due to the physical location. However, Virtual Data Room opens up global markets for M&A, takeovers and property deals compared with purely face-to-face and hardcopy document transactions (i.e. business letters).
- Information cannot be downloaded and taken away in a true Virtual Data Room - only viewed by a user with the correct permissions

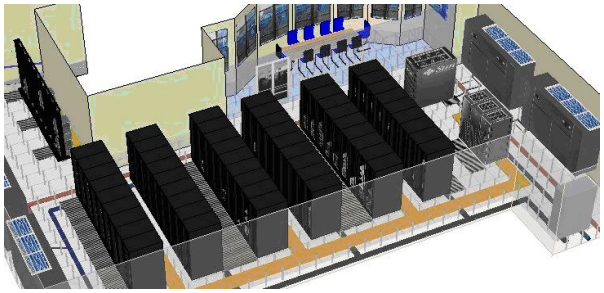
Virtual facility

A **Virtual Facility** (VF) is a highly realistic digital representation of a data center (primarily). The term virtual in Virtual Facility refers to the use of the word as in Virtual Reality rather than the abstraction of computer resources as in platform virtualization. The VF mirrors the characteristics of the physical facility over time and allows modeling all relevant characteristics of a physical data center with a high degree of precision.



A Virtual Facility snapshot created with 6SigmaDC software.

VF Model includes

- Three-dimensional physical facility layout
- Network connectivity of facility equipment
- Full inventory of facility equipment, including electronics and electrical systems such as Power Distribution Units (PDU's) and Uninterruptible Power Supplies (UPS's)
- Full air conditioning system (ACU's) and controls within the room

The term Virtual Facility was introduced by Future Facilities, a data centre design consultancy focused on delivering Design and Operational solutions to address the emerging environmental problems facing the modern Mission Critical Facility (MCF). The concept is in essence a convergence of the fields of Virtual Reality (VR), Computer Simulation and Expert Systems, applied to the specific domain of facilities.

The VF type of computer simulation allows detailed analysis and prototyping of air flow in the data center by making use of Computational Fluid Dynamics (CFD) techniques. This in turn allows the air flow and temperatures of the facility to be analyzed visually (Scientific Visualisation) and numerically to study and predict what will happen in the real facility. The importance of scientific methods in design of mission critical facilities has become a necessity, since the performance gains predicted by Moore's Law go hand in hand with a rise in power and heat dissipated by equipment. Rules of thumb have proven to be no longer adequate.

VF design purposes

- Green field design
- Asset management
- Troubleshooting existing data centers
- Making existing data centers more resilient
- Making existing data centers more energy efficient
- Cost prediction
- Staff training
- Capacity planning
- Load growth management

The VF is now being employed by many large organizations as a way of virtually assessing a situation before having to spend huge sums of money trying to solve a problem in the real facility.

It is essential to know whether adding new equipment or changing equipment will cause a logistical or thermal problem. The VF allows the designer or operator to assess the best course of action and gives in depth understanding on unintuive behaviours.

Network-neutral data center

A **network-neutral data center** (or **carrier-neutral data center**) is a data center (or carrier hotel) which allows interconnection between multiple telecommunication carriers and/or colocation providers. Network-neutral data centers exist all over the world and vary in size and power.

While some data centers are owned and operated by a telecommunications or Internet service provider, *network-neutral* data centers are operated by a third party who has little or no part in providing Internet service to the end-user. This encourages competition and diversity as a server in a colocation centre can have one provider, multiple providers or only connect back to the headquarters of the company who owns the server.

One benefit of hosting in a network-neutral data center is the ability to switch providers without physically moving the server to another location.

Related Technologies

Virtual directory

In computing, the term **virtual directory** has a couple of meanings. It may simply designate (for example in IIS) a folder which appears in a path but which is not actually a subfolder of the preceding folder in the path. However, this article will discuss the term in the context of directory services and identity management.

A virtual directory or **virtual directory server** in this context is a software layer that delivers a single access point for identity management applications and service platforms. A virtual directory operates as a high-performance, lightweight abstraction layer that resides between client applications and disparate types of identity-data repositories, such as proprietary and standard directories, databases, web services, and applications.

A virtual directory receives queries and directs them to the appropriate data sources by abstracting and virtualizing data. The virtual directory integrates identity data from multiple heterogeneous data stores and presents it as though it were coming from one source. This ability to reach into disparate repositories makes virtual directory technology ideal for consolidating data stored in a distributed environment.

As of 2011[1], virtual directory servers most commonly use the LDAP protocol, but more sophisticated virtual directories can also support SQL as well as DSML and SPML.

Industry experts have heralded the importance of the virtual directory in modernizing the identity infrastructure. According to Dave Kearns of Network World,[2] “Virtualization is hot and a virtual directory is the building block, or foundation, you should be looking at for your next identity management project." In addition, Gartner analyst, Bob Blakley[3] said that virtual directories are playing an increasingly vital role. In his report, “The Emerging Architecture of Identity Management,” Blakley wrote: “In the first phase, production of identities will be separated from consumption of identities through the introduction of a virtual directory interface.”

Capabilities of Virtual Directories

Virtual directories can have some or all of the following capabilities:

- Aggregate identity data across sources to create a single point of access.
- Create high-availability for authoritative data stores.
- Act as identity firewall by preventing denial-of-service attacks on the primary data stores through an additional virtual layer.
- Support a common searchable namespace for centralized authentication.
- Present a unified virtual view of user information stored across multiple systems.
- Delegate authentication to backend sources through source-specific security means.
- Virtualize data sources to support migration from legacy data stores without modifying the applications that rely on them.
- Enrich identities with attributes pulled from multiple data stores, based on a link between user entries.

Some advanced identity virtualization platforms can also:

- Enable application-specific, customized views of identity data without violating internal or external regulations governing identity data.Reveal contextual relationships between objects through hierarchical directory structures.
- Develop advanced correlation across diverse sources using correlation rules.
- Build a global user identity by correlating unique user accounts across various data stores, and enrich identities with attributes pulled from multiple data stores, based on a link between user entries.

- Enable constant data refresh for real-time updates through a persistent cache.

Advantages of virtual directories

Virtual Directories:

- Enable faster deployment because users do not need to add and sync additional application-specific data sources
- Leverage existing identity infrastructure and security investments to deploy new services
- Deliver high availability of data sources
- Provide application-specific views of identity data which can help avoid the need to develop a master enterprise schema
- Allow a single view of identity data without violating internal or external regulations governing identity data
- Act as identity firewalls by preventing denial-of-service attacks on the primary data-stores and providing further security on access to sensitive data
- Can reflect changes made to authoritative sources in real-time
- Present a unified virtual view of user information from multiple systems so that it appears to reside in a single system
- Can secure all backend storage locations with a single security policy

Disadvantages

An original disadvantage is public perception of "push & pull technologies" which is the general classification of "virtual directories" depending on the nature of their deployment. Virtual directories were initially designed and later deployed with "Push technologies" in mind, which also contravened with "Privacy laws" in the USA. This is no longer the case. There are, however, other disadvantages in the current technologies.

- The classical virtual directory based on proxy cannot modify underlying data structures or create new views based on the relationships of data from across multiple systems. So if an application requires a different structure, such as a flattened list of identities, or a deeper hierarchy for delegated administration, a virtual directory is limited.
- Many virtual directories cannot correlate same-users across multiple diverse sources in the case of duplicate users
- Virtual directories without advanced caching technologies cannot scale to heterogeneous, high-volume environments.

Sample terminology

- Unify metadata: Extract schemas from the local data source, map them to a common format, and link the same identities from different data silos based on a unique identifier.
- Namespace joining: Create a single large directory by bringing multiple directories together at the namespace level. For instance, if one directory has the namespace "ou=internal,dc=domain,dc=com" and a second directory has the namespace "ou=external,dc=domain,dc=com," then creating a virtual directory with both namespaces is an example of namespace joining.
- Identity joining: Enrich identities with attributes pulled from multiple data stores, based on a link between user entries. For instance if the user joeuser exists in a directory as "cn=joeuser,ou=users" and in a database with a username of "joeuser" then the "joeuser" identity can be constructed from both the directory and the database.
- Data remapping: The translation of data inside of the virtual directory. For instance, mapping “uid” to “samaccountname,” so a client application that only supports a standard LDAP-compliant data source is able to search an Active Directory namespace, as well.
- Query routing: Route requests based on certain criteria, such as “write operations going to a master, while read operations are forwarded to replicas.”

- Identity routing: Virtual directories may support the routing of requests based on certain criteria (such as write operations going to a master while read operations being forwarded to replicas).
- Authoritative source: A "virtualized" data repository, such as a directory or database, that the virtual directory can trust for user data.
- Server groups: Group one or more servers containing the same data and functionality. A typical implementation is the multi-master, multi-replica environment in which replicas process "read" requests and are in one server group, while masters process "write" requests and are in another, so that servers are grouped by their response to external stimuli, even though all share the same data.

Sample Virtual Directory Use Cases

- Integrating multiple directory namespaces to create a central enterprise directory.
- Supporting infrastructure integrations after mergers and acquisitions.
- Centralizing identity storage across the infrastructure, making identity information available to applications through various protocols (including LDAP, JDBC, and web services).
- Creating a single access point for web access management (WAM) tools.
- Enabling web single sign-on (SSO) across varied sources or domains.
- Supporting role-based, fine-grained authorization policies
- Enabling authentication across different security domains using each domain's specific credential checking method.
- Improving secure access to information both inside and outside of the firewall.

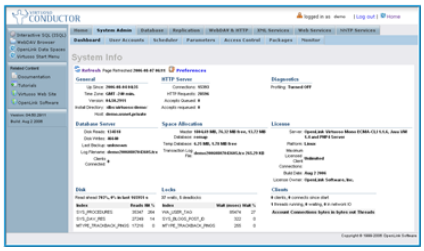
Virtuoso Universal Server

Virtuoso Universal Server



Virtuoso Conductor (Database Administration User Interface)

Developer(s)	OpenLink Software
Stable release	7.1.0 / February 2014
Operating system	Cross-platform
Type	Triplestore, RDBMS, Application server, Web server
License	GPLv2 and proprietary
Website	virtuoso.openlinksw.com [1]

Virtuoso Universal Server is a middleware and database engine hybrid that combines the functionality of a traditional RDBMS, ORDBMS, virtual database, RDF, XML, free-text, web application server and file server functionality in a single system. Rather than have dedicated servers for each of the aforementioned functionality realms, Virtuoso is a "universal server"; it enables a single multithreaded server process that implements multiple protocols. The open source edition of Virtuoso Universal Server is also known as **OpenLink Virtuoso**. The software has been developed by OpenLink Software with Kingsley Uyi Idehen and Orri Erling as the chief software architects.

Database structure

Core database engine

Virtuoso provides an extended object-relational model, which combines the flexibility of relational access with inheritance, run time data typing, late binding, and identity based access. Virtuoso Universal Server database includes physical file and in memory storage and operating system processes that interact with the storage. There is one main process, which has listeners on a specified port for HTTP, SOAP, and other protocols.

Architecture

Virtuoso is designed to take advantage of operating system threading support and multiple CPUs. It consists of a single process with an adjustable pool of threads shared between clients. Multiple threads may work on a single index tree with minimal interference with each other. One cache of database pages is shared among all threads and old dirty pages are written back to disk as a background process.

The database has at all times a clean checkpoint state and a delta of committed or uncommitted changes to this checkpointed state. This makes it possible to do a clean backup of the checkpoint state while transactions proceed on the commit state.

A transaction log file records all transactions since the last checkpoint. Transaction log files may be preserved and archived for an indefinite time, providing a full, recoverable history of the database.

A single set of files is used for storing all tables. A separate set of files is used for all temporary data. The maximum size of a file set is 32 terabytes, for 4G × 8K pages.

Locking

Virtuoso provides dynamic locking, starting with row level locks and escalating to page level locks when a cursor holds a large percentage of a page's rows or when it has a history of locking entire pages. Lock escalation only happens when no other transactions hold locks on the same page, hence it never deadlocks. Virtuoso SQL provides means for exclusive read and for setting transaction isolation.

Transactions

All four levels of isolation are supported: Dirty read, read committed, repeatable read and serializable. The level of isolation may be specified operation by operation within a single transaction. Virtuoso can also act as a resource manager and/or transaction coordinator under Microsoft's Distributed Transaction Coordinator (MS DTC) or the XA standard.

Data integrity

Virtuoso ORDBMS database supports entity integrity and referential integrity. Virtuoso ensures that relationships between records in related tables are valid by enforcing referential integrity. Integrity constraints include:

- NOT NULL - Within the definition of a table, Virtuoso allows data to contain a NULL value. This NULL value is not really a value at all and is considered an absence of value. The constraint of NOT NULL forces a value to be given to a column.
- Unique Key - Uniqueness for a column or set of columns means that the values in that column or set of columns must be different from all other columns or set of columns in that table. A unique key may contain NULL values since they are by definition a unique non-valued value.
- Primary Key - Primary key are much like unique keys except that they are designed to uniquely identify a row in a table. They can consist of a single column or multiple columns. The primary key cannot contain a NULL value.
- CHECK Constraint - Virtuoso provides on a column an integrity constraint that requires certain conditions to be met before the data is inserted or modified. If the checks are not satisfied then the transaction cannot be completed.

Data dictionary

Virtuoso stores all its information about all user objects in the database in the system catalog tables designated by db.dba*.

Components and files

Components

Virtuoso is made up of client and server components. These are the components typically used to communicate with a local or remote Virtuoso server which include:

- Virtuoso Drivers for ODBC, JDBC, ADO.NET and OLE DB
- Conductor, a Web Based Database Administration User Interface
- ISQL (Interactive SQL) and ISQO Utilities
- Documentation and Tutorials
- Samples

All database installation come with two databases, a default database and a demo database.

History

The Virtuoso project was born in 1998 from a merger of the **OpenLink** data access middleware and **Kubl** RDBMS.

Kubl RDBMS

The Kubl ORDBMS was one of a list of relational database systems with roots in Finland. This list also includes MySQL, InnoDB, and Solid RDBMS/Solid Technologies.

As is the case with most technology products, key personnel behind OpenLink Virtuoso, InnoDB, and Solid share periods of professional overlap that provide noteworthy insight into the history of database technology development in Finland. Heikki Tuuri (creator of InnoDB), Ora Lassila (W3C and Nokia Research, a technology lead and visionary in the areas RDF and Semantic Web in general alongside Tim Berners-Lee), and Orri Erling (Virtuoso Program Manager at OpenLink Software) all worked together in a startup company called Entity Systems in Finland - where they were developing Common Lisp and Prolog development environments for the early generation of PC's circa. 1986–88.

Later, Orri Erling worked with VIA International, the developer of VIA/DRE in designing a LISP based object-oriented data access layer atop the company's DBMS product. The core development team of VIA, following the company's demise in 1992, went on to found Solid Technologies under the direction of Artturi Tarjanne.

Heikki Tuuri worked at Solid for a while before starting his own database development project which became InnoDB (acquired by Oracle in 2005).

Orri Erling started his own DBMS development work in 1994, which was to become Kubl. Development of Kubl was initially financed by Infosto Group, publisher of Finland's largest free ads paper, as part of their in-house software development project for their on-line services. The on-line version of *Keltainen Pörssi* was at one time said to be Finland's most popular web site with 500,000 registered users. The Kubl database was prominently displayed in a *"Powered by Kubl"* logo on the search results.

A free trial version of Kubl was made available for download on November 7, 1996.

Kubl was marketed as a high performance lightweight database for embedded use; the development aim was to achieve top scores in Transactions Per Second tests. Pricing of the product was especially favorable to Linux users with a Linux license priced at $199.

Kubl became the cornerstone of OpenLink Virtuoso, after the technology paths of Kingsley Uyi Idehen and Orri Erling crossed in 1998, leading to the acquisition of Kubl by OpenLink Software.

Functionality realms

Virtuoso provides functionality that covers a broad range of traditionally distinct functionality realms as part of a single product offering. The realms include:

- Object-relational database engine for (SQL, XML, RDF and plain text)
- Web services computing platform
- Web application server
- Web content management system (WCMS)
- NNTP-based Discussion Management
- Replication of Homogeneous and Heterogeneous Data
- Mail Storage Sink and (POP3) Service Proxy
- DataPortability

Protocols implemented

In addition to the functionality realms above, the product implements of a broad range of industry standard Web & Internet protocols that includes: HTTP, WebDAV, CalDAV, CardDAV, SOAP, UDDI, WSDL, WS-Policy, WS-Security, WS-ReliableMessaging, WS-Routing, WS-Referral, WS-Attachment, WS-BPEL, SyncML, GData, SPARQL, SPARUL, NNTP

API support

For the database application developer and systems integrator, Virtuoso implements a variety of industry standard data access APIs (client and server) that includes: ODBC, JDBC, OLE DB, ADO.NET, ADO.NET Entity Framework, XMLA

Content syndication and interchange format support

For the Web application developer, content syndicate(s), content publishers, and content consumers, Virtuoso implements support for standards such as: Atom, RSS 2.0, RSS 1.0, OPML, XBEL, FOAF, SIOC

Query language support

SQL, SPARQL (with numerous extensions), XQuery (implementation of Core functions library is seriously incomplete), XPath (1.0 only), XSLT (1.0 only)

Schema definition language support

SQL's Data Definition Language, XML Schema

Usage scenarios

Virtuoso is a solution for the following system integration challenges:

- Enterprise Information Integration (EII)
- Programming Language Independent Web application deployment
- Monolithic application decomposition that leverages the principles of service-oriented architecture
- Web service based enterprise application integration via a significant amount of WS-* protocols support
- Business process management via BPEL
- Semantic Web Data Spaces Generation
- Deployment Platform for injecting RDF-based Linked Data into the Semantic Data Web

Related products and tools

In addition to Virtuoso, OpenLink Software produces several related tools and applications.

- OpenLink Data Spaces a Virtuoso based platform for cost-effective creation and management of Semantic Web / Linked Data Web presence. It provides a data junction box for integrating data across third party Social network service, Blog, File sharing, Shared & Social bookmarking, Wiki, E-mail, Photo Sharing, RSS 2.0, Atom, and RSS 1.1 Content Aggregation services. In addition, to its third party integration functionality, it also includes its own rich collection of Linked Data compliant distributed collaborative applications, across each of the aforementioned Web application realms.
- Universal Data Access Drivers - High-performance data access drivers for ODBC, JDBC, ADO.NET, and OLE DB that provide transparent access to enterprise databases across multiple platforms and databases.

Platforms

Virtuoso is supported on a number of 32- & 64-bit platforms including cross-platform Windows, UNIX (HP, AIX, Sun, DEC, BSD, SCO), Linux (Red Hat, SUSE), and Mac OS X.

Licensing

In April 2006, an open source version of Virtuoso was made available under the GNU General Public License v2. The software is now available in Commercial and Open Source license variants.

Workflow engine

A **workflow engine** is a software application that defines a process, the rules governing process decisions, and routes information.[1] It is a key component in workflow technology and typically makes use of a database server.

A workflow manages and monitors the state of activities, such as the processing and approval of a loan application form, and determines which new activity to transition to according to defined processes (workflows).[2] The actions may be anything from saving an application form in a document management system to sending a reminder e-mail to users or escalating overdue items to management. A workflow engine facilitates the flow of information, tasks, and events.[3] Workflow engines may also be referred to as a Workflow Orchestration Engines.[4]

Workflow engines mainly have three functions:

- Verification of the current status: Check whether the command is valid in executing a task.
- Determine the authority of users: Check if the current user is permitted to execute the task.
- Executing condition script: After passing the previous two steps, workflow engine begins to evaluate condition script in which two processes are carried out, if the condition is true, workflow engine execute the task, and if execution successfully complete, it returns the success, if not, it reports the error to trigger and roll back the change.[5]

A workflow engine is a core technique for task allocation software application, such as BPM in which the workflow engine allocates task to different executors with communicating data among participants. A workflow engine can execute any arbitrary sequence of steps, for example, a healthcare data analysis.

Metadata Models

Metadata

Metadata is "data about data". The term is ambiguous, as it is used for two fundamentally different concepts (types). **Structural metadata** is about the design and specification of data structures and is more properly called "data about the containers of data"; **descriptive metadata**, on the other hand, is about individual instances of application data, the data content.

Metadata are traditionally found in the card catalogs of libraries. As information has become increasingly digital, metadata are also used to describe digital data using metadata standards specific to a particular discipline. By describing the contents and context of data files, the quality of the original data/files is greatly increased. For example, a webpage may include metadata specifying what language it is written in, what tools were used to create it, and where to go for more on the subject, allowing browsers to automatically improve the experience of users.

Definition

Metadata (metacontent) are defined as the data providing information about one or more aspects of the data, such as:

- Means of creation of the data
- Purpose of the data
- Time and date of creation
- Creator or author of the data
- Location on a computer network where the data were created
- Standards used

For example, a digital image may include metadata that describe how large the picture is, the color depth, the image resolution, when the image was created, and other data. A text document's metadata may contain information about how long the document is, who the author is, when the document was written, and a short summary of the document.

Metadata are data. As such, metadata can be stored and managed in a database, often called a metadata registry or metadata repository.[1] However, without context and a point of reference, it might be impossible to identify metadata just by looking at them. For example: by itself, a database containing several numbers, all 13 digits long could be the results of calculations or a list of numbers to plug into an equation - without any other context, the numbers themselves can be perceived as the data. But if given the context that this database is a log of a book collection, those 13-digit numbers may now be identified as ISBNs - information that refers to the book, but is not itself the information within the book.

The term "metadata" was coined in 1968 by Philip Bagley, in his book "Extension of programming language concepts" where it is clear that he uses the term in the ISO 11179 "traditional" sense, which is "structural metadata" i.e. "data about the containers of data"; rather than the alternate sense "content about individual instances of data content" or metacontent, the type of data usually found in library catalogues.[2] Since then the fields of information management, information science, information technology, librarianship and GIS have widely adopted the term. In these fields the word *metadata* is defined as "data about data". While this is the generally accepted definition, various disciplines have adopted their own more specific explanation and uses of the term.

Libraries

Metadata have been used in various forms as a means of cataloging archived information. The Dewey Decimal System employed by libraries for the classification of library materials is an early example of metadata usage. Library catalogues used 3x5 inch cards to display a book's title, author, subject matter, and a brief plot synopsis along with an abbreviated alpha-numeric identification system which indicated the physical location of the book within the library's shelves. Such data help classify, aggregate, identify, and locate a particular book. Another form of older metadata collection is the use by US Census Bureau of what is known as the "Long Form." The Long Form asks questions that are used to create demographic data to find patterns of distribution.

Photographs

Metadata may be written into a digital photo file that will identify who owns it, copyright and contact information, what camera created the file, along with exposure information and descriptive information such as keywords about the photo, making the file searchable on the computer and/or the Internet. Some metadata are written by the camera and some is input by the photographer and/or software after downloading to a computer. However, not all digital cameras enable you to edit metadata; this functionality has been available on most Nikon DSLRs since the Nikon D3 and on most new Canon cameras since the Canon EOS 7D.

Photographic Metadata Standards are governed by organizations that develop the following standards. They include, but are not limited to:

- IPTC Information Interchange Model IIM (International Press Telecommunications Council),
- IPTC Core Schema for XMP
- XMP – Extensible Metadata Platform (an ISO standard)
- Exif – Exchangeable image file format, Maintained by CIPA (Camera & Imaging Products Association) and published by JEITA (Japan Electronics and Information Technology Industries Association)
- Dublin Core (Dublin Core Metadata Initiative – DCMI)
- PLUS (Picture Licensing Universal System).

Video

Metadata are particularly useful in video, where information about its contents (such as transcripts of conversations and text descriptions of its scenes) are not directly understandable by a computer, but where efficient search is desirable.

Web pages

Web pages often include metadata in the form of meta tags. Description and keywords meta tags are commonly used to describe the Web page's content. Most search engines use these data when adding pages to their search index.

Creation of metadata

Metadata can be created either by automated information processing or by manual work. Elementary metadata captured by computers can include information about when an object was created, who created it, when it was last updated, file size and file extension.

For the purposes of this article, an "object" refers to any of the following:

- A physical item such as a book, CD, DVD, map, chair, table, flower pot, etc.
- An electronic file such as a digital image, digital photo, document, program file, database table, etc.

Metadata types

The metadata application is manyfold covering a large variety of fields of application there are nothing but specialised and well accepted models to specify types of metadata. Bretheron & Singley (1994) distinguish between two distinct classes: structural/control metadata and guide metadata. **Structural metadata** are used to describe the structure of database objects such as tables, columns, keys and indexes. **Guide metadata** are used to help humans find specific items and are usually expressed as a set of keywords in a natural language. According to Ralph Kimball metadata can be divided into 2 similar categories: technical metadata and business metadata. **Technical metadata** correspond to internal metadata, *business metadata* - to external metadata. Kimball adds a third category named **process metadata**. On the other hand, NISO distinguishes among three types of metadata: descriptive, structural and administrative. **Descriptive metadata** are the information used to search and locate an object such as title, author, subjects, keywords, publisher; **structural metadata** give a description of how the components of the object are organised; and **administrative metadata** refer to the technical information including file type. Two sub-types of administrative metadata are rights management metadata and preservation metadata.

Metadata structures

Metadata (metacontent), or more correctly, the vocabularies used to assemble metadata (metacontent) statements, are typically structured according to a standardized concept using a well-defined metadata scheme, including: metadata standards and metadata models. Tools such as controlled vocabularies, taxonomies, thesauri, data dictionaries and metadata registries can be used to apply further standardization to the metadata. Structural metadata commonality is also of paramount importance in data model development and in database design.

Metadata syntax

Metadata (metacontent) syntax refers to the rules created to structure the fields or elements of metadata (metacontent). A single metadata scheme may be expressed in a number of different markup or programming languages, each of which requires a different syntax. For example, Dublin Core may be expressed in plain text, HTML, XML and RDF.

A common example of (guide) metacontent is the bibliographic classification, the subject, the Dewey Decimal class number. There is always an implied statement in any "classification" of some object. To classify an object as, for example, Dewey class number 514 (Topology) (i.e. books having the number 514 on their spine) the implied statement is: "<book><subject heading><514>. This is a subject-predicate-object triple, or more importantly, a class-attribute-value triple. The first two elements of the triple (class, attribute) are pieces of some structural metadata having a defined semantic. The third element is a value, preferably from some controlled vocabulary, some reference (master) data. The combination of the metadata and master data elements results in a statement which is a metacontent statement i.e. "metacontent = metadata + master data". All these elements can be thought of as "vocabulary". Both metadata and master data are vocabularies which can be assembled into metacontent statements. There are many sources of these vocabularies, both meta and master data: UML, EDIFACT, XSD, Dewey/UDC/LoC, SKOS, ISO-25964, Pantone, Linnaean Binomial Nomenclature etc. Using controlled vocabularies for the components of metacontent statements, whether for indexing or finding, is endorsed by ISO-25964 [3]: "If both the indexer and the searcher are guided to choose the same term for the same concept, then relevant documents will be retrieved." This is particularly relevant when considering the behemoth of the internet, Google. It simply indexes pages then matches text strings using its complex algorithm, there is no intelligence or "inferencing" occurring. Just the illusion thereof.

Hierarchical, linear and planar schemata

Metadata schema can be hierarchical in nature where relationships exist between metadata elements and elements are nested so that parent-child relationships exist between the elements. An example of a hierarchical metadata schema is the IEEE LOM schema where metadata elements may belong to a parent metadata element. Metadata schema can also be one-dimensional, or linear, where each element is completely discrete from other elements and classified according to one dimension only. An example of a linear metadata schema is Dublin Core schema which is one dimensional. Metadata schema are often two dimensional, or planar, where each element is completely discrete from other elements but classified according to two orthogonal dimensions.

Metadata hypermapping

In all cases where the metadata schemata exceed the planar depiction, some type of hypermapping is required to enable display and view of metadata according to chosen aspect and to serve special views. Hypermapping frequently applies to layering of geographical and geological information overlays.

Granularity

The degree to which the data or metadata are structured is referred to as their granularity. Metadata with a high granularity allow for deeper structured information and enable greater levels of technical manipulation however, a lower level of granularity means that metadata can be created for considerably lower costs but will not provide as detailed information. The major impact of granularity is not only on creation and capture, but moreover on maintenance. As soon as the metadata structures get outdated, the access to the referred data will get outdated. Hence granularity shall take into account the effort to create as well as the effort to maintain.

Metadata standards

International standards apply to metadata. Much work is being accomplished in the national and international standards communities, especially ANSI (American National Standards Institute) and ISO (International Organization for Standardization) to reach consensus on standardizing metadata and registries.

The core standard is ISO/IEC 11179-1:2004 and subsequent standards (see ISO/IEC 11179). All yet published registrations according to this standard cover just the definition of metadata and do not serve the structuring of metadata storage or retrieval neither any administrative standardisation. It is important to note that this standard refers to metadata as the data about containers of the data and not to metadata (metacontent) as the data about the data contents. It should also be noted that this standard describes itself originally as a "data element" registry, describing disembodied data elements, and explicitly disavows the capability of containing complex structures. Thus the original term "data element" is more applicable than the later applied buzzword "metadata".

The Dublin Core metadata terms are a set of vocabulary terms which can be used to describe resources for the purposes of discovery. The original set of 15 classic metadata terms, known as the Dublin Core Metadata Element Set are endorsed in the following standards documents:

- IETF RFC 5013
- ISO Standard 15836-2009
- NISO Standard Z39.85.

Although not a standard, Microformat (also mentioned in the section metadata on the internet below) is a web-based approach to semantic markup which seeks to re-use existing HTML/XHTML tags to convey metadata. Microformat follows XHTML and HTML standards but is not a standard in itself. One advocate of microformats, Tantek Çelik, characterized a problem with alternative approaches:

> Here's a new language we want you to learn, and now you need to output these additional files on your server. It's a hassle. (Microformats) lower the barrier to entry.

Metadata usage

Data virtualization

Data virtualization has emerged as the new software technology to complete the virtualization stack in the enterprise. Metadata are used in data virtualization servers which are enterprise infrastructure components, alongside database and application servers. Metadata in these servers are saved as persistent repository and describe business objects in various enterprise systems and applications. Structural metadata commonality is also important to support data virtualization.

Statistics and census services

Standardization work has had a large impact on efforts to build metadata systems in the statistical community[*citation needed*]. Several metadata standardsWikipedia:Avoid weasel words are described, and their importance to statistical agencies is discussed. Applications of the standardsWikipedia:Avoid weasel words at the Census Bureau, Environmental Protection Agency, Bureau of Labor Statistics, Statistics Canada, and many others are described[*citation needed*]. Emphasis is on the impact a metadata registry can have in a statistical agency.

Library and information science

Libraries employ metadata in library catalogues, most commonly as part of an Integrated Library Management System. Metadata are obtained by cataloguing resources such as books, periodicals, DVDs, web pages or digital images. These data are stored in the integrated library management system, ILMS, using the MARC metadata standard. The purpose is to direct patrons to the physical or electronic location of items or areas they seek as well as to provide a description of the item/s in question.

More recent and specialized instances of library metadata include the establishment of digital libraries including e-print repositories and digital image libraries. While often based on library principles, the focus on non-librarian use, especially in providing metadata, means they do not follow traditional or common cataloging approaches. Given the custom nature of included materials, metadata fields are often specially created e.g. taxonomic classification fields, location fields, keywords or copyright statement. Standard file information such as file size and format are usually automatically included.

Standardization for library operation has been a key topic in international standardization (ISO) for decades. Standards for metadata in digital libraries include Dublin Core, METS, MODS, DDI, ISO standard Digital Object Identifier (DOI), ISO standard Uniform Resource Name (URN), PREMIS schema, Ecological Metadata Language, and OAI-PMH. Leading libraries in the world give hints on their metadata standards strategies.

Metadata and the law

United States

Problems involving metadata in litigation in the United States are becoming widespread.Wikipedia:Manual of Style/Dates and numbers#Chronological items Courts have looked at various questions involving metadata, including the discoverability of metadata by parties. Although the Federal Rules of Civil Procedure have only specified rules about electronic documents, subsequent case law has elaborated on the requirement of parties to reveal metadata. In October 2009, the Arizona Supreme Court has ruled that metadata records are public record.

Document metadata have proven particularly important in legal environments in which litigation has requested metadata, which can include sensitive information detrimental to a party in court.

Using metadata removal tools to "clean" documents can mitigate the risks of unwittingly sending sensitive data. This process partially (see Data remanence) protects law firms from potentially damaging leaking of sensitive data through electronic discovery.

Metadata in healthcare

Australian researches in medicine started a lot of metadata definition for applications in health care. That approach offers the first recognized attempt to adhere to international standards in medical sciences instead of defining a proprietary standard under the WHO umbrella first.

The medical community yet did not approve the need to follow metadata standards despite respective research.[3]

Metadata and data warehousing

Data warehouse (DW) is a repository of an organization's electronically stored data. Data warehouses are designed to manage and store the data whereas the business intelligence (BI) focuses on the usage of the data to facilitate reporting and analysis.[4]

The purpose of a data warehouse is to house standardized, structured, consistent, integrated, correct, cleansed and timely data, extracted from various operational systems in an organization. The extracted data are integrated in the data warehouse environment in order to provide an enterprise wide perspective, one version of the truth. Data are structured in a way to specifically address the reporting and analytic requirements. The design of structural metadata commonality using a data modeling method such as entity relationship model diagramming is very important in any data warehouse development effort.

An essential component of a data warehouse/business intelligence system is the metadata and tools to manage and retrieve the metadata. Ralph Kimball describes metadata as the DNA of the data warehouse as metadata defines the elements of the data warehouse and how they work together.

Kimball et al. refers to three main categories of metadata: Technical metadata, business metadata and process metadata. Technical metadata are primarily definitional, while business metadata and process metadata are primarily descriptive. Keep in mind that the categories sometimes overlap.

- **Technical metadata** define the objects and processes in a DW/BI system, as seen from a technical point of view. The technical metadata include the system metadata which define the data structures such as: tables, fields, data types, indexes and partitions in the relational engine, and databases, dimensions, measures, and data mining models. Technical metadata define the data model and the way it is displayed for the users, with the reports, schedules, distribution lists and user security rights.
- **Business metadata** are a content from the data warehouse described in more user-friendly terms. The business metadata tell you what data you have, where they come from, what they mean and what their relationship is to other data in the data warehouse. Business metadata may also serve as a documentation for the DW/BI system. Users who browse the data warehouse are primarily viewing the business metadata.
- **Process metadata** are used to describe the results of various operations in the data warehouse. Within the ETL process, all key data from tasks are logged on execution. This includes start time, end time, CPU seconds used, disk reads, disk writes and rows processed. When troubleshooting the ETL or query process, this sort of data becomes valuable. Process metadata are the fact measurement when building and using a DW/BI system. Some organizations make a living out of collecting and selling this sort of data to companies - in that case the process metadata becomes the business metadata for the fact and dimension tables. Collecting process metadata is in the interest of business people who can use the data to identify the users of their products, which products they are using and what level of service they are receiving.

Metadata on the Internet

The HTML format used to define web pages allows for the inclusion of a variety of types of metadata, from basic descriptive text, dates and keywords to further advanced metadata schemes such as the Dublin Core, e-GMS, and AGLS[5] standards. Pages can also be geotagged with coordinates. Metadata may be included in the page's header or in a separate file. Microformats allow metadata to be added to on-page data in a way that users do not see, but computers can readily access.

Interestingly, many search engines are cautious about using metadata in their ranking algorithms due to exploitation of metadata and the practice of search engine optimization, SEO, to improve rankings. See Meta element article for further discussion. Studies show that search engines respond to web pages with metadata implementations.[6]

Metadata in the broadcast industry

In broadcast industry, metadata are linked to audio and video Broadcast media to:

- *identify* the media: clip or playlist names, duration, timecode, etc.
- *describe* the content: notes regarding the quality of video content, rating, description (for example, during a sport event, keywords like *goal*, *red card* will be associated to some clips)
- *classify* media: metadata allow to sort the media or to easily and quickly find a video content (a TV news could urgently need some archive content for a subject). For example, the BBC have a large subject classification system, Lonclass, a customized version of the more general-purpose Universal Decimal Classification.

These metadata can be linked to the video media thanks to the video servers. All latest broadcasted sport events like FIFA World Cup or Olympic Games use these metadata to distribute their video content to TV stations through keywords. It's often the host broadcaster who is in charge of organizing metadata through its *International Broadcast Centre* and its video servers. Those metadata are recorded with the images and are entered by metadata operators (*loggers*) who associate in live metadata available in *metadata grids* through software (such as Multicam(LSM) or IPDirector used during FIFA World Cup or Olympic Games).

Geospatial metadata

Metadata that describe geographic objects (such as datasets, maps, features, or simply documents with a geospatial component) have a history dating back to at least 1994 (refer MIT Library page on FGDC Metadata [8]). This class of metadata is described more fully on the Geospatial metadata page.

Ecological and environmental metadata

Ecological and environmental metadata are intended to document the who, what, when, where, why, and how of data collection for a particular study. Metadata should be generated in a format commonly used by the most relevant science community, such as Darwin Core, Ecological Metadata Language, or Dublin Core. Metadata editing tools exist to facilitate metadata generation (e.g. Metavist, Mercury: Metadata Search System, Morpho). Metadata should describe provenance of the data (where they originated, as well as any transformations the data underwent) and how to give credit for (cite) the data products.

Digital music

CDs such as recordings of music will carry a layer of metadata about the recordings such as dates, artist, genre, copyright owner, etc. The metadata, not normally displayed by CD players, can be accessed and displayed by specialized music playback and/or editing applications.

The metadata for compressed and uncompressed digital music is often encoded in the ID3 tag. Common editors such as TagLib support MP3, Ogg Vorbis, FLAC, MPC, Speex, WavPack TrueAudio, WAV, AIFF, MP4 and ASF file formats.

Cloud applications

With the availability of Cloud applications, which include those to add metadata to content, metadata is increasingly available over the Internet.

Metadata administration and management

Metadata storage

Metadata can be stored either *internally*, in the same file as the data, or *externally*, in a separate file. Metadata that are embedded with content is called *embedded metadata*. A data repository typically stores the metadata *detached* from the data. Both ways have advantages and disadvantages:

- Internal storage allows transferring metadata together with the data they describe; thus, metadata are always at hand and can be manipulated easily. This method creates high redundancy and does not allow holding metadata together.
- External storage allows bundling metadata, for example in a database, for more efficient searching. There is no redundancy and metadata can be transferred simultaneously when using streaming. However, as most formats use URIs for that purpose, the method of how the metadata are linked to their data should be treated with care. What if a resource does not have a URI (resources on a local hard disk or web pages that are created on-the-fly using a content management system)? What if the metadata can only be evaluated if there is a connection to the Web, especially when using RDF? How to realize that a resource is replaced by another with the same name but different content?

Moreover, there is the question of data format: storing metadata in a human-readable format such as XML can be useful because users can understand and edit it without specialized tools. On the other hand, these formats are not optimized for storage capacity; it may be useful to store metadata in a binary, non-human-readable format instead to speed up transfer and save memory.

Metadata management

Metadata management is the end-to-end process and governance framework for creating, controlling, enhancing, attributing, defining and managing a metadata schema, model or other structured aggregation, either independently or within a repository and the associated supporting processes (often to enable the management of content). The world Wide Web Consortium (W3C) has identified Governance as a key challenge in the advancement of third generation Web Technologies (Web 3.0, Semantic Web), and a number of research prototypes, such as S3DB, explore the use of semantic modeling to identify practical solutions.

Database management

Each relational database system has its own mechanisms for storing metadata. Examples of relational-database metadata include:

- Tables of all tables in a database, their names, sizes and number of rows in each table.
- Tables of columns in each database, what tables they are used in, and the type of data stored in each column.

In database terminology, this set of metadata is referred to as the catalog. The SQL standard specifies a uniform means to access the catalog, called the information schema, but not all databases implement it, even if they implement other aspects of the SQL standard. For an example of database-specific metadata access methods, see Oracle metadata. Programmatic access to metadata is possible using APIs such as JDBC, or SchemaCrawler.

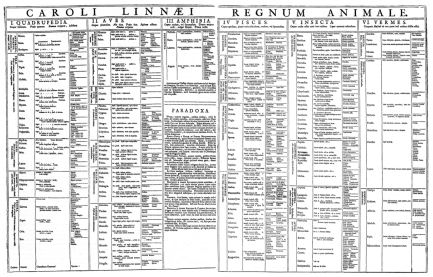
Meta-data management

Meta-data management (also known as metadata management, without the hyphen) involves managing data about *other data*, whereby this "other data" is generally referred to as *content* data. The term is used most often in relation to Digital media, but older forms of metadata are catalogs, dictionaries, and taxonomies. For example, the Dewey Decimal Classification is a metadata management system for books developed in 1876 for libraries.



Linnaean taxonomy, a metadata system used historically for grouping animals in zoos, first published in 1735

Metadata schema

Metadata management can be defined as the end-to-end process and governance framework for creating, controlling, enhancing, attributing, defining and managing a metadata schema, model or other structured aggregation system, either independently or within a repository and the associated supporting processes (often to enable the management of content). For web-based systems, URLs, images, video etc. may be referenced from a triples table of object, attribute and value.

Scope

With specific knowledge domains, the boundaries of the metadata for each must be managed, since a general ontology is not useful to experts in one field whose language is knowledge-domain specific.

Metadata manager

If one is in the process of making a knowledge management solution, creating a metadata schema and developing a system in which metadata is managed are very important. In such a project, a dedicated metadata manager may be appointed in order to maintain adherence to metadata and information management standards. [*citation needed*] This is a person who will be responsible for the metadata strategy, and possibly, the implementation. A metadata manager does not need to know about and be involved with everything concerning the solution, but it does help to have an understanding of as much of the process as possible to make sure a relevant schema is developed.

Card catalog and digital media access point

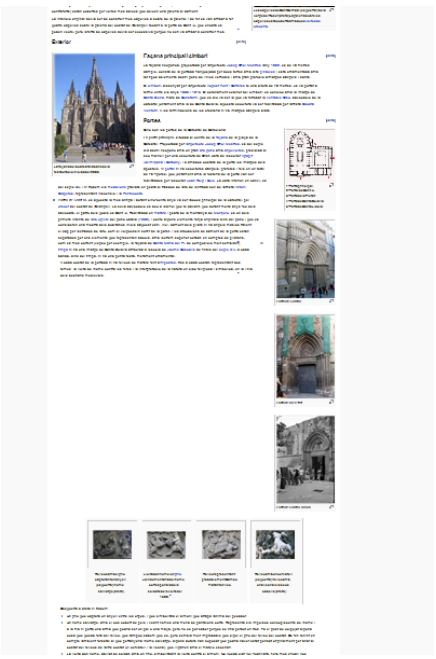
Metadata management over time

Managing the metadata in a knowledge management solution is an important step in a metadata strategy. It is part of the strategy to make sure that the metadata are complete, current and correct at any given time. Managing a metadata project is also about making sure that users of the system are aware of the possibilities allowed by a well-designed metadata system and how to maximize the benefits of metadata. Regular monitoring the metadata to ensure that the schema remains relevant is advised.

Wikipedia metadata

Wikipedia is a project that actively manages metadata for its articles and files. For example, volunteer editors carefully curate new biographical articles based on the notability (*claim to fame*), name, birth, and/or death dates.[1] Similarly, volunteer editors carefully curate new architectural articles based on name, municipality, or geo coordinates.[2] When new articles with a valid alternate spelling are added to Wikipedia that match up to existing articles based on metadata, these are then manually checked and if needed, tagged for merging.[3] When new articles are added that are considered out of scope or otherwise unfit for Wikipedia, these are nominated for deletion.[4] To help keep track of metadata on Wikipedia, the new Wikimedia project Wikidata was established in 2012. Click on the pictures to view more metadata about these images:

This picture of the Barcelona Cathedral was uploaded to the English Wikipedia in 2003 to illustrate its Wikipedia article, and was transferred to Wikimedia Commons in 2007 so it could be used in other language versions of Wikipedia.



This screenprint of the Catalan Wikipedia page on the cathedral features several photos including this one. The screenprint was uploaded to Wikimedia Commons in 2007 soon after the photo was available there, but that article on the Catalan Wikipedia has since been expanded.

Metadatabase

Metadatabase is a database model for (1) **metadata** management, (2) global query of independent databases, and (3) distributed data processing.[1][2][3][4][5] The word *metadatabase* is an addition to the dictionary. Originally, metadata was only a common term referring simply to "data about data", such as tags, keywords, and markup headers. However, in this technology, the concept of metadata is extended to also include such data and knowledge representation as information models (e.g., relations, entities-relationships, and objects), application logic (e.g., production rules), and analytic models (e.g., simulation, optimization, and mathematical algorithms). In the case of analytic models, it is also referred to as a **Modelbase**.[6]

These classes of metadata are integrated with some modeling ontology[7] to give rise to a stable set of meta-relations (tables of metadata). Individual models are interpreted as metadata and entered into these tables. As such, models are inserted, retrieved, updated, and deleted in the same manner as ordinary data do in an ordinary (relational) database. Users will also formulate global queries and requests for processing of local databases through the Metadatabase, using the globally integrated metadata. The Metadatabase structure can be implemented in any open technology for relational databases.

Significance

The Metadatabase technology is developed at Rensselaer Polytechnic Institute at Troy, New York, by a group of faculty and students (see the references at the end of the article), starting in late 1980s. Its main contribution includes the extension of the concept of metadata and metadata management, and the original approach of designing a database for metadata applications. These conceptual results continue to motivate new research and new applications. At the level of particular design, its openness and scalability is tied to that of the particular ontology proposed: It requires reverse-representation of the application models in order to save them into the meta-relations. In theory, the ontology is neutral, and it has been proven in some industrial applications.[8] However, it needs more development to establish it for the field as an open technology. The requirement of reverse-representation is common to any global information integration technology. A way to facilitate it is in the Metadatabase approach is to distribute a core portion of it at each local site, to allow for peer-to-peer translation on the fly.

Metadirectory

A **metadirectory** system provides for the flow of data between one or more directory services and databases, in order to maintain synchronization of that data, and is an important part of identity management systems. The data being synchronized typically are collections of entries that contain user profiles and possibly authentication or policy information. Most metadirectory deployments synchronize data into at least one LDAP-based directory server, to ensure that LDAP-based applications such as single sign-on and portal servers have access to recent data, even if the data is mastered in a non-LDAP data source.

Metadirectory products support filtering and transformation of data in transit.

Most identity management suites from commercial vendors include a metadirectory product, or a user provisioning product.

Open source software

Ldap Synchronization Connector [1] synchronize data from any data source including databases, LDAP directories or files by reading, transforming and comparing these data between the source and the target referentials. These connectors can then be used to continuously synchronize a data source to a directory, for a one shot import or just to compare differences by outputting CSV or LDIF format reports.

Metadata controller

Metadata controller (or MDC) is a storage area network (SAN) technology for managing file locking, space allocation and data access authorization. This is needed when several clients are given block level access to the same disk volume.

The abstract for the patent describing this technology can be read here [1]

Data element

In metadata, the term **data element** is an atomic unit of data that has precise meaning or precise semantics. A data element has:

1. An identification such as a data element name
2. A clear data element definition
3. One or more representation terms
4. Optional enumerated values Code (metadata)
5. A list of synonyms to data elements in other metadata registries Synonym ring

Data elements usage can be discovered by inspection of software applications or application data files through a process of manual or automated Application Discovery and Understanding. Once data elements are discovered they can be registered in a metadata registry.

In telecommunication, the term **data element** has the following components:

1. A named unit of data that, in some contexts, is considered indivisible and in other contexts may consist of data items.
2. A named identifier of each of the entities and their attributes that are represented in a database.
3. A basic unit of information built on standard structures having a unique meaning and distinct units or values.
4. In electronic record-keeping, a combination of characters or bytes referring to one separate item of information, such as name, address, or age.

In the areas of databases and data systems more generally a data element is a concept forming part of a data model. As an element of data representation, a collection of data elements forms a data structure.[1]

In Practice

In practice, data elements (fields, columns, attributes, etc.) are sometimes "over loaded", meaning a given data element will have multiple potential meanings. While a known bad practice, over loading is nevertheless a very real factor or barrier to understanding what a system is doing.

Metadata publishing

Metadata publishing is the process of making metadata data elements available to external users, both people and machines using a formal review process and a commitment to change control processes.

Metadata publishing is the foundation upon which advanced distributed computing functions are being built. But like building foundations, care must be taken in metadata publishing systems to ensure the structural integrity of the systems built on top of them.

Definition of metadata publishing

Published metadata has the following characteristics:

1. Metadata structures available to the general public on a public web site or by a download
2. There is a documented review and approval process for adding or updating data elements to the system
3. New releases are made available without disturbing prior versions
4. A publishing organization that makes a commitment to change control process

Benefits of metadata publishing

When classifying benefits of metadata publishing two groups are usually considered. External parties are usually consumers of information that are not part of the publishing organization. Internal parties are usually the various business units or departments within an organization.

Benefits to external parties

1. Allows external systems (both people and agents) to have a clear understanding of the semantics of data elements in a system
2. Allows third parties to build semantic maps between data models and import and export data between systems
3. Promotes service oriented architectures and allow horizontal sharing of information between traditional information silos
4. Allows systems to participate in accurately indexed and federated search processes

Benefits to internal parties

1. allows parties from diverse business units to agree on shared data definitions and separate department or function specific definitions
2. makes Extract, transform, load (ETL) operations more precise for data warehousing
3. allows user interface designers to access a common pool of screen and report header labels
4. promotion of model-driven architecture

Objections to metadata publishing

- Organizations that publish their metadata could make it easier for unauthorized people to find sensitive data if they breach an organization's firewall
- Vendors that publish their metadata risk customers creating tools that could allow their customers to export their data from computer systems therefor making it easier to migrate off of a vendor's system

Core process in metadata publishing

The following are some of the core processes in metadata publishing

1. Gathering of metadata requirements
2. Selection of metadata registry and metadata publishing tools
3. Training of metadata concepts to project participants
4. Stakeholder group formation
5. Metadata harvesting
6. Glossary consolidation
7. Initial upper ontology construction (abstract data elements)
8. Draft data element loading
9. Data element review process
10. Publishing approved metadata elements in a variety of output formats (see below)
11. Creation and maintenance of versions and depreciation of unused or redundant data elements

File format metadata publishing

Organizations that create applications that store data in file systems can also publish metadata definitions. One common way to perform this is to store application data in a compressed XML file format. The XML files can be uncompressed and validated against an external XML Schema. An example of this is done by the Open Source FreeMind tool.

Metadata publishing formats

1. HTML - used for browsing a web site and indexing by text-based search engines
2. Web Ontology Language (OWL) - used by metadata search engines such as Swoogle
3. XML Metadata Interchange (XMI) - OMG standard for exchanging metadata
4. Common Warehouse Metamodel (CMW) - OMG standard for data warehouse metadata
5. Topic maps - an ISO standard for the representation and interchange of knowledge, with an emphasis on the findability of information.
6. KM3 or Kernel Meta Meta Model as used in the Metamodel Zoos. The AtlanticZoo [1] is an open source library of more than 100 metamodels under EPL License. KM3 [2] is a simple Domain Specific Language for specifying metamodels. A number of transformations are available to translate from KM3 to other notations like XMI.

Metadata registry

A **metadata registry** is a central location in an organization where metadata definitions are stored and maintained in a controlled method.

Use of Metadata Registries

Metadata registries are used whenever data must be used consistently within an organization or group of organizations. Examples of these situations include:

- Organizations that transmit data using structures such as XML, Web Services or EDI
- Organizations that need consistent definitions of data across time, between databases, between organizations or between processes, for example when an organization builds a data warehouse
- Organizations that are attempting to break down "silos" of information captured within applications or proprietary file formats

Central to the charter of any metadata management programme is the process of creating trusting relationships with stakeholders and that definitions and structures have been reviewed and approved by appropriate parties.

Common characteristics of a metadata registry

A metadata registry typically has the following characteristics:

- Protected environment where only authorized individuals may make changes
- Stores data elements that include both semantics and representations
- Semantic areas of a metadata registry contain the meaning of a data element with precise definitions
- Representational areas of a metadata registry define how the data is represented in a specific format, such as in a database or a structured file format (e.g., XML)

Clear separation of semantics and system-specific constraints

Because metadata registries are used to store both semantics (the meaning of a data element) and systems-specific constraints (for example the maximum length of a string) it is important to identify what systems impose these constraints and to document them. For example the maximum length of a string should not change the meaning of a data element.

The International Organization for Standardization (ISO) has published standards for a metadata registry called ISO/IEC 11179 and also ISO15000-3 and ISO15000-4 ebXML registry and repository (regrep) [1] EbXML RegRep

ISO standards

There are two ISO standards which are commonly referred to as metadata registry standards: ISO 11179 and ISO 15000-3. There are some who believe that ISO 11179 and ISO 15000-3 are interchangeable or at least in some way similar. e.g.

"Of interest is that the ISO 11179 model was one of the inputs to the ebXML RIM (registry information model) and so has much functional equivalence to the "registry" region of the ISO 11179 conceptual model." [2]

This is however incorrect. Although the specification ebRIM v2.0 (5 december 2001) says at the beginning in its Design Objectives: "Leverage as much as possible the work done in the OASIS [OAS] and the ISO 11179 [ISO] Registry models" [3] by the time of ebRIM v3.0 (2 May 2005) all reference to ISO/IOEC 11179 is reduced to a mention under informative references on page 76 of 78. [4] It was recognised by some team members that the ebXML RIM data model had no place to store "fine grained artifacts" [5] ie. the data elements which are at the heart of ISO/IEC 11179, but not until 2009 can an explicit and definitive statement from the team be found. [6]

ISO/IEC 11179

ISO/IEC 11179 says that it is concerned with "traditional" metadata: "We limit the scope of the term as it is used here in ISO/IEC 11179 to descriptions of data - the more traditional use of the term." Originally the standard named itself a "data element" registry. It describes data elements: "data elements are the fundamental units of data" and "data elements themselves contain various kinds of data that include characters, images, sound, etc." It also describes a registry with an analogy: "This is analogous to the registries maintained by governments to keep track of motor vehicles. A description of each motor vehicle is entered in the registry, but not the vehicle itself."

ebXML

The ebXML RIM says about its Repository and Registry that it is

- "... capable of storing any type of electronic content such as XML documents, text documents, images, sound and video … RepositorytItems (sic) are stored in a content repository".

It also says that it is

- "... capable of storing standardized metadata that MAY be used to further describe RepositoryItems" which metadata "… are stored in the registry".

It also describes itself with "...this familiar metaphor. An ebXML Registry is like your local library. The repository is like the bookshelves in the library. The repository items in the repository are like book (sic) on the bookshelves." It goes on to say "The registry is like the card catalog … A RegistryObject is like a card in the card catalog."

What should be immediately apparent is that something which holds catalogue cards is not "like" a catalogue, it IS a catalogue.

Unfortunately for a number of organisations that have implemented ebXML RIM to satisfy a requirement for an ISO/IEC 11179 registry, ebXML RIM

- is neither a registry

- nor does it store metadata.

It is

- a "content repository"
- and a "metacontent catalogue".

Metadata registry roles

A metadata registry is frequently set up and administered by an organization's data architect or data modeling team.

Data elements are frequently assigned to data stewards or data stewardship teams that are responsible for the maintenance of individual data elements.

Metadata element workflow

Metadata registries frequently have a formal data element submission, approval and publishing approval process. Each data element should be accepted by a data stewardship team and reviewed before data elements are published. After publication change control processes should be used.

Metadata navigation, search and publishing

Metadata registries are frequently large and complex structures and require navigation, visualization and searching tools. Use of hierarchical viewing tools are frequently an essential part of a metadata registry system. Metadata publishing consists of making data element definitions and structures available to both people and other systems.

Examples of public metadata registries

- Agency for Healthcare Research and Quality- United States Health Information Knowledgebase (USHIK) [7]
- Apelon Medical Registry [8]
- Australian Institute of Health and Welfare [9]
- Dublin Core Metadata Registry [10]
- Knowledge Network for Biocomplexity [11]
- Cancer Data Standards Repository [12]
- Global Justice XML Data Model (GJXDM) [13]
- Minnesota Department of Education Metadata Registry (K-12 Data)[14]
- National Information Exchange Model [15]
- NIST ebXML Registry for HL7 / HIMSS / IHE [16]
- Open Metadata Registry (formerly the National Science Digital Library (NSDL) Metadata Registry) [17]
- US Department of Defense Metadata Registry (requires sponsored registration) [18]
- US Environmental Protection Agency - Environmental Data Registry [19]

Metadata facility for Java

The **Metadata Facility for Java** is a specification for Java that defines an API for annotating fields, methods, and classes as having particular attributes that indicate they should be processed in specific ways by development tools, deployment tools, or run-time libraries.

The specification was developed under the Java Community Process as JSR 175, and was released as a part of J2SE 5.0 (Tiger).

Object Management Group

Object Management Group	
Abbreviation	OMG
Motto	We Set the Standard
Formation	1989
Headquarters	109 Highland Ave Needham, Massachusetts
Website	www.omg.org [1]

Object Management Group (**OMG**) is an international, open membership, not-for-profit computer industry standards consortium. OMG Task Forces develop enterprise integration standards for a wide range of technologies and an even wider range of industries. OMG's modeling standards enable powerful visual design, execution and maintenance of software and other processes. Originally aimed at standardizing distributed object-oriented systems, the company now focuses on modeling (programs, systems and business processes) and model-based standards.

Overview

OMG provides only specifications, and does not provide implementations. But before a specification can be accepted as a standard by OMG, the members of the winning submitter team must guarantee that they will bring a conforming product to market within a year. This is an attempt to prevent unimplemented (and unimplementable) standards.

Other private companies or open source groups are encouraged to produce conforming products and OMG is attempting to develop mechanisms to enforce true interoperability.

OMG hosts technical meetings for its members and interested nonmembers. The Technical meetings provide a neutral forum to discuss, develop and adopt standards that enable software interoperability for a wide range of industries including: Finance, Manufacturing, CORBA, Security and more. In December 2013, the TC meeting will be in Santa Clara, California; in March 2014, in Reston, Virginia; in June 2014, in Boston, MA; in September 2014 in Austin, Texas, in September 2014, in Long Beach, California; and in March 2015, they return to Reston, VA. [2]

History

Founded in 1989 by eleven companies (including Hewlett-Packard, IBM, Sun Microsystems, Apple Computer, American Airlines and Data General), OMG's initial focus was to create a heterogeneous distributed object standard. The founding executive team included Christopher Stone, Richard Soley, Bill Hoffman [3] and John Slitz. As of November, 2012, the leadership includes Chairman and CEO Richard Soley, President and COO Bill Hoffman [3] and Vice President and Technical Director Andrew Watson.

Since 2000, the OMG's International Headquarters have been located in Needham, Massachusetts. In November, 2012, the headquarters was moved from 140 Kendrick St to 109 Highland Ave.

OMG Headquarters

The goal was a common portable and interoperable object model with methods and data that work using all types of development environments on all types of platforms.

In 1997, the Unified Modeling Language (UML) was added to the list of OMG adopted technologies. UML is a standardized general-purpose modeling language in the field of object-oriented software engineering.

In June 2005, the Business Process Management Initiative (BPMI.org) and OMG announced the merger of their respective Business Process Management (BPM) activities to form the Business Modeling and Integration Domain Task Force (BMI DTF).

In 2006 the BPMN language specification was adopted as a standard by OMG.

In 2007 the Business Motivation Model (BMM) was adopted as a standard by the OMG. The BMM is a metamodel that provides a vocabulary for corporate governance and strategic planning and is particularly relevant to businesses undertaking governance, regulatory compliance, business transformation and strategic planning activities.

In 2009 OMG, together with the Software Engineering Institute at Carnegie Mellon, launched the Consortium of IT Software Quality (CISQ). CISQ brings together industry executives from Global 2000 IT organizations, system integrators, outsourcers, and package vendors to jointly address the challenge of standardizing the measurement of IT software quality and to promote a market-based ecosystem to support its deployment.

In 2011 OMG formed the Cloud Standards Customer Council [4]. Founding sponsors included CA, IBM, Kaavo, Rackspace and Software AG. The CSCC is an OMG end user advocacy group dedicated to accelerating cloud's successful adoption, and drilling down into the standards, security and interoperability issues surrounding the transition to the cloud. The Council is not a standards organization, but will complement existing cloud standards efforts and establish a core set of client-driven requirements to ensure cloud users will have the same freedom of choice, flexibility, and openness they have with traditional IT environments. CSCC is open to all end-user organizations.

In September, 2011, the OMG Board of Directors unanimously voted to adopt the Vector Signal and Image Processing Library (VSIPL) as the latest OMG specification. Work for adopting the specification was led by Mentor Graphics' Embedded Software Division, RunTime Computing Solutions, The Mitre Corporation as well as the High Performance Embedded Computing Software Initiative (HPEC-SI). VSIPL is an application programming interface (API) defined by an open standard developed by embedded signal and image processing hardware and software vendors, academia, application developers, and government labs. VSIPL and VSIPL++ contain hundreds of functions used for common signal processing kernel and other computations. These functions include basic arithmetic, trigonometric, transcendental, signal processing, linear algebra, and image processing. The VSIPL family of libraries has been implemented by multiple vendors for a range of processor architectures, including x86, PowerPC, Cell, and NVIDIA GPUs. VSIPL and VSIPL++ are designed to achieve high performance, increase programmer productivity and maintain portability across a range of processor architectures. Additionally, VSIPL++ was designed from the start to include support for parallelism.

Late 2012 early 2013, The Object Management Group Board of Directors has adopted the Automated Function Point (AFP) specification.[5] The push for adoption was led by the Consortium for IT Software Quality (CISQ). AFP provides a standard for automating the popular Function Point measure according to the counting guidelines of the International Function Point User Group (IFPUG).

Hot Topics

On the company's website, there is a Hot Topics [6] page featuring a few of the different technology areas that are currently trending. As of December 4, 2013, the hot topics include: Data Distribution Service, Financial Industry Business Ontology (FIBO), Security Fabric, and Software-defined networking(SDN).

OMG products

Common Object Request Broker Architecture

At its founding, OMG set out to create the initial Common Object Request Broker Architecture (CORBA) standard which appeared in 1991. CORBA is a standard that enables software components written in multiple computer languages and running on multiple computers to work together (i.e., it supports multiple platforms). OMG has also developed a core set of standards adapting CORBA for embedded and real-time systems. Implementations of real time CORBA are widely used in control systems in ships and aircraft.

Data Distribution Service

Data Distribution Service for real-time systems (DDS) is a specification of a publish/subscribe middleware for distributed systems created in response to the need to augment CORBA with a data-centric publish-subscribe specification.[7]

Model Driven Architecture

OMG evolved towards modeling standards by creating the standard for Unified Modeling Language (UML) followed by related standards for

- Meta-Object Facility (MOF),
- XML Metadata Interchange (XMI)
- MOF Query/Views/Transformation (QVT).
- Model to text transformation language (MOFM2T).

These together provide the foundation for Model Driven Architecture (MDA), and related set of standards, building upon the success of UML and MOF.

Systems Modeling Language (SysML), a modeling language based on UML for use in Systems Engineering, has been standardized in collaboration with INCOSE.

Significant progress has also been made in bringing the world of UML modeling and the Semantic Web together through the adoption of the *Ontology Definition Metamodel* which relates UML models in a standard way with RDF and Web Ontology Language (OWL) models.

Semantics of Business Vocabulary and Business Rules (SBVR) is a landmark for the OMG, the first OMG specification to incorporate the formal use of natural language in modeling and the first to provide explicitly a model of formal logic. Based on a fusion of linguistics, logic, and computer science, and two years in preparation, SBVR provides a way to capture specifications in natural language and represent them in formal logic so they can be machine-processed. SBVR is an integral part of MDA.

Architecture Driven Modernization

Architecture Driven Modernization (ADM) is the reverse of MDA. ADMTF is an OMG group similar to ADTF with high potential.

Knowledge Discovery Metamodel (KDM), a common intermediate representation for existing software systems and their operating environments. Knowledge Discovery Metamodel is designed as the OMG's foundation for software modernization and software assurance. Knowledge Discovery Metamodel uses Meta-Object Facility to define an XMI interchange format between tools that work with existing software and an abstract interface for the next-generation assurance and modernization tools.

The Software Process Engineering Metamodel (SPEM) is an OMG-standard for Meta-Process Modeling.

Abstract Syntax Tree Metamodel (ASTM), a modeling language for fine grained reverse engineering.

Semantics of Business Vocabulary and Business Rules (SBVR) and KDM are designed as two parts of a unique OMG Technology Stack for software analytics related to existing software systems. KDM defines an ontology related to software artifacts and thus provides an initial formalization of the information related to a software system. SBVR is further used to formalize complex compliance rules related to the software.

Domain models

- Business models : OMG manages a number of standards for business modeling, including BPMN, the Business Motivation Model (BMM) and the Semantics of Business Vocabulary and Business Rules (SBVR) specification.
- Verticals : Considerable progress has also been made in developing vertical model-based standards in the healthcare, finance, telecommunications, manufacturing, software-defined radio, space/ground systems communications and some dozen other technology areas.

Software assurance and regulatory compliance

New activities have been initiated to address important concerns of *Regulatory Compliance* and *Software Assurance*, building upon the base standards of MDA.

Certification

OMG offers a number of professional certifications:

- OCEB - OMG Certified Expert in Business Process Management (BPM)[8]
- OCUP - OMG Certified UML Professional[9]
- OCSMP - OMG Certified Systems Modeling Professional[10]
- OCRES - OMG Certified Real-time and Embedded Systems Specialist[11]

In 2013, OMG announced that it has updated its OCEB program to reflect improvements made to the BPMN specification in Version 2.0. As of December, 2013, only the updated OCEB 2 Fundamental certification level has been made available with Business Intermediate and Technical Intermediate updates expected to be released in the next few months.[12]

Semantics of Business Vocabulary and Business Rules

The **Semantics of Business Vocabulary and Business Rules** (SBVR) is an adopted standard of the Object Management Group (OMG) intended to be the basis for formal and detailed natural language declarative description of a complex entity, such as a business. SBVR is intended to formalize complex compliance rules, such as operational rules for an enterprise, security policy, standard compliance, or regulatory compliance rules. Such formal vocabularies and rules can be interpreted and used by computer systems. SBVR is an integral part of the OMG's Model Driven Architecture (MDA).

Overview

The SBVR defines the vocabulary and rules for documenting the semantics of business vocabularies, business facts, and business rules; as well as an XMI schema for the interchange of business vocabularies and business rules among organizations and between software tools.

SBVR allows the production of business vocabularies and rules; vocabulary plus rules constitute a shared domain model with the same expressive power of standard ontological languages. SBVR allows multilingual development, since it is based on separation between symbols and their meaning. SBVR enables making business rules accessible to software tools, including tools that support the business experts in creating, finding, validating, and managing business rules, and tools that support the information technology experts in converting business rules into implementation rules for automated systems.

SBVR uses OMG's Meta-Object Facility (MOF) to provide interchange capabilities MOF/XMI mapping rules, enable generating MOF-compliant models and define an XML schema. SBVR proposes Structured English as one of possibly many notations that can map to the SBVR Metamodel.

SBVR and Knowledge Discovery Metamodel (KDM) are designed as two parts of a unique OMG Technology Stack for software analytics related to existing software systems. KDM defines an ontology related to software artifacts and thus provides an initial formalization of the information related to a software system. SBVR can be further used to formalize complex compliance rules related to the software.

Background

Business rules represent the primary means by which an organization can direct its business, defining the operative way to reach its objectives and perform its actions.

A rule-based approach to managing business and the information used by that business is a way of *identifying and articulating the rules which define the structure and control the operation of an enterprise* it represents a new way to think about enterprise and its rules, in order to enable a complete business representation made by and for business people. Business rules can play an important role in defining business semantics: they can influence or guide behaviours and support policies, responding to environmental situations and events. *Semantics of Business Vocabulary and Business Rules* (SBVR) is the OMG implementation of the business rules approach.

History

In June 2003 OMG issued the Business Semantics of Business Rule (BSBR) Request For Proposal, in order to create a standard *to allow business people to define the policies and rules by which they run their business in their own language, in terms of the things they deal with in the business, and to capture those rules in a way that is clear, unambiguous and readily translatable into other representations.* The SBVR proposal was developed by the Business Rules Team, a consortium organized in August 2003 to respond to the BSBR RFP.[1][2]

In September 2005, The Business Modeling and Integration Task Force and the Architecture Board of the Object Management Group approved the proposal *Semantics of Business Vocabulary and Business Rules (SBVR)* to become a final adopted specification in response to the RFP. Later SBVR proposal was ratified by the Domain Technical Committee (DTC), approved of the OMG Board of Directors, and SBVR finalization task force was launched to convert the proposal into ISO/OMG standard format and perform final editing prior to release as an OMG formal specification.

In January 2008, the finalization phase was completed and the Semantics of Business Vocabulary and Business Rules (SBVR), Version 1.0 formal specification was released and is publicly available[3] at the Catalog of OMG Business Strategy, Business Rules and Business Process Management Specifications [4] web page.

Conceptual Formalization

SBVR is a landmark for the OMG, the first OMG specification to incorporate the formal use of natural language in modeling and the first to provide explicitly a model of formal logic. Based on a fusion of linguistics, logic, and computer science, and two years in preparation, SBVR provides a way to capture specifications in natural language and represent them in formal logic so they can be machine-processed.

Methodologies used in software development are typically applied only when a problem is already formulated and well described. The actual difficulty lies in the previous step, that is describing problems and expected functionalities. Stakeholders involved in software development can express their ideas using a language very close to them, but they usually are not able to formalize these concepts in a clear and unambiguous way. This implies a large effort in order to interpret and understand real meanings and concepts hidden among stakeholders' words. Special constraints on syntax or predefined linguistic structures can be used in order to overcome this problem, enabling natural language to well represent and formally define problems and requirements.

The main purpose of natural language modelling is hence to make natural language suitable for conceptual modelling. The focus is on semantic aspects and shared meanings, while syntax is thought in a perspective based on formal logic mapping.

Conceptualization and representation play fundamental roles in thinking, communicating, and modeling. For each concept there is a triad of 1) the concept in our minds, 2) the real-world things conceptualized by the concept, and 3) a representation of the concept that we can use to think and communicate about the concept and its corresponding real-world things. (Note that real-world things include both concrete things and representations of those concrete things as records and processes in operational information systems.)

A conceptual model is a formal structure representing a possible world, comprising a conceptual schema and a set of facts that instantiate the conceptual schema. The conceptual schema is a combination of concepts and facts of what is possible, necessary, permissible, and obligatory in each possible world. The set of facts instantiates the conceptual schema by assertion to describe one possible world. A rule is a fact that asserts either a logical necessity or an obligation. Obligations are not necessarily satisfied by the facts; necessities are always satisfied.

SBVR contains a vocabulary for conceptual modeling and captures expressions based on this vocabulary as formal logic structures. The SBVR vocabulary allows one to formally specify representations of concepts, definitions, instances, and rules of any knowledge domain in natural language, including tabular forms. These features make SBVR well suited for describing business domains and requirements for business processes and information systems

to implement business models.

Fact-orientation

People communicate facts, that is the fact is the unit of communication. The fact-oriented approach enables multidimensional categorization.

- The fact-oriented approach supports time changeability.
- The fact-oriented approach provides semantic stability.
- The fact-oriented approach enables extensibility and reuse.
- The fact-oriented approach involves breaking down compound fact types into elementary (atomic) ones.

Conceptual formalization describes a business domain, and is composed of 1) a conceptual schema (fact structure) and 2) a population of ground facts. A business domain (universe of discourse) comprises those aspects of the business that are of interest.

The schema declares:

- the relevant fact types (kinds of ground fact, e.g. *Employee works for Department*)
- the relevant business rules (typically constraints or derivation rules).

A fact is a proposition taken to be true by the business. Population facts are restricted to elementary and existential facts.

Constraints can be static or dynamic:

- A static constraint imposes a restriction on what fact populations are possible or permitted, for each fact population taken individually e.g. *Each Employee was born on at most one Date.*
- A dynamic constraint imposes a restriction on transitions between fact populations

e.g. *a person's marital status may change from single to married, but not from divorced to single*

Derivation of facts.

- Derivation means either, how a fact type may be derived from one or more other fact types e.g.
  - *Person1 is an uncle of Person2 if Person1 is a brother of some Person3 who is a parent of Person2*
- Or, how a noun concept (object type) may be defined in terms of other object types and fact types e.g.
  - *Each FemaleAustralian is a Person who was born in Country 'Australia' and has Gender 'Female'*

Rule-based approach

Rules play a very important role in defining business semantics: they can influence or guide behaviours and support policies, responding to environmental situations and events. This means that rules represent the primary means by which an organization can direct its business, defining the operative way to reach its objectives and perform its actions.

The rule-based approach aims to address two different kinds of users:

- it addresses business communities, in order to provide them with a structured approach, based on a clear set of concepts and used to access and manage business rules;
- it addresses IT professionals, in order to provide them with a deep understanding about business rules and to help them in models creation. The rules-based approach also helps bridge the rift that can occur between the data managers and the software designers.

The essence of the rule-based conceptual formalizations is that *rules build on facts, and facts build on concepts as expressed by* terms

This mantra is memorable, but a simplification since in SBVR: Meaning is separate from expression; Fact Types (Verb Concepts) are built on Noun Concepts; Noun Concepts are represented by Terms; and Fact Types are

represented by Fact Symbols (verb phrases).

Rule statements are expressed using either alethic modality or deontic modality and require elements of modal logic as formalization.

SBVR **Structural Business Rules** use two alethic modal operators:

it is necessary that …

it is possible that …

SBVR **Operative Business Rules** use two deontic modal operators:

it is obligatory that …

it is permitted that …

Structural business rules (static constraints) are treated as alethic necessities by default, where each state of the fact model corresponds to a possible world. Pragmatically, the rule is understood to apply to all future states of the fact model, until the rule is revoked or changed. For the model theory, the necessity operator is omitted from the formula. Instead, the rule is merely tagged as a necessity. For compliance with Common Logic, such formulae can be treated as irregular expressions, with the necessity modal operator treated as an uninterpreted symbol.

If the rule includes exactly one deontic operator, e.g. O (obligation), and this is at the front, then the rule may be formalized as Op, where p is a first-order formula that is tagged as obligatory. In SBVR, this tag is assigned the informal semantics: it ought to be the case that p (for all future states of the fact model, until the constraint is revoked or changed). From a model-theoretic perspective, a model is an interpretation where each non-deontic formula evaluates to true, and the model is classified as: a permitted model if the p in each deontic formula (of the form Op) evaluates to true, otherwise the model is a forbidden model (though still a model). This approach removes any need to assign a truth value to expressions of the form Op.

SBVR is formal logic with a natural language interface

SBVR is for modeling in natural language. Based on linguistics and formal logic, SBVR provides a way to represent statements in controlled natural languages as logic structures called semantic formulations. SBVR is intended for expressing business vocabulary and business rules, and for specifying business requirements for information systems in natural language. SBVR models are declarative, not imperative or procedural. SBVR has the greatest expressivity of any OMG modeling language. The logics supported by SBVR are typed first order predicate logic with equality, restricted higher order logic (Henkin semantics), restricted deontic and alethic modal logic, set theory with bag comprehension, and mathematics. SBVR also includes projections, to support definitions and answers to queries, and questions, for formulating queries. Interpretation of SBVR semantic formulations is based on model theory. SBVR has a MOF model, so models can be structurally linked at the level of individual facts with other MDA models based on MOF.

SBVR is aligned with Common Logic – published by ISO as ISO/IEC 24707:2007.

SBVR captures business facts and business rules that may be expressed either informally or formally. Business rule expressions are formal only if they are expressed purely in terms of: fact types in the pre-declared schema for the business domain, certain logical/ mathematical operators, quantifiers etc. Formal rules are transformed into a logical formulation that is used for exchange with other rules-based software tools. Informal rules may be exchanged as un-interpreted comments. An approach to automatically generate SBVR business rules from natural language specification is presented in.

SBVR and other OMG standards

SBVR specification defines a metamodel and allows to instance it, in order to create different vocabularies and to define the related business rules; it is also possible to complete these models with data suitable to describe a specific organization. the SBVR approach provides means (i.e. mapping rules) to translate natural language artifacts into MOF-compliant artifacts; this allows to exploit all the advantages related to MOF (repository facilities, interchangeability, tools, …).

Several MDA-related OMG works in progress are expected to incorporate SBVR, including:

- Business Process Definition Metamodel (BPDM)
- Organization Structure Metamodel (OSM)
- Business Motivation Model (BMM)
- UML Profile for Production Rule Representation (PRR)
- UML Profile for the Department of Defense Architecture Framework/Ministry of Defense(Canada) Architecture Framework (DoDAF/MODAF).
- Knowledge Discovery Metamodel (KDM)
- Wider interest in SBVR– Semantic Web, OASIS

The Ontology Definition Metamodel (ODM) has been made compatible with SBVR, primarily by aligning the logic grounding of the ISO Common Logic specification (CL) referenced by ODM with the SBVR Logical Formulation of Semantics vocabulary. CL itself was modified specifically so it potentially can include the modal sentence requirements of SBVR. ODM provides a bridge to link SBVR to the Web Ontology Language for Services (OWL-S), Resource Description Framework Schema (RDFS), Unified Modeling Language (UML), Topic Map (TM), Entity Relationship Modeling (ER), Description Logic (DL), and CL.

Other programs outside the OMG are adopting SBVR. The Digital Business Ecosystem (DBE), an integrated project of the European Commission Framework Programme 6, has adopted SBVR as the basis for its Business Modeling Language.[*citation needed*] The World Wide Web Consortium (W3C) is assessing SBVR for use in the Semantic Web, through the bridge provided by ODM.[*citation needed*] SBVR will extend the capability of MDA in all these areas.

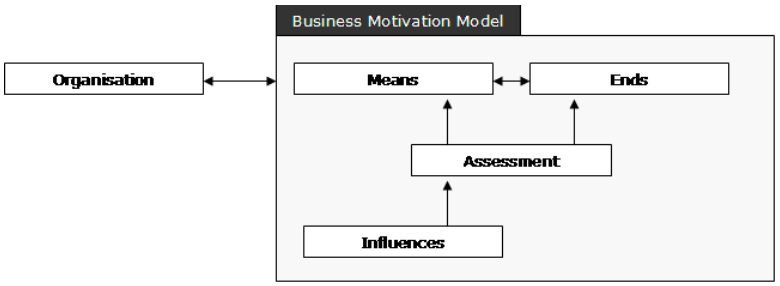
Business Motivation Model

The **Business Motivation Model** (BMM) in enterprise architecture provides a scheme and structure for developing, communicating, and managing business plans in an organized manner.[1] Specifically, the Business Motivation Model does all of the following:



Business Motivation Model

- identifies factors that motivate the establishing of business plans;
- identifies and defines the elements of business plans; and
- indicates how all these factors and elements inter-relate.

BMM Elements

"BMM captures business requirements across different dimensions to rigorously capture and justify why the business wants to do something, what it is aiming to achieve, how it plans to get there, and how it assesses the result."[2]

The main elements of BMM are:

- Ends: *What* (as oppose to *how*) the business wants to accomplish
- Means: *How* the business intends to accomplish its *ends*
- Directives: The *rules* and *policies* that *constrain* or *govern* the available means
- Influencers: Can cause changes that affect the organization in its employment of its Means or achievement of its Ends. Influencers are *neutral* by definition.
- Assessment: A *judgment* of an Influencer that affects the organization's ability to achieve its Ends or use its Means.

BMM History

Initially developed by the Business Rules Group (BRG) [3]

"Since 1997, the BRG has focused its energies on understanding business Rules from a business perspective. This in turn required a full, business-oriented understanding of how the elements of business plans should be organized. The BRG found that although many professionals have used planning methodologies over the years, no standard existed in that area, and many of the basic concepts were hazy and ad hoc."[4]

"In September 2005, the Object Management Group (OMG) voted to accept the Business Motivation Model as the subject of a Request for Comment (RFC). This meant that the OMG was willing to consider the Business Motivation Model as a specification to be adopted by the OMG, subject to comment from any interested parties. Adoption as an OMG specification carries the intention that the Business Motivation Model would, in time, be submitted to the International Organization for Standardization (ISO) as a standard."[5]

In August 2008 version 1.0 was released by OMG.

In May 2010 version 1.1 of BMM specification [6] was released and as of July 2011 it is the latest stable release.

Business Process Definition Metamodel

The **Business Process Definition Metamodel** (**BPDM**) is a standard definition of concepts used to express business process models (a metamodel), adopted by the OMG (Object Management Group). Metamodels define concepts, relationships, and semantics for exchange of user models between different modeling tools. The exchange format is defined by XSD (XML Schema) and XMI (XML for Metadata Interchange), a specification for transformation of OMG metamodels to XML. Pursuant to the OMG's policies, the metamodel is the result of an open process involving submissions by member organizations, following a Request for Proposal [1] (RFP) issued in 2003. BPDM was adopted in initial form in July 2007, and finalized in July 2008.

BPDM provides abstract concepts as the basis for consistent interpretation of specialized concepts used by business process modelers. For example, the ordering of many of the graphical elements in a BPMN (Business Process Modeling Notation) diagram is depicted by arrows between those elements, but the specific elements can have a variety of characteristics. For example, all BPMN events have some common characteristics, and a variety of specific events are designated by the type of circle and the icon in the circle. The abstract BPDM concepts ensure implementers of different modeling tools will associate the same characteristics and semantics with the modeling elements to ensure models are interpreted the same way when moved to a different tool. Users of the modeling tools do not need to be concerned with the abstractions-they only see the specialized elements.

BPDM extends business process modeling beyond the elements defined by BPMN and BPEL to include interactions between otherwise-independent business processes executing in different business units or enterprises (choreography). A choreography can be specified independently of its participants, and used as a requirement for the specification of the orchestration implemented by a participant. BPDM provides for the binding of orchestration to choreography to ensure compatibility. Many current business process models focus on specification of executable business processes that execute within an enterprise (orchestration).

The BPDM specification addresses the objectives of the OMG RFP [1] on which it is based:

- BPDM "will define a set of abstract business process definition elements for specification of executable business processes that execute within an enterprise, and may collaborate between otherwise-independent business processes executing in different business units or enterprises."
- common metamodel to unify the diverse business process definition notations that exist in the industry containing semantics compatible with leading business process modeling notations.
- A metamodel that complements existing UML metamodels so that business processes specifications can be part of complete system specifications to assure consistency and completenes.
- The ability to integrate process models for workflow management processes, automated business processes, and collaborations between business units.
- Support for the specification of web services choreography, describing the collaboration between participating entities and the ability to reconcile the choreography with supporting internal business processes.
- The ability to exchange business process specifications between modeling tools, and between tools and execution environments using XMI.

The RFP seeks to "improve communication between modelers, including between business and software modelers, provide flexible selection of tools and execution environments, and promote the development of more specialized tools for the analysis and design of processes."

For exchange of business process models, BPDM is an alternative to the existing process interchange format XPDL (XML Process Definition Language) from the WfMC (Workflow Management Coalition). The two specifications are similar in that they can be used by process design tools to exchange business process definitions. They are different in that BPDM provides a specification of semantics integrated in a metamodel, and it includes additional modeling capabilities such as choreography, discussed above. In addition, XPDL has many implementations, though only some support for XPDL 2.x, needed for interchanging BPMN. BPDM implementations are in preparation, including support for BPMN, and translation to XPDL.

Knowledge Discovery Metamodel

Knowledge Discovery Metamodel (**KDM**) is publicly available specification from the Object Management Group (OMG). KDM is a common intermediate representation for existing software systems and their operating environments, that defines common metadata required for deep semantic integration of Application Lifecycle Management tools. KDM was designed as the OMG's foundation for software modernization, IT portfolio management and software assurance. KDM uses OMG's Meta-Object Facility to define an XMI interchange format between tools that work with existing software as well as an abstract interface (API) for the next-generation assurance and modernization tools. KDM standardizes existing approaches to knowledge discovery in software engineering artifacts, also known as software mining.

History of KDM

- In November 2003, the OMG's Architecture-Driven Modernization Task Force recommended, and the Platform Technical Committee issued, the Knowledge Discovery Metamodel (KDM) RFP. The objective of this RFP was to *provide a common repository structure to represent information about existing software assets and their operating environment.* The goal of KDM was defined as *exchanging information related to transformation of existing software assets*. The RFP stated that KDM shall provide *the ability to document existing systems, discover reusable components in existing software, support transformations to other languages and to MDA, or enable other potential transformations. The Knowledge Discovery Metamodel will also enable information about existing software artifacts to be exchanged among different tools. This will enable vendors that specialize on certain languages, platforms or types of transformations to deliver customer solutions in conjunction with other vendors.*
- The original KDM RFP is available to OMG members for download (document lt/03-11-04 [1]).
- Throughout 2004 and 2005 12 companies collaborated to prepare a joint response to the KDM RFP. More than 30 organizations from 5 countries have contributed to the development and review of the KDM specification.
- In May 2006, the Team's submission -- the Knowledge Discovery Metamodel (KDM) -- moved into the finalization stage of the OMG's standards adoption process. The OMG adopted Specification for KDM became publicly available (OMG document ptc/06-06-07).
- In March 2007 the KDM Finalization Task Force finished the finalization stage of the OMG's standards adoption process. The formal KDM specification KDM 1.0 is available from OMG (http://www.omg.org/spec/KDM/1.0/KDM 1.0]).
- KDM Analytics maintains Open portal for KDM news, reference and education materials and tools [2]

Overview of KDM

The goal of KDM is to ensure interoperability between tools for maintenance, evolution, assessment and modernization. KDM is defined as a metamodel that can be also viewed as an ontology for describing the key aspects of knowledge related to the various facets of enterprise software. KDM support means investment into the KDM ecosystem - a growing open-standard based cohesive community of tool vendors, service providers, and commercial components.

KDM represents entire enterprise software systems, not just code. KDM is a wide-spectrum entity-relationship representation for describing existing software. KDM represents structural and behavior elements of existing software systems. The key concept of KDM is a *container*: an entity that owns other entities. This allows KDM to represent existing systems at various degrees of granularity.

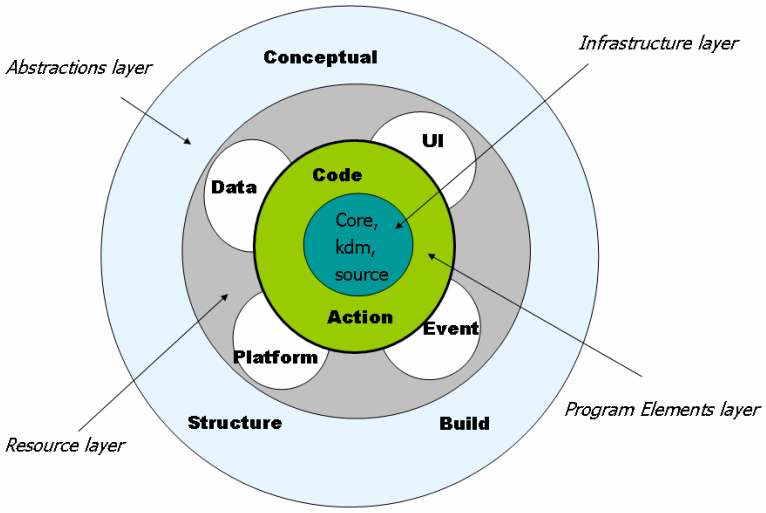
KDM defines precise semantic foundation for representing behavior, the so-called *micro-KDM*. It provides a high-fidelity intermediate representation which can be used, for example, for performing static analysis of existing software systems. micro-KDM is similar in purpose to a Virtual machine for KDM, although KDM is not an executable model, or a constraint model, but a representation of existing artifacts for analysis purposes.

KDM facilitates incremental analysis of existing software systems, where the initial KDM representation is analyzed and more pieces of knowledge are extracted and made explicit as KDM to KDM transformation performed entirely within the KDM technology space. The steps of the knowledge extraction process can be performed by tools, and may involve the analyst.

KDM is the uniform language- and platform- independent representation. Its extensibility mechanism allows addition of domain-, application- and implementation-specific knowledge.

Architecture of KDM

KDM packages are arranged into the following four layers:



Knowledge Discovery Metamodel consists of 12 packages arranged into 4 layers.

Infrastructure Layer

The KDM Infrastructure Layer consists of the **Core**, **kdm**, and **Source** packages which provide a small common core for all other packages, the inventory model of the artifacts of the existing system and full traceability between the meta-model elements as links back to the source code of the artifacts, as well as the uniform extensibility mechanism. The Core package determines several of patterns that are reused by other KDM packages. Although KDM is a meta-model that uses Meta-Object Facility, there is an alignment between the KDM Core and Resource Description Framework (RDF).

Program Elements Layer

The Program Elements Layer consists of the Code and Action packages.

- The **Code package** represents programming elements as determined by programming languages, for example data types, procedures, classes, methods, variables, etc. This package is similar in purpose to the Common Application Meta-model (CAM) from another OMG specification, called Enterprise Application Integration (EAI). KDM Code package provides greater level of detail and is seamlessly integrated with the architecturally significant views of the software system. Representation of datatypes in KDM is aligned with ISO standard ISO/IEC 11404 (see also General Purpose Datatypes).
- The **Action package** captures the low level behavior elements of applications, including detailed control- and data flow between statements. Code and Action package in combination provide a high-fidelity intermediate representation of each component of the enterprise software system

Resource Layer

The Resource Layer represents the operational environment of the existing software system. It is related to the area of Enterprise Application Integration (EAI).

- **Platform package** represents the operating environment of the software, related to the operating system, middleware, etc. including the control flows between components as they are determined by the runtime platform
- **UI package** represents the knowledge related to the user interfaces of the existing software system
- **Event package** represents the knowledge related to events and state-transition behavior of the existing software system
- **Data package** represents the artifacts related to persistent data, such as indexed files, relational databases, and other kinds of data storage. These assests are key to enterprise software as they represent the enterprise metadata. The KDM Data package is aligned with another OMG specification, called Common Warehouse Metamodel (CWM)

Abstractions Layer

The Abstraction Layer represents domain and application abstractions.

- **Conceptual package** represent business domain knowledge and business rules, insofar as this information can be mined from existing applications. These packages are aligned with another OMG specification, called Semantics of Business Vocabulary and Business Rules (SBVR)
- **Structure package** describes the meta-model elements for representing the logical organization of the software system into subsystems, layers and components
- **Build** package represents the engineering view of the software system

Resources, events, agents (accounting model)

Resources, events, agents (**REA**) is a model of how an accounting system can be re-engineered for the computer age. REA was originally proposed in 1982 by William E. McCarthy as a generalized accounting model, and contained the concepts of resources, events and agents (McCarthy 1982).

REA is a popular model in teaching accounting information systems (AIS). But it is rare in business practice—companies cannot easily dismantle their legacy systems to meet REA's radical demands. Workday, Inc., IBM Scalable Architecture for Financial Reporting, REATechnology, and ISO 15944-4 are exceptions.

The REA model gets rid of many accounting objects that are not necessary in the computer age. Most visible of these are debits and credits—double-entry bookkeeping disappears in an REA system. Many general ledger accounts also disappear, at least as persistent objects; e.g., accounts receivable or accounts payable. The computer can generate these accounts in real time using source document records.

REA treats the accounting system as a virtual representation of the actual business. In other words, it creates computer objects that directly represent real-world-business objects. In computer science terms, REA is an ontology. The real objects included in the REA model are:

- goods, services or money, i.e., resources
- business transactions or agreements that affect resources, i.e., events
- people or other human agencies (other companies, etc.), i.e., agents

These objects contrast with conventional accounting terms such as asset or liability, which are less directly tied to real-world objects. For example, a conventional accounting asset such as goodwill is not an REA resource.

There is a separate REA model for each business process in the company. A business process roughly corresponds to a functional department, or a function in Michael Porter's value chain. Examples of business processes would be sales, purchases, conversion or manufacturing, human resources, and financing.

At the heart of each REA model there is usually a pair of events, linked by an exchange relationship, typically referred to as the "duality" relation. One of these events usually represents a resource being given away or lost, while the other represents a resource being received or gained. For example, in the sales process, one event would be "sales"—where goods are given up—and the other would be "cash receipt", where cash is received. These two events are linked; a cash receipt occurs in exchange for a sale, and vice versa. The duality relationship can be more complex, e.g., in the manufacturing process, it would often involve more than two events (see Dunn et al. [2004] for examples).

REA systems have usually been modeled as relational databases with entity-relationship diagrams, though this is not compulsory. Workday uses an in-memory database. This is similar to Palantir Technologies' Object Model.

> "The breakthrough that Workday achieves is to move away from a fixed database structure. The SQL database in a traditional business management application defines the meaning of data into the table structure, and that is its achilles' heel. Workday's database tables reflect the needs of the object-oriented application architecture — there are just three tables, for 'instances', attributes' and 'references' — and the data and definitions stored in the table are instantiated only when the application runs. The definitions are therefore as easy to change as the data."

The philosophy of REA draws on the idea of reusable Design Patterns, though REA patterns are used to describe databases rather than object oriented programs, and are quite different from the 23 canonical patterns in the original designs pattern book by Gamma et al. Research in REA emphasizes patterns (e.g., Hruby et al. 2006). Here is an example of the basic REA pattern:

The pattern is extended to encompass commitments (promises to engage in transactions, e.g., a sales order), policies, and other constructs. Dunn et al. (2004) provide a good overview at an undergraduate level (for accounting majors),

while Hruby et al. (2006) is an advanced reference for computer scientists.

REA is a continuing influence on the electronic commerce standard ebXML, with W. McCarthy actively involved in the standards committee. The competing XBRL GL standard however is at odds with the REA concept, as it closely mimics double-entry book-keeping.

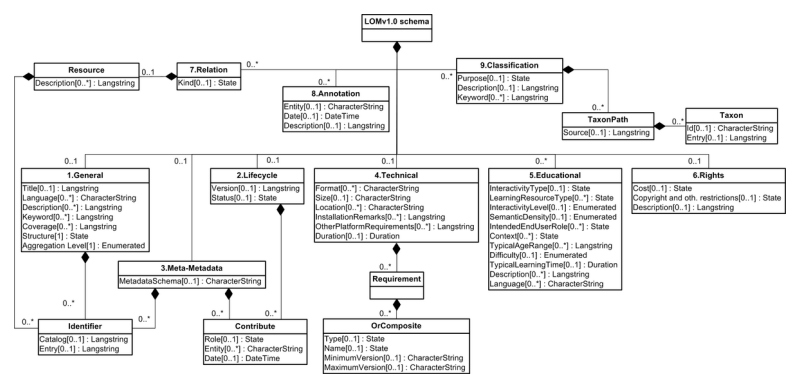
Learning object metadata

Learning Object Metadata is a data model, usually encoded in XML, used to describe a learning object and similar digital resources used to support learning. The purpose of learning object metadata is to support the reusability of learning objects, to aid discoverability, and to facilitate their interoperability, usually in the context of online learning management systems (LMS).



A schematic representation of the hierarchy of elements in the LOM data model

The IEEE 1484.12.1 – 2002 Standard for Learning Object Metadata is an internationally-recognised open standard (published by the Institute of Electrical and Electronics Engineers Standards Association, New York) for the description of "learning objects". Relevant attributes of learning objects to be described include: type of object; author; owner; terms of distribution; format; and pedagogical attributes, such as teaching or interaction style.

IEEE 1484.12.1 – 2002 Standard for Learning Object Metadata

In brief

The IEEE working group that developed the standard defined learning objects, *for the purposes of the standard,* as being "any entity, digital or non-digital, that may be used for learning, education or training." This definition has struck many commentators as being rather broad in its scope, but the definition was intended to provide a broad class of objects to which LOM metadata might usefully be associated rather than to give an instructional or pedagogic definition of a learning object. *IEEE 1484.12.1* is the first part of a multipart standard, and describes the LOM data model. The LOM data model specifies which aspects of a learning object should be described and what vocabularies may be used for these descriptions; it also defines how this data model can be amended by additions or constraints. Other parts of the standard are being drafted to define bindings of the LOM data model, i.e. define how LOM records should be represented in XML and RDF (*IEEE 1484.12.3* and *IEEE 1484.12.4* respectively). This article focuses on the LOM data model rather than issues relating to XML or other bindings.

IMS Global Learning Consortium is an international consortium that contributed to the drafting of the IEEE Learning Object Metadata (together with the ARIADNE Foundation [1]) and endorsed early drafts of the data model as part of the IMS Learning Resource Meta-data specification (IMS LRM, versions 1.0 – 1.2.2). Feedback and suggestions from the implementers of IMS LRM fed into the further development of the LOM, resulting in some drift between version 1.2 of the IMS LRM specification and what was finally published at the LOM standard. Version 1.3 of the IMS LRM specification realigns the IMS LRM data model with the IEEE LOM data model and specifies that the IEEE XML binding should be used. Thus, we can now use the term 'LOM' in referring to both the IEEE standard and version 1.3 of the IMS specification. The IMS LRM specification also provides an extensive *Best Practice and Implementation Guide*, and an *XSL transform* that can be used to migrate metadata instances from the older versions of the IMS LRM XML binding to the IEEE LOM XML binding.

Technical details

How the data model works

The LOM comprises a **hierarchy of elements**. At the first level, there are nine categories, each of which contains sub-elements; these sub-elements may be simple elements that hold data, or may themselves be aggregate elements, which contain further sub-elements. The semantics of an element are determined by its context: they are affected by the parent or container element in the hierarchy and by other elements in the same container. For example, the various *Description* elements (1.4, 5.10, 6.3, 7.2.2, 8.3 and 9.3) each derive their context from their parent element. In addition, description element 9.3 also takes its context from the value of element 9.1 *Purpose* in the same instance of *Classification*.

The data model specifies that some elements may be repeated either individually or as a group; for example, although the elements 9.3 (*Description*) and 9.1 (*Purpose*) can only occur once within each instance of the *Classification* container element, the *Classification* element may be repeated - thus allowing many descriptions for different purposes.

The data model also specifies the **value space** and **datatype** for each of the simple data elements. The value space defines the restrictions, if any, on the data that can be entered for that element. For many elements, the value space allows any string of Unicode character to be entered, whereas other elements entries must be drawn from a declared list (i.e. a controlled vocabulary) or must be in a specified format (e.g. date and language codes). Some element datatypes simply allow a string of characters to be entered, and others comprise two parts, as described below:

- **LangString** items contain Language and String parts, allowing the same information to be recorded in multiple languages
- **Vocabulary** items are constrained in such a way that their entries have to be chosen from a controlled list of terms - composed of Source-Value pairs - with the Source containing the name of the list of terms being used and the Value containing the chosen term
- **DateTime** and **Duration** items contain one part that allows the date or duration to be given in a machine readable format, and a second that allows a description of the date or duration (for example “mid summer, 1968”).

When implementing the LOM as a data or service provider, it is not necessary to support all the elements in the data model, nor need the LOM data model limit the information which may be provided. The creation of an application profile allows a community of users to specify which elements and vocabularies they will use. Elements from the LOM may be dropped and elements from other metadata schemas may be brought in; likewise, the vocabularies in the LOM may be supplemented with values appropriate to that community.

Requirements

The key requirements for exploiting the LOM as a data or service provider are to:

- Understand user/community needs and to express these as an application profile
- Have a strategy for creating high quality metadata
- Store this metadata in a form which can be exported as LOM records
- Agree a binding for LOM instances when they are exchanged
- Be able to exchange records with other systems either as single instances or *en masse*.

Related specifications

There are many metadata specifications; of particular interest is the Dublin Core Metadata Element Set (commonly known as Simple Dublin Core, standardised as *ANSI/NISO Z39.85 – 2001*), which provides a simpler, more loosely-defined set of elements with some overlap with the LOM, and which is useful for sharing metadata across a wide range of disparate services. The Dublin Core Metadata Initiative is also working on a set of terms which allow the Dublin Core Element Set to be used with greater semantic precision (Qualified Dublin Core). The Dublin Education Working Group aims to provide refinements of Dublin Core for the specific needs of the education community. Details of Dublin Core can be found at the Dublin Core website [2].

Many other education-related specifications allow for LO metadata to be embedded within XML instances, such as: describing the resources in an IMS Content Package or Resource List; describing the vocabularies and terms in an IMS VDEX (Vocabulary Definition and Exchange) file; and describing the question items in an IMS QTI (Question and Test Interoperability) file. Details of these can be found at the IMS Global website [3].

The IMS Vocabulary Definition and Exchange (VDEX) specification has a double relation with the LOM, since not only can the LOM provide metadata on the vocabularies in a VDEX instance, but VDEX can be used to describe the controlled vocabularies which are the value space for many LOM elements.

LOM records can be transported between systems using a variety of protocols, perhaps the most widely used being OAI-PMH.

Application profiles

UK LOM Core

For UK Further and Higher Education, the most relevant family of application profiles are those based around the *UK LOM Core*.[4] The UK LOM Core is currently a draft schema researched by a community of practitioners to identify common UK practice in learning object content, by comparing 12 metadata schemas. UK LOM is currently legacy work, it is not in active development.

CanCore

CanCore provides detailed guidance for the interpretation and implementation of each data element in the LOM standard. These guidelines (2004) constitute a 250-page document, and have been developed over three years under the leadership of Norm Friesen, and through consultation with experts across Canada and throughout the world. These guidelines are also available at no charge from the CanCore Website [5].

ANZ-LOM

ANZ-LOM [6] is a metadata profile developed for the education sector in Australia and New Zealand. The profile provides interpretations of metadata structures and illustrates how to apply controlled vocabularies, especially using the "classification" element. It is supported by detailed examples of learning resource metadata, including regional vocabularies. The ANZ-LOM profile was first published by The Le@rning Federation (TLF) in January, 2008.

Vetadata

The Australian Vocational Training and Education (VET) sector uses an application profile of the IEEE LOM called Vetadata [7]. The profile contains five mandatory elements, and makes use of a number of vocabularies specific to the Australian VET sector. This application profile was first published in 2005. The Vetadata and ANZ-LOM profiles are closely aligned.

NORLOM

NORLOM [8] is the Norwegian LOM profile. The profile is managed by NSSL [9] (The Norwegian Secretariat for Standardization of Learning Technologies)

ISRACore

ISRACORE [10] is the Israeli LOM profile. The Israel Internet Association (ISOC-IL [11]) and Inter University Computational Center (IUCC [12]) have teamed up to manage and establish an e-learning objects database.

SWE-LOM

SWE-LOM [13] is the Swedish LOM profile that is managed by IML [14] at Umeå University as a part of the work with the national standardization group TK450 at Swedish Standards Institute.

TWLOM

TWLOM [15] is the Taiwanese LOM profile that is managed by Industrial Development and Promotion of Archives and e-Learning Project [16]

LOM-FR

LOM-FR [17] is a metadata profile developed for the education sector in France. This application profile was first published in 2006.

NL LOM

NL LOM [18] is the Dutch metadata profile for educational resources in the Netherlands. This application profile was the result of merging the Dutch higher education LOM profile with the one used in primary and secondary Dutch education. The final version was released in 2011.

LOM-CH

LOM-CH [19] is a metadata profile developed for the education sector in Switzerland. It is current available in French and German. This application profile was published in 2013.

Others

Other application profiles are those developed by the Celebrate project[20] and the metadata profile that is part of the SCORM reference model.[21]

E-mail Lists

- The CETIS Metadata and Digital Repository special interest group (http://metadata.cetis.ac.uk/) has two email lists:
- The SIG list (http://www.jiscmail.ac.uk/lists/CETIS-METADATA.html) will keep you up to date on all SIG activities and spec development related to metadata and digital repositories
- The LOM-cataloguing list (http://www.jiscmail.ac.uk/lists/LOM-CATALOGUING.html) is for queries relating to the creation and management of LOM descriptions.

Metadata Editors

- Reload (http://www.reload.ac.uk/) includes an open-source editor for IMS LRM.
- Curriculum Online Tagging Tool (http://www.curriculumonline.gov.uk/SupplierCentre/taggingtool.htm) is used for creating metadata for online resource made available to schools in England.
- LomPad (https://sourceforge.net/projects/lompad/) Lompad is a metatagging tool for learning object. It is bilingual(Fr,En) supports the IEEE-lom spec and SCORM, CANCORE and Normetic profiles.

Repositories/Catalogues

- MERLOT (http://www.merlot.org)(Multimedia Education Resource for Learning and Online Teaching) is a free and open peer-reviewed collection of learning and online teaching materials and faculty-developed services contributed and used by an international education community. It is an international consortium of over 20 institutions (and systems) of higher education, industry partners, professional organizations and individuals devoted to identifying, peer reviewing, organizing and making available existing WWW resources in a range of academic disciplines for use by higher education faculty and students.
- OER Commons (http://oercommons.org) is a freely accessible online library for teachers and others to search, discover, share, and evaluate Open Educational Resources (OER) and other freely available instructional materials. OER Commons is a project created by ISKME (http://www.iskme.org), an independent non-profit organization based in Half Moon Bay, California.
- OpenScout (http://learn.openscout.net) is a hub for open educational resources for business and management education and training. It has international materials from around the globe and provides tools for adapting resources to the context.
- Learning Resource Exchange (http://lreforschools.eun.org) from European Schoolnet offers more than 200,000 multilingual Open Educational Resources for the K-12 sector from more than 50 content providers.
- Desire2Learn Learning Repository (http://www.desire2learn.com/learningrepository/) is a repository system with rich support for IEEE LOM, Dublin Core, CanCore, and other customisable and templatable profiles. It also supports harvesting of metadata from other repository/catalogue systems. It is used by hundreds of educational and commercial organisations.
- Intrallect intraLibrary (http://www.intrallect.com/products) is a commercial repository system, with rich support for the IEEE LOM, including customisable application profiles
- The Xtensis Open Architecture is a foundation for building customised learning object repository and learning content management systems.

- HarvestRoad Hive (http://www2.harvestroad.com.au/cgi-bin/hr/loadframes_tmp.cgi?lcms) is a commercial federated digital repository system (based out of Australia), i.e. it is designed share content across multiple repositories.
- The Jorum project (http://www.jorum.ac.uk) uses Intrallect intraLibrary (http://www.intrallect.com/products) for its ongoing service.
- The National Learning Network, using Xtensis, is a UK repository of over 2000 learning objects, commissioned by Becta and the LSC.
- Kursnavet (http://kursnavet.cfl.se) (Swedish), is a repository containing around 11 000 (2007) unique learning objects, free of use non-commersial. From the Swedish Agency for Flexible Learning, CFL (http://www.cfl.se).
- LearnAlberta.ca is a Canadian learning object repository maintained by Alberta Education, the Province of Alberta's education Ministry.
- The Learning Object Repository Network (http://lorn.flexiblelearning.net.au) (LORN) is Australia's national learning object repository network for the vocational education and training (VET) sector. It contains nearly 3000 learning objects.
- Agrega is Spain's national learning object repository network. It contains nearly 100.000 learning objects.
- Spindeln (http://itforpedagoger.skolverket.se/hitta_material/) (the Spider), is a Swedish learning object repository brokerage service that connects a number of Swedish LORs. Spindeln is provided by the Nat. Agency for Education.
- North Carolina Learning Object Repository - The k-20 learning object repository used by the State of North Carolina and managed by the North Carolina Community College System.
- EQUELLA (www.equella.com (http://www.equella.com)) is a digital repository implemented by the editorial giant Pearson that integrates with various learning management systems, supports IMS packages and all metadata schemas including IEEE LOM.

Learning object

A **learning object** is "a collection of content items, practice items, and assessment items that are combined based on a single learning objective". The term is credited to Wayne Hodgins when he created a working group in 1994 bearing the name though the concept was first described by Gerard in 1967. Learning objects go by many names, including content objects, chunks, educational objects, information objects, intelligent objects, knowledge bits, knowledge objects, learning components, media objects, reusable curriculum components, nuggets, reusable information objects, reusable learning objects, testable reusable units of cognition, training components, and units of learning.

Learning objects offer a new conceptualization of the learning process: rather than the traditional "several hour chunk", they provide smaller, self-contained, re-usable units of learning.

They will typically have a number of different components, which range from descriptive data to information about rights and educational level. At their core, however, will be instructional content, practice, and assessment. A key issue is the use of metadata.

Learning object design raises issues of portability, and of the object's relation to a broader learning management system.

Definitions

The Institute of Electrical and Electronics Engineers (IEEE) defines a learning object as "any entity, digital or non-digital, that may be used for learning, education or training".

Chiappe defined Learning Objects as: "A digital self-contained and reusable entity, with a clear educational purpose, with at least three internal and editable components: content, learning activities and elements of context. The learning objects must have an external structure of information to facilitate their identification, storage and retrieval: the metadata."

The following definitions focus on the relation between learning object and digital media. RLO-CETL, a British inter-university Learning Objects Center, defines "reusable learning objects" as "web-based interactive chunks of e-learning designed to explain a stand-alone learning objective". Daniel Rehak and Robin Mason define it as "a digitized entity which can be used, reused or referenced during technology supported learning".

Adapting a definition from the Wisconsin Online Resource Center, Robert J. Beck suggests that learning objects have the following key characteristics:

- Learning objects are a new way of thinking about learning content. Traditionally, content comes in a several hour chunk. Learning objects are much smaller units of learning, typically ranging from 2 minutes to 15 minutes.
- Are self-contained – each learning object can be taken independently
- Are reusable – a single learning object may be used in multiple contexts for multiple purposes
- Can be aggregated – learning objects can be grouped into larger collections of content, including traditional course structures
- Are tagged with metadata – every learning object has descriptive information allowing it to be easily found by a search

Components

The following is a list of some of the types of information that may be included in a learning object and its metadata:

- General Course Descriptive Data, including: course identifiers, language of content (English, Spanish, etc.), subject area (Maths, Reading, etc.), descriptive text, descriptive keywords
- Life Cycle, including: version, status
- Instructional Content, including: text, web pages, images, sound, video
- Glossary of Terms, including: terms, definition, acronyms
- Quizzes and Assessments, including: questions, answers
- Rights, including: cost, copyrights, restrictions on Use
- Relationships to Other Courses, including prerequisite courses
- Educational Level, including: grade level, age range, typical learning time, and difficulty. [IEEE 1484.12.1:2002]
- Typology as defined by Churchill (2007): presentation, practice, simulation, conceptual models, information, and contextual representation [1]

Metadata

One of the key issues in using learning objects is their identification by search engines or content management systems.[*citation needed*] This is usually facilitated by assigning descriptive learning object metadata. Just as a book in a library has a record in the card catalog, learning objects must also be tagged with metadata. The most important pieces of metadata typically associated with a learning object include:

1. **objective:** The educational objective the learning object is instructing
2. **prerequisites:** The list of skills (typically represented as objectives) which the learner must know before viewing the learning object
3. **topic:** Typically represented in a taxonomy, the topic the learning object is instructing
4. **interactivity:** The Interaction Model of the learning object.
5. **technology requirements:** The required system requirements to view the learning object.

Mutability

A mutated learning object is, according to Michael Shaw, a learning object that has been "re-purposed and/or re-engineered, changed or simply re-used in some way different from its original intended design". Shaw also introduces the term "contextual learning object", to describe a learning object that has been "designed to have specific meaning and purpose to an intended learner".

Portability

Before any institution invests a great deal of time and energy into building high-quality e-learning content (which can cost over $10,000 per classroom hour),[2] it needs to consider how this content can be easily loaded into a Learning Management System. It is possible for example, to package learning objects with SCORM specification and load it in Moodle Learning Management System or Desire2Learn Learning Environment.

If all of the properties of a course can be precisely defined in a common format, the content can be serialized into a standard format such as XML and loaded into other systems. When it is considered that some e-learning courses need to include video, mathematical equations using MathML, chemistry equations using CML and other complex structures, the issues become very complex, especially if the systems needs to understand and validate each structure and then place it correctly in a database.[*citation needed*]

Criticism

In 2001, David Wiley criticized learning object theory in his paper, The Reusability Paradox [3] which is summarized by D'Arcy Norman [4] as, *If a learning object is useful in a particular context, by definition it is not reusable in a different context. If a learning object is reusable in many contexts, it isn't particularly useful in any.* In Three Objections to Learning Objects and E-learning Standards [5], Norm Friesen, Canada Research Chair in E-Learning Practices at Thompson Rivers University, points out that the word *neutrality* in itself implies *a state or position that is antithetical ... to pedagogy and teaching.*

OGML

Ontology Grounded Metalanguage (OGML) is a metalanguage like MOF. The goal of OGML is to tackle the difficulties of MOF:[1] linear modeling architecture, ambiguous constructs and incomprehensible/unclear architecture. OGML provides a nested modeling architecture with three fixed layers (models, languages and metalanguage), therefore it is clear how the different models conform to each other and can be handled. Constructs in OGML are chosen from the science of Ontology, making the distinction between properties / objects and classes / objects very clear. This commitment makes explicit certain oddities of the definition of, for example, relations. Furthermore, OGML provides an explicit notion of instantiation:[2] model elements encode their types and languages define the semantics of instantiation. This extra information is needed in the relative modeling architecture to distinguish between structural and conceptual views on models, for example: we may want to view a UML model as an instance of the Object language and an instance of the Class model (Clabject). By providing this dual view on metamodel layer and on the language layer, OGML provides a very precise modeling architecture and an expressive way to deal with models.

File:Flag of Israel.svg *Source*: http://en.wikipedia.org/w/index.php?title=File:Flag_of_Israel.svg *License*: Public Domain *Contributors*: "The Provisional Council of State Proclamation of the Flag of the State of Israel" of 25 Tishrei 5709 (28 October 1948) provides the official specification for the design of the Israeli flag. The color of the Magen David and the stripes of the Israeli flag is not precisely specified by the above legislation. The color depicted in the current version of the image is typical of flags used in Israel today, although individual flags can and do vary. The flag legislation officially specifies dimensions of 220 cm × 160 cm. However, the sizes of actual flags vary (although the aspect ratio is usually retained).
