Introduction

Data management

Data management comprises all the disciplines related to managing data as a valuable resource.

Overview

The official definition provided by DAMA International, the professional organization for those in the data management profession, is: "Data Resource Management is the development and execution of architectures, policies, practices and procedures that properly manage the full data lifecycle needs of an enterprise." {{DAMA International}} This definition is fairly broad and encompasses a number of professions which may not have direct technical contact with lower-level aspects of data management, such as relational database management.

Alternatively, the definition provided in the DAMA Data Management Body of Knowledge (DAMA-DMBOK) is: "Data management is the development, execution and supervision of plans, policies, programs and practices that control, protect, deliver and enhance the value of data and information assets."[1]

The concept of "Data Management" arose in the 1980s as technology moved from sequential processing (first cards, then tape) to random access processing. Since it was now technically possible to store a single fact in a single place and access that using random access disk, those suggesting that "Data Management" was more important than "Process Management" used arguments such as "a customer's home address is stored in 75 (or some other large number) places in our computer systems." During this period, random access processing was not competitively fast, so those suggesting "Process Management" was more important than "Data Management" used batch processing time as their primary argument. As applications moved more and more into real-time, interactive applications, it became obvious to most practitioners that both management processes were important. If the data was not well defined, the data would be mis-used in applications. If the process wasn't well defined, it was impossible to meet user needs.

Data Management shows manageable of data through specific data source

Corporate Data Quality Management

Corporate Data Quality Management (CDQM) is, according to the European Foundation for Quality Management and the Competence Center Corporate Data Quality (CC CDQ, University of St. Gallen), the whole set of activities intended to improve corporate data quality (both reactive and preventive). Main premise of CDQM is the business relevance of high-quality corporate data. CDQM comprises with following activity areas:[2]

- **Strategy for Corporate Data Quality**: As CDQM is affected by various business drivers and requires involvement of multiple divisions in an organization; it must be considered a company-wide endeavor.
- **Corporate Data Quality Controlling**: Effective CDQM requires compliance with standards, policies, and procedures. Compliance is monitored according to previously defined metrics and performance indicators and reported to stakeholders.
- **Corporate Data Quality Organization**: CDQM requires clear roles and responsibilities for the use of corporate data. The CDQM organization defines tasks and privileges for decision making for CDQM.
- **Corporate Data Quality Processes and Methods**: In order to handle corporate data properly and in a standardized way across the entire organization and to ensure corporate data quality, standard procedures and guidelines must be embedded in company’s daily processes.

- **Data Architecture for Corporate Data Quality**: The data architecture consists of the data object model - which comprises the unambiguous definition and the conceptual model of corporate data - and the data storage and distribution architecture.
- **Applications for Corporate Data Quality**: Software applications support the activities of Corporate Data Quality Management. Their use must be planned, monitored, managed and continuously improved.

Topics in Data Management

Topics in Data Management, grouped by the DAMA DMBOK Framework,[3] include:

1. Data governance • Data asset • Data governance • Data steward 3. Data Architecture, Analysis and Design • Data analysis • Data architecture • Data modeling 5. Database Management • Data maintenance • Database administration • Database management system 7. Data Security Management • Data access • Data erasure • Data privacy • Data security 9. Data Quality Management • Data cleansing • Data integrity • Data enrichment • Data quality • Data quality assurance	1. Reference and Master Data Management • Data integration • Master data management • Reference data 3. Data Warehousing and Business Intelligence Management • Business intelligence • Data mart • Data mining • Data movement (extract, transform and load) • Data warehousing 5. Document, Record and Content Management • Document management system • Records management 7. Meta Data Management • Meta-data management • Metadata • Metadata discovery • Metadata publishing • Metadata registry 9. Contact Data Management • Business continuity planning • Marketing operations • Customer data integration • Identity management • Identity theft • Data theft • ERP software • CRM software • Address (geography) • Postal code • Email address • Telephone number

Body of Knowledge

The DAMA Guide to the Data Management Body of Knowledge" (DAMA-DMBOK Guide), under the guidance of a new DAMA-DMBOK Editorial Board. This publication is available from April 5, 2009.

Usage

In modern management usage, one can easily discern a trend away from the term 'data' in composite expressions to the term information or even knowledge when talking in non-technical context. Thus there exists not only data management, but also information management and knowledge management. This is a misleading trend as it obscures that traditional data is managed or somehow processed on second looks. The distinction between data and

derived values can be seen in the information ladder. While data can exist as such, 'information' and 'knowledge' are always in the "eye" (or rather the brain) of the beholder and can only be measured in relative units.

Integrated data management

Integrated data management (IDM) is a tools approach to facilitate data management and improve performance. IDM consists of an integrated, modular environment to manage enterprise application data, and optimize data-driven applications over its lifetime.[4][5][6][7] IDM's purpose is to

- Produce enterprise-ready applications faster
- Improve data access, speed iterative testing
- Empower collaboration between architects, developers and DBAs

Consistently achieve service level targets

- Automate and simplify operations
- Provide contextual intelligence across the solution stack

Support business growth

- Accommodate new initiatives without expanding infrastructure
- Simplify application upgrades, consolidation and retirement

Facilitate alignment, consistency and governance

- Define business policies and standards up front; share, extend, and apply throughout the lifecycle

Database

A **database** is an organized collection of data. The data are typically organized to model relevant aspects of reality in a way that supports processes requiring this information. For example, modeling the availability of rooms in hotels in a way that supports finding a hotel with vacancies.

Database management systems (**DBMS**s) are specially designed software applications that interact with the user, other applications, and the database itself to capture and analyze data. A general-purpose DBMS is a software system designed to allow the definition, creation, querying, update, and administration of databases. Well-known DBMSs include MySQL, MariaDB, PostgreSQL, SQLite, Microsoft SQL Server, Oracle, SAP HANA, dBASE, FoxPro, IBM DB2, LibreOffice Base and FileMaker Pro. A database is not generally portable across different DBMSs, but different DBMSs can interoperate by using standards such as SQL and ODBC or JDBC to allow a single application to work with more than one database.

Terminology and overview

Formally, "database" refers to the data themselves and supporting data structures. Databases are created to operate large quantities of information by inputting, storing, retrieving, and managing that information. Databases are set up so that one set of software programs provides all users with access to all the data.

A "database management system" (DBMS) is a suite of computer software providing the interface between users and a database or databases. Because they are so closely related, the term "database" when used casually often refers to both a DBMS and the data it manipulates.

Outside the world of professional information technology, the term *database* is sometimes used casually to refer to any collection of data (perhaps a spreadsheet, maybe even a card index). This article is concerned only with databases where the size and usage requirements necessitate use of a database management system.[1]

The interactions catered for by most existing DBMSs fall into four main groups:

- **Data definition –** Defining new data structures for a database, removing data structures from the database, modifying the structure of existing data.
- **Update –** Inserting, modifying, and deleting data.
- **Retrieval –** Obtaining information either for end-user queries and reports or for processing by applications.
- **Administration –** Registering and monitoring users, enforcing data security, monitoring performance, maintaining data integrity, dealing with concurrency control, and recovering information if the system fails.

A DBMS is responsible for maintaining the integrity and security of stored data, and for recovering information if the system fails.

Both a database and its DBMS conform to the principles of a particular database model.[2] "Database system" refers collectively to the database model, database management system, and database.[3]

Physically, database servers are dedicated computers that hold the actual databases and run only the DBMS and related software. Database servers are usually multiprocessor computers, with generous memory and RAID disk arrays used for stable storage. RAID is used for recovery of data if any of the disks fail. Hardware database accelerators, connected to one or more servers via a high-speed channel, are also used in large volume transaction processing environments. DBMSs are found at the heart of most database applications. DBMSs may be built around a custom multitasking kernel with built-in networking support, but modern DBMSs typically rely on a standard operating system to provide these functions. [*citation needed*] Since DBMSs comprise a significant economical market, computer and storage vendors often take into account DBMS requirements in their own development plans.[*citation needed*]

Databases and DBMSs can be categorized according to the database model(s) that they support (such as relational or XML), the type(s) of computer they run on (from a server cluster to a mobile phone), the query language(s) used to access the database (such as SQL or XQuery), and their internal engineering, which affects performance, scalability, resilience, and security.

Applications and roles

Most organizations in developed countries today depend on databases for their business operations. Increasingly, databases are not only used to support the internal operations of the organization, but also to underpin its online interactions with customers and suppliers (see Enterprise software). Databases are not used only to hold administrative information, but are often embedded within applications to hold more specialized data: for example engineering data or economic models. Examples of database applications include computerized library systems, flight reservation systems, and computerized parts inventory systems.

Client-server or transactional DBMSs are often complex to maintain high performance, availability and security when many users are querying and updating the database at the same time. Personal, desktop-based database systems tend to be less complex. For example, FileMaker and Microsoft Access come with built-in graphical user interfaces.

General-purpose and special-purpose DBMSs

A DBMS has evolved into a complex software system and its development typically requires thousands of person-years of development effort.[4] Some general-purpose DBMSs such as Adabas, Oracle and DB2 have been undergoing upgrades since the 1970s. General-purpose DBMSs aim to meet the needs of as many applications as possible, which adds to the complexity. However, the fact that their development cost can be spread over a large number of users means that they are often the most cost-effective approach. However, a general-purpose DBMS is not always the optimal solution: in some cases a general-purpose DBMS may introduce unnecessary overhead. Therefore, there are many examples of systems that use special-purpose databases. A common example is an email system: email systems are designed to optimize the handling of email messages, and do not need significant portions of a general-purpose DBMS functionality.

Many databases have application software that accesses the database on behalf of end-users, without exposing the DBMS interface directly. Application programmers may use a wire protocol directly, or more likely through an application programming interface. Database designers and database administrators interact with the DBMS through dedicated interfaces to build and maintain the applications' databases, and thus need some more knowledge and understanding about how DBMSs operate and the DBMSs' external interfaces and tuning parameters.

General-purpose databases are usually developed by one organization or community of programmers, while a different group builds the applications that use it. In many companies, specialized database administrators maintain databases, run reports, and may work on code that runs on the databases themselves (rather than in the client application).

History

Following the technology progress in the areas of processors, computer memory, computer storage and computer networks, the sizes, capabilities, and performance of databases and their respective DBMSs have grown in orders of magnitude. The development of database technology can be divided into three eras based on data model or structure: navigational,[5] SQL/relational, and post-relational.

The two main early navigational data models were the hierarchical model, epitomized by IBM's IMS system, and the CODASYL model (network model), implemented in a number of products such as IDMS.

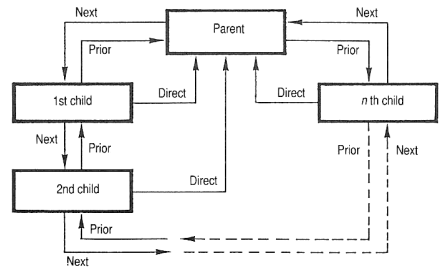
The relational model, first proposed in 1970 by Edgar F. Codd, departed from this tradition by insisting that applications should search for data by content, rather than by following links. The relational model employs sets of ledger-style tables, each used for a different type of entity. Only in the mid-1980s did computing hardware became powerful enough to allow the wide deployment of relational systems (DBMSs plus applications). By the early 1990s, however, relational systems dominated in all large-scale data processing applications, and as of 2014[6] they remain dominant except in niche areas. The dominant database language, standardised SQL for the relational model, has influenced database languages for other data models.[*citation needed*]

Object databases developed in the 1980s to overcome the inconvenience of object-relational impedance mismatch, which led to the coining of the term "post-relational" and also the development of hybrid object-relational databases.

The next generation of post-relational databases in the late 2000s became known as NoSQL databases, introducing fast key-value stores and document-oriented databases. A competing "next generation" known as NewSQL databases attempted new implementations that retained the relational/SQL model while aiming to match the high performance of NoSQL compared to commercially available relational DBMSs.

1960s, navigational DBMS

The introduction of the term *database* coincided with the availability of direct-access storage (disks and drums) from the mid-1960s onwards. The term represented a contrast with the tape-based systems of the past, allowing shared interactive use rather than daily batch processing. The Oxford English dictionary cites a 1962 report by the System Development Corporation of California as the first to use the term "data-base" in a specific technical sense.



A closed chain of records in a navigational database model (e.g. CODASYL), with ***next pointers***, ***prior pointers*** and ***direct pointers*** provided by keys in the various records.

Illustration of a set type using a ***Bachman diagram***

The record set, basic structure of navigational (e.g. CODASYL) databse model. A set consists of one parent record (also called "the owner"), and n child records (also called members records)

Basic structure of navigational CODASYL database model.

As computers grew in speed and capability, a number of general-purpose database systems emerged; by the mid-1960s a number of such systems had come into commercial use. Interest in a standard began to grow, and Charles Bachman, author of one such product, the Integrated Data Store (IDS), founded the "Database Task Group" within CODASYL, the group responsible for the creation and standardization of COBOL. In 1971 theDatabase Task Group delivered their standard, which generally became known as the "CODASYL approach", and soon a number of commercial products based on this approach entered the market.

The CODASYL approach relied on the "manual" navigation of a linked data set which was formed into a large network. Applications could find records by one of three methods:

- use of a primary key (known as a CALC key, typically implemented by hashing)
- navigating relationships (called sets) from one record to another
- scanning all the records in a sequential order.

Later systems added B-Trees to provide alternate access paths. Many CODASYL databases also added a very straightforward query language. However, in the final tally, CODASYL was very complex and required significant training and effort to produce useful applications.

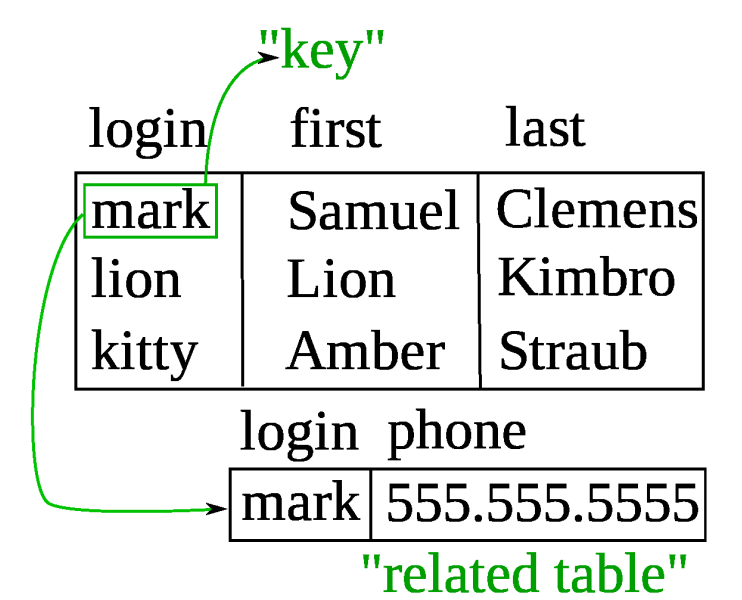
IBM also had their own DBMS system in 1968, known as *IMS*. IMS was a development of software written for the Apollo program on the System/360. IMS was generally similar in concept to CODASYL, but used a strict hierarchy for its model of data navigation instead of CODASYL's network model. Both concepts later became known as navigational databases due to the way data was accessed, and Bachman's 1973 Turing Award presentation was *The Programmer as Navigator*. IMS is classifiedWikipedia:Manual of Style/Words to watch#Unsupported attributions as a hierarchical database. IDMS and Cincom Systems' TOTAL database are classified as network databases. IMS remains in use as of 2014[6].

1970s, relational DBMS

Edgar Codd worked at IBM in San Jose, California, in one of their offshoot offices that was primarily involved in the development of hard disk systems. He was unhappy with the navigational model of the CODASYL approach, notably the lack of a "search" facility. In 1970, he wrote a number of papers that outlined a new approach to database construction that eventually culminated in the groundbreaking *A Relational Model of Data for Large Shared Data Banks*.[7]

In this paper, he described a new system for storing and working with large databases. Instead of records being stored in some sort of linked list of free-form records as in CODASYL, Codd's idea was to use a "table" of fixed-length records, with each table used for a different type of entity. A linked-list system would be very inefficient when storing "sparse" databases where some of the data for any one record could be left empty. The relational model solved this by splitting the data into a series of normalized tables (or *relations*), with optional elements being moved out of the main table to where they would take up room only if needed. Data may be freely inserted, deleted and edited in these tables, with the DBMS doing whatever maintenance needed to present a table view to the application/user.

The relational model also allowed the content of the database to evolve without constant rewriting of links and pointers. The relational part comes from entities referencing other entities in what is known as one-to-many relationship, like a traditional hierarchical model, and many-to-many relationship, like a navigational (network) model. Thus, a relational model can express both hierarchical and navigational models, as well as its native tabular model, allowing for pure or combined modeling in terms of these three models, as the application requires.



In the relational model, related records are linked together with a "key"

For instance, a common use of a database system is to track information about users, their name, login information, various addresses and phone numbers. In the navigational approach all of these data would be placed in a single record, and unused items would simply not be placed in the database. In the relational approach, the data would be *normalized* into a user table, an address table and a phone number table (for instance). Records would be created in these optional tables only if the address or phone numbers were actually provided.

Linking the information back together is the key to this system. In the relational model, some bit of information was used as a "key", uniquely defining a particular record. When information was being collected about a user, information stored in the optional tables would be found by searching for this key. For instance, if the login name of a user is unique, addresses and phone numbers for that user would be recorded with the login name as its key. This simple "re-linking" of related data back into a single collection is something that traditional computer languages are not designed for.

Just as the navigational approach would require programs to loop in order to collect records, the relational approach would require loops to collect information about any *one* record. Codd's solution to the necessary looping was a set-oriented language, a suggestion that would later spawn the ubiquitous SQL. Using a branch of mathematics known as tuple calculus, he demonstrated that such a system could support all the operations of normal databases (inserting, updating etc.) as well as providing a simple system for finding and returning *sets* of data in a single operation.

Codd's paper was picked up by two people at Berkeley, Eugene Wong and Michael Stonebraker. They started a project known as INGRES using funding that had already been allocated for a geographical database project and student programmers to produce code. Beginning in 1973, INGRES delivered its first test products which were generally ready for widespread use in 1979. INGRES was similar to System R in a number of ways, including the

use of a "language" for data access, known as QUEL. Over time, INGRES moved to the emerging SQL standard.

IBM itself did one test implementation of the relational model, PRTV, and a production one, Business System 12, both now discontinued. Honeywell wrote MRDS for Multics, and now there are two new implementations: Alphora Dataphor and Rel. Most other DBMS implementations usually called *relational* are actually SQL DBMSs.

In 1970, the University of Michigan began development of the MICRO Information Management System[8] based on D.L. Childs' Set-Theoretic Data model.[9][10][11] Micro was used to manage very large data sets by the US Department of Labor, the U.S. Environmental Protection Agency, and researchers from the University of Alberta, the University of Michigan, and Wayne State University. It ran on IBM mainframe computers using the Michigan Terminal System.[12] The system remained in production until 1998.

Integrated approach

In the 1970s and 1980s attempts were made to build database systems with integrated hardware and software. The underlying philosophy was that such integration would provide higher performance at lower cost. Examples were IBM System/38, the early offering of Teradata, and the Britton Lee, Inc. database machine.

Another approach to hardware support for database management was ICL's CAFS accelerator, a hardware disk controller with programmable search capabilities. In the long term, these efforts were generally unsuccessful because specialized database machines could not keep pace with the rapid development and progress of general-purpose computers. Thus most database systems nowadays are software systems running on general-purpose hardware, using general-purpose computer data storage. However this idea is still pursued for certain applications by some companies like Netezza and Oracle (Exadata).

Late 1970s, SQL DBMS

IBM started working on a prototype system loosely based on Codd's concepts as *System R* in the early 1970s. The first version was ready in 1974/5, and work then started on multi-table systems in which the data could be split so that all of the data for a record (some of which is optional) did not have to be stored in a single large "chunk". Subsequent multi-user versions were tested by customers in 1978 and 1979, by which time a standardized query language – SQL[*citation needed*] – had been added. Codd's ideas were establishing themselves as both workable and superior to CODASYL, pushing IBM to develop a true production version of System R, known as *SQL/DS*, and, later, *Database 2* (DB2).

Larry Ellison's Oracle started from a different chain, based on IBM's papers on System R, and beat IBM to market when the first version was released in 1978.[*citation needed*]

Stonebraker went on to apply the lessons from INGRES to develop a new database, Postgres, which is now known as PostgreSQL. PostgreSQL is often used for global mission critical applications (the .org and .info domain name registries use it as their primary data store, as do many large companies and financial institutions).

In Sweden, Codd's paper was also read and Mimer SQL was developed from the mid-1970s at Uppsala University. In 1984, this project was consolidated into an independent enterprise. In the early 1980s, Mimer introduced transaction handling for high robustness in applications, an idea that was subsequently implemented on most other DBMSs.

Another data model, the entity-relationship model, emerged in 1976 and gained popularity for database design as it emphasized a more familiar description than the earlier relational model. Later on, entity-relationship constructs were retrofitted as a data modeling construct for the relational model, and the difference between the two have become irrelevant.[*citation needed*]

1980s, on the desktop

The 1980s ushered in the age of desktop computing. The new computers empowered their users with spreadsheets like Lotus 1,2,3 and database software like dBASE. The dBASE product was lightweight and easy for any computer user to understand out of the box. C. Wayne Ratliff the creator of dBASE stated: “dBASE was different from programs like BASIC, C, FORTRAN, and COBOL in that a lot of the dirty work had already been done. The data manipulation is done by dBASE instead of by the user, so the user can concentrate on what he is doing, rather than having to mess with the dirty details of opening, reading, and closing files, and managing space allocation.“ [13] dBASE was one of the top selling software titles in the 1980s and early 1990s.

1980s, object-oriented

The 1980s, along with a rise in object oriented programming, saw a growth in how data in various databases were handled. Programmers and designers began to treat the data in their databases as objects. That is to say that if a person's data were in a database, that person's attributes, such as their address, phone number, and age, were now considered to belong to that person instead of being extraneous data. This allows for relations between data to be relations to objects and their attributes and not to individual fields.[14] The term "object-relational impedance mismatch" described the inconvenience of translating between programmed objects and database tables. Object databases and object-relational databases attempt to solve this problem by providing an object-oriented language (sometimes as extensions to SQL) that programmers can use as alternative to purely relational SQL. On the programming side, libraries known as object-relational mappings (ORMs) attempt to solve the same problem.

2000s, NoSQL and NewSQL

The next generation of post-relational databases in the 2000s became known as NoSQL databases, including fast key-value stores and document-oriented databases. XML databases are a type of structured document-oriented database that allows querying based on XML document attributes.

NoSQL databases are often very fast, do not require fixed table schemas, avoid join operations by storing denormalized data, and are designed to scale horizontally.

In recent years there was a high demand for massively distributed databases with high partition tolerance but according to the CAP theorem it is impossible for a distributed system to simultaneously provide consistency, availability and partition tolerance guarantees. A distributed system can satisfy any two of these guarantees at the same time, but not all three. For that reason many NoSQL databases are using what is called eventual consistency to provide both availability and partition tolerance guarantees with a maximum level of data consistency.

The most popular NoSQL systems include: MongoDB, Couchbase, Riak, memcached, Redis, CouchDB, Hazelcast, Apache Cassandra and HBase. Note that all are open-source software products.

A number of new relational databases continuing use of SQL but aiming for performance comparable to NoSQL are known as NewSQL.

Research

Database technology has been an active research topic since the 1960s, both in academia and in the research and development groups of companies (for example IBM Research). Research activity includes theory and development of prototypes. Notable research topics have included models, the atomic transaction concept and related concurrency control techniques, query languages and query optimization methods, RAID, and more.

The database research area has several dedicated academic journals (for example, ACM Transactions on Database Systems-TODS, Data and Knowledge Engineering-DKE) and annual conferences (e.g., ACM SIGMOD, ACM PODS, VLDB, IEEE ICDE).

Examples

One way to classify databases involves the type of their contents, for example: bibliographic, document-text, statistical, or multimedia objects. Another way is by their application area, for example: accounting, music compositions, movies, banking, manufacturing, or insurance. A third way is by some technical aspect, such as the database structure or interface type. This section lists a few of the adjectives used to characterize different kinds of databases.

- An in-memory database is a database that primarily resides in main memory, but is typically backed-up by non-volatile computer data storage. Main memory databases are faster than disk databases, and so are often used where response time is critical, such as in telecommunications network equipment.SAP HANA platform is a very hot topic for in-memory database. By May 2012, HANA was able to run on servers with 100TB main memory powered by IBM. The co founder of the company claimed that the system was big enough to run the 8 largest SAP customers.
- An active database includes an event-driven architecture which can respond to conditions both inside and outside the database. Possible uses include security monitoring, alerting, statistics gathering and authorization. Many databases provide active database features in the form of database triggers.
- A cloud database relies on cloud technology. Both the database and most of its DBMS reside remotely, "in the cloud", while its applications are both developed by programmers and later maintained and utilized by (application's) end-users through a web browser and Open APIs.
- Data warehouses archive data from operational databases and often from external sources such as market research firms. The warehouse becomes the central source of data for use by managers and other end-users who may not have access to operational data. For example, sales data might be aggregated to weekly totals and converted from internal product codes to use UPCs so that they can be compared with ACNielsen data. Some basic and essential components of data warehousing include retrieving, analyzing, and mining data, transforming, loading and managing data so as to make them available for further use.
- A deductive database combines logic programming with a relational database, for example by using the Datalog language.
- A distributed database is one in which both the data and the DBMS span multiple computers.
- A document-oriented database is designed for storing, retrieving, and managing document-oriented, or semi structured data, information. Document-oriented databases are one of the main categories of NoSQL databases.
- An embedded database system is a DBMS which is tightly integrated with an application software that requires access to stored data in such a way that the DBMS is hidden from the application's end-users and requires little or no ongoing maintenance.[15]
- **End-user databases** consist of data developed by individual end-users. Examples of these are collections of documents, spreadsheets, presentations, multimedia, and other files. Several products exist to support such databases. Some of them are much simpler than full fledged DBMSs, with more elementary DBMS functionality.

- A federated database system comprises several distinct databases, each with its own DBMS. It is handled as a single database by a federated database management system (FDBMS), which transparently integrates multiple autonomous DBMSs, possibly of different types (in which case it would also be a heterogeneous database system), and provides them with an integrated conceptual view.
- Sometimes the term *multi-database* is used as a synonym to federated database, though it may refer to a less integrated (e.g., without an FDBMS and a managed integrated schema) group of databases that cooperate in a single application. In this case typically middleware is used for distribution, which typically includes an atomic commit protocol (ACP), e.g., the two-phase commit protocol, to allow distributed (global) transactions across the participating databases.
- A graph database is a kind of NoSQL database that uses graph structures with nodes, edges, and properties to represent and store information. General graph databases that can store any graph are distinct from specialized graph databases such as triplestores and network databases.
- In a hypertext or hypermedia database, any word or a piece of text representing an object, e.g., another piece of text, an article, a picture, or a film, can be hyperlinked to that object. Hypertext databases are particularly useful for organizing large amounts of disparate information. For example, they are useful for organizing online encyclopedias, where users can conveniently jump around the text. The World Wide Web is thus a large distributed hypertext database.
- A knowledge base (abbreviated **KB**, **kb** or Δ[16]) is a special kind of database for knowledge management, providing the means for the computerized collection, organization, and retrieval of knowledge. Also a collection of data representing problems with their solutions and related experiences.
- A mobile database can be carried on or synchronized from a mobile computing device.
- Operational databases store detailed data about the operations of an organization. They typically process relatively high volumes of updates using transactions. Examples include customer databases that record contact, credit, and demographic information about a business' customers, personnel databases that hold information such as salary, benefits, skills data about employees, enterprise resource planning systems that record details about product components, parts inventory, and financial databases that keep track of the organization's money, accounting and financial dealings.
- A parallel database seeks to improve performance through parallelization for tasks such as loading data, building indexes and evaluating queries.

  The major parallel DBMS architectures which are induced by the underlying hardware architecture are:

  - **Shared memory architecture**, where multiple processors share the main memory space, as well as other data storage.
  - **Shared disk architecture**, where each processing unit (typically consisting of multiple processors) has its own main memory, but all units share the other storage.
  - **Shared nothing architecture**, where each processing unit has its own main memory and other storage.
- Probabilistic databases employ fuzzy logic to draw inferences from imprecise data.
- Real-time databases process transactions fast enough for the result to come back and be acted on right away.
- A spatial database can store the data with multidimensional features. The queries on such data include location based queries, like "Where is the closest hotel in my area?".
- A temporal database has built-in time aspects, for example a temporal data model and a temporal version of SQL. More specifically the temporal aspects usually include valid-time and transaction-time.
- A terminology-oriented database builds upon an object-oriented database, often customized for a specific field.
- An unstructured data database is intended to store in a manageable and protected way diverse objects that do not fit naturally and conveniently in common databases. It may include email messages, documents, journals,

multimedia objects, etc. The name may be misleading since some objects can be highly structured. However, the entire possible object collection does not fit into a predefined structured framework. Most established DBMSs now support unstructured data in various ways, and new dedicated DBMSs are emerging.

Design and modeling

The first task of a database designer is to produce a conceptual data model that reflects the structure of the information to be held in the database. A common approach to this is to develop an entity-relationship model, often with the aid of drawing tools. Another popular approach is the Unified Modeling Language. A successful data model will accurately reflect the possible state of the external world being modeled: for example, if people can have more than one phone number, it will allow this information to be captured. Designing a good conceptual data model requires a good understanding of the application domain; it typically involves asking deep questions about the things of interest to an organisation, like "can a customer also be a supplier?", or "if a product is sold with two different forms of packaging, are those the same product or different products?", or "if a plane flies from New York to Dubai via Frankfurt, is that one flight or two (or maybe even three)?". The answers to these questions establish definitions of the terminology used for entities (customers, products, flights, flight segments) and their relationships and attributes.

Producing the conceptual data model sometimes involves input from business processes, or the analysis of workflow in the organization. This can help to establish what information is needed in the database, and what can be left out. For example, it can help when deciding whether the database needs to hold historic data as well as current data.

Having produced a conceptual data model that users are happy with, the next stage is to translate this into a schema that implements the relevant data structures within the database. This process is often called logical database design, and the output is a logical data model expressed in the form of a schema. Whereas the conceptual data model is (in theory at least) independent of the choice of database technology, the logical data model will be expressed in terms of a particular database model supported by the chosen DBMS. (The terms *data model* and *database model* are often used interchangeably, but in this article we use *data model* for the design of a specific database, and *database model* for the modelling notation used to express that design.)

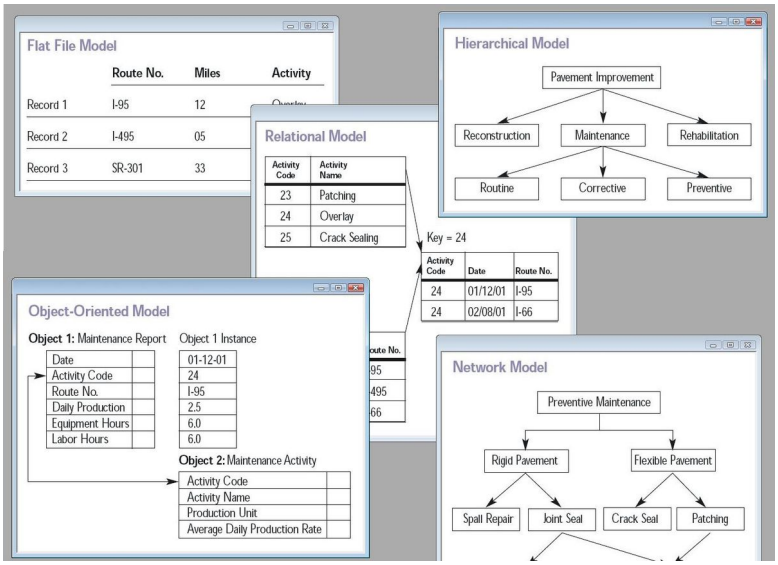
The most popular database model for general-purpose databases is the relational model, or more precisely, the relational model as represented by the SQL language. The process of creating a logical database design using this model uses a methodical approach known as normalization. The goal of normalization is to ensure that each elementary "fact" is only recorded in one place, so that insertions, updates, and deletions automatically maintain consistency.

The final stage of database design is to make the decisions that affect performance, scalability, recovery, security, and the like. This is often called *physical database design*. A key goal during this stage is data independence, meaning that the decisions made for performance optimization purposes should be invisible to end-users and applications. Physical design is driven mainly by performance requirements, and requires a good knowledge of the expected workload and access patterns, and a deep understanding of the features offered by the chosen DBMS.

Another aspect of physical database design is security. It involves both defining access control to database objects as well as defining security levels and methods for the data itself.

Models

A database model is a type of data model that determines the logical structure of a database and fundamentally determines in which manner data can be stored, organized, and manipulated. The most popular example of a database model is the relational model (or the SQL approximation of relational), which uses a table-based format.



Collage of five types of database models.

Common logical data models for databases include:

- Hierarchical database model
- Network model
- Relational model
- Entity–relationship model
  - Enhanced entity–relationship model
- Object model
- Document model
- Entity–attribute–value model
- Star schema

An object-relational database combines the two related structures.

Physical data models include:

- Inverted index
- Flat file

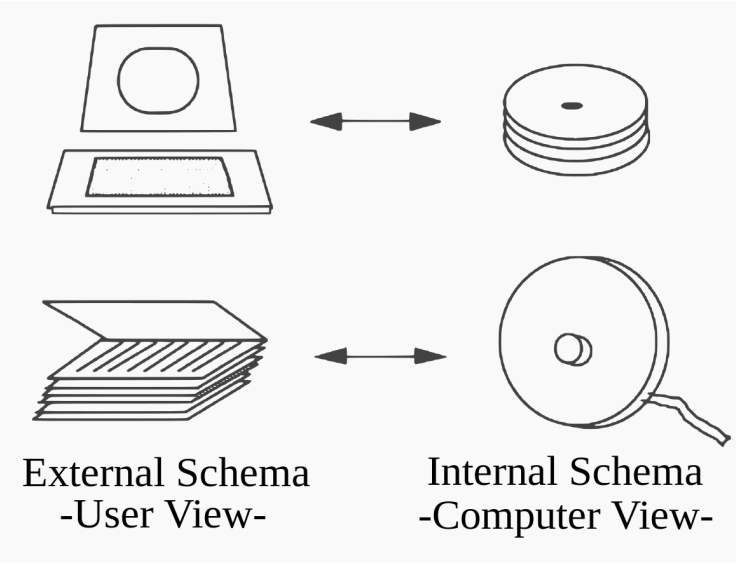
Other models include:

- Associative model
- Multidimensional model
- Multivalue model
- Semantic model
- XML database
- Named graph

External, conceptual, and internal views

A database management system provides three views of the database data:

- The **external level** defines how each group of end-users sees the organization of data in the database. A single database can have any number of views at the external level.
- The **conceptual level** unifies the various external views into a compatible global view. It provides the synthesis of all the external views. It is out of the scope of the various database end-users, and is rather of interest to database application developers and database administrators.



Traditional view of data[17]

- The **internal level** (or *physical level*) is the internal organization of data inside a DBMS (see Implementation section below). It is concerned with cost, performance, scalability and other operational matters. It deals with storage layout of the data, using storage structures such as indexes to enhance performance. Occasionally it stores data of individual views (materialized views), computed from generic data, if performance justification exists for such redundancy. It balances all the external views' performance requirements, possibly conflicting, in an attempt to optimize overall performance across all activities.

While there is typically only one conceptual (or logical) and physical (or internal) view of the data, there can be any number of different external views. This allows users to see database information in a more business-related way rather than from a technical, processing viewpoint. For example, a financial department of a company needs the payment details of all employees as part of the company's expenses, but does not need details about employees that are the interest of the human resources department. Thus different departments need different *views* of the company's database.

The three-level database architecture relates to the concept of *data independence* which was one of the major initial driving forces of the relational model. The idea is that changes made at a certain level do not affect the view at a higher level. For example, changes in the internal level do not affect application programs written using conceptual level interfaces, which reduces the impact of making physical changes to improve performance.

The conceptual view provides a level of indirection between internal and external. On one hand it provides a common view of the database, independent of different external view structures, and on the other hand it abstracts away details of how the data is stored or managed (internal level). In principle every level, and even every external view, can be presented by a different data model. In practice usually a given DBMS uses the same data model for both the external and the conceptual levels (e.g., relational model). The internal level, which is hidden inside the DBMS and depends on its implementation (see Implementation section below), requires a different level of detail and uses its own types of data structure types.

Separating the *external*, *conceptual* and *internal* levels was a major feature of the relational database model implementations that dominate 21st century databases.

Languages

Database languages are special-purpose languages, which do one or more of the following:

- Data definition language – defines data types and the relationships among them
- Data manipulation language – performs tasks such as inserting, updating, or deleting data occurrences
- Query language – allows searching for information and computing derived information

Database languages are specific to a particular data model. Notable examples include:

- SQL combines the roles of data definition, data manipulation, and query in a single language. It was one of the first commercial languages for the relational model, although it departs in some respects from the relational model as described by Codd (for example, the rows and columns of a table can be ordered). SQL became a standard of the American National Standards Institute (ANSI) in 1986, and of the International Organization for Standardization (ISO) in 1987. The standards have been regularly enhanced since and is supported (with varying degrees of conformance) by all mainstream commercial relational DBMSs.
- OQL is an object model language standard (from the Object Data Management Group). It has influenced the design of some of the newer query languages like JDOQL and EJB QL.
- XQuery is a standard XML query language implemented by XML database systems such as MarkLogic and eXist, by relational databases with XML capability such as Oracle and DB2, and also by in-memory XML processors such as Saxon.
- SQL/XML combines XQuery with SQL.

A database language may also incorporate features like:

- DBMS-specific Configuration and storage engine management
- Computations to modify query results, like counting, summing, averaging, sorting, grouping, and cross-referencing
- Constraint enforcement (e.g. in an automotive database, only allowing one engine type per car)
- Application programming interface version of the query language, for programmer convenience

Performance, security, and availability

Because of the critical importance of database technology to the smooth running of an enterprise, database systems include complex mechanisms to deliver the required performance, security, and availability, and allow database administrators to control the use of these features.

Storage

Database storage is the container of the physical materialization of a database. It comprises the *internal* (physical) *level* in the database architecture. It also contains all the information needed (e.g., metadata, "data about the data", and internal data structures) to reconstruct the *conceptual level* and *external level* from the internal level when needed. Putting data into permanent storage is generally the responsibility of the database engine a.k.a. "storage engine". Though typically accessed by a DBMS through the underlying operating system (and often utilizing the operating systems' file systems as intermediates for storage layout), storage properties and configuration setting are extremely important for the efficient operation of the DBMS, and thus are closely maintained by database administrators. A DBMS, while in operation, always has its database residing in several types of storage (e.g., memory and external storage). The database data and the additional needed information, possibly in very large amounts, are coded into bits. Data typically reside in the storage in structures that look completely different from the way the data look in the conceptual and external levels, but in ways that attempt to optimize (the best possible) these levels' reconstruction when needed by users and programs, as well as for computing additional types of needed information from the data (e.g., when querying the database).

Some DBMSs support specifying which character encoding was used to store data, so multiple encodings can be used in the same database.

Various low-level database storage structures are used by the storage engine to serialize the data model so it can be written to the medium of choice. Techniques such as indexing may be used to improve performance. Conventional storage is row-oriented, but there are also column-oriented and correlation databases.

Materialized views

Often storage redundancy is employed to increase performance. A common example is storing *materialized views*, which consist of frequently needed *external views* or query results. Storing such views saves the expensive computing of them each time they are needed. The downsides of materialized views are the overhead incurred when updating them to keep them synchronized with their original updated database data, and the cost of storage redundancy.

Replication

Occasionally a database employs storage redundancy by database objects replication (with one or more copies) to increase data availability (both to improve performance of simultaneous multiple end-user accesses to a same database object, and to provide resiliency in a case of partial failure of a distributed database). Updates of a replicated object need to be synchronized across the object copies. In many cases the entire database is replicated.

Security

Database security deals with all various aspects of protecting the database content, its owners, and its users. It ranges from protection from intentional unauthorized database uses to unintentional database accesses by unauthorized entities (e.g., a person or a computer program).

Database access control deals with controlling who (a person or a certain computer program) is allowed to access what information in the database. The information may comprise specific database objects (e.g., record types, specific records, data structures), certain computations over certain objects (e.g., query types, or specific queries), or utilizing specific access paths to the former (e.g., using specific indexes or other data structures to access information). Database access controls are set by special authorized (by the database owner) personnel that uses dedicated protected security DBMS interfaces.

This may be managed directly on an individual basis, or by the assignment of individuals and privileges to groups, or (in the most elaborate models) through the assignment of individuals and groups to roles which are then granted entitlements. Data security prevents unauthorized users from viewing or updating the database. Using passwords, users are allowed access to the entire database or subsets of it called "subschemas". For example, an employee database can contain all the data about an individual employee, but one group of users may be authorized to view only payroll data, while others are allowed access to only work history and medical data. If the DBMS provides a way to interactively enter and update the database, as well as interrogate it, this capability allows for managing personal databases.

Data security in general deals with protecting specific chunks of data, both physically (i.e., from corruption, or destruction, or removal; e.g., see physical security), or the interpretation of them, or parts of them to meaningful information (e.g., by looking at the strings of bits that they comprise, concluding specific valid credit-card numbers; e.g., see data encryption).

Change and access logging records who accessed which attributes, what was changed, and when it was changed. Logging services allow for a forensic database audit later by keeping a record of access occurrences and changes. Sometimes application-level code is used to record changes rather than leaving this to the database. Monitoring can be set up to attempt to detect security breaches.

Transactions and concurrency

Database transactions can be used to introduce some level of fault tolerance and data integrity after recovery from a crash. A database transaction is a unit of work, typically encapsulating a number of operations over a database (e.g., reading a database object, writing, acquiring lock, etc.), an abstraction supported in database and also other systems. Each transaction has well defined boundaries in terms of which program/code executions are included in that transaction (determined by the transaction's programmer via special transaction commands).

The acronym ACID describes some ideal properties of a database transaction: Atomicity, Consistency, Isolation, and Durability.

Migration

See also section Database migration in article Data migration

A database built with one DBMS is not portable to another DBMS (i.e., the other DBMS cannot run it). However, in some situations it is desirable to move, migrate a database from one DBMS to another. The reasons are primarily economical (different DBMSs may have different total costs of ownership or TCOs), functional, and operational (different DBMSs may have different capabilities). The migration involves the database's transformation from one DBMS type to another. The transformation should maintain (if possible) the database related application (i.e., all related application programs) intact. Thus, the database's conceptual and external architectural levels should be maintained in the transformation. It may be desired that also some aspects of the architecture internal level are maintained. A complex or large database migration may be a complicated and costly (one-time) project by itself, which should be factored into the decision to migrate. This in spite of the fact that tools may exist to help migration between specific DBMSs. Typically a DBMS vendor provides tools to help importing databases from other popular DBMSs.

Building, maintaining, and tuning

After designing a database for an application, the next stage is building the database. Typically an appropriate general-purpose DBMS can be selected to be utilized for this purpose. A DBMS provides the needed user interfaces to be utilized by database administrators to define the needed application's data structures within the DBMS's respective data model. Other user interfaces are used to select needed DBMS parameters (like security related, storage allocation parameters, etc.).

When the database is ready (all its data structures and other needed components are defined) it is typically populated with initial application's data (database initialization, which is typically a distinct project; in many cases using specialized DBMS interfaces that support bulk insertion) before making it operational. In some cases the database becomes operational while empty of application data, and data is accumulated during its operation.

After the database is created, initialised and populated it needs to be maintained. Various database parameters may need changing and the database may need to be tuned (tuning) for better performance; application's data structures may be changed or added, new related application programs may be written to add to the application's functionality, etc. Databases are often confused with spreadsheets such as Microsoft Excel (Microsoft Access is a database management system, Excel is a spreadsheet program). Both can be used to store information, however a database is more efficient and flexible at storing large amounts of data. Below is a simple comparison of spreadsheets and databases.

Spreadsheet strengths	Spreadsheet Weaknesses
Very simple data storage	Data integrity problems, including inaccurate, inconsistent and out of date data and formulas.
Relatively easy to use	Difficult to validate data e.g. an incorrect formula
Require less planning	

Database strengths	Database Weaknesses
Methods for keeping data up to date and consistent	Require more planning and designing
Data is of higher quality than data stored in spreadsheets	Harder to change structure once database is built
Good for storing and organizing information.	Requires more technical knowledge to administrate

Backup and restore

Sometimes it is desired to bring a database back to a previous state (for many reasons, e.g., cases when the database is found corrupted due to a software error, or if it has been updated with erroneous data). To achieve this a **backup** operation is done occasionally or continuously, where each desired database state (i.e., the values of its data and their embedding in database's data structures) is kept within dedicated backup files (many techniques exist to do this effectively). When this state is needed, i.e., when it is decided by a database administrator to bring the database back to this state (e.g., by specifying this state by a desired point in time when the database was in this state), these files are utilized to **restore** that state.

Other

Other DBMS features might include:

- Database logs
- Graphics component for producing graphs and charts, especially in a data warehouse system
- **Query optimizer –** Performs query optimization on every query to choose for it the most efficient *query plan* (a partial order (tree) of operations) to be executed to compute the query result. May be specific to a particular storage engine.
- Tools or hooks for database design, application programming, application program maintenance, database performance analysis and monitoring, database configuration monitoring, DBMS hardware configuration (a DBMS and related database may span computers, networks, and storage units) and related database mapping (especially for a distributed DBMS), storage allocation and database layout monitoring, storage migration, etc.

Database system

A **database** is an organized collection of data. The data are typically organized to model relevant aspects of reality in a way that supports processes requiring this information. For example, modeling the availability of rooms in hotels in a way that supports finding a hotel with vacancies.

Database management systems (**DBMS**s) are specially designed software applications that interact with the user, other applications, and the database itself to capture and analyze data. A general-purpose DBMS is a software system designed to allow the definition, creation, querying, update, and administration of databases. Well-known DBMSs include MySQL, MariaDB, PostgreSQL, SQLite, Microsoft SQL Server, Oracle, SAP HANA, dBASE, FoxPro, IBM DB2, LibreOffice Base and FileMaker Pro. A database is not generally portable across different DBMSs, but different DBMSs can interoperate by using standards such as SQL and ODBC or JDBC to allow a single application to work with more than one database.

Terminology and overview

Formally, "database" refers to the data themselves and supporting data structures. Databases are created to operate large quantities of information by inputting, storing, retrieving, and managing that information. Databases are set up so that one set of software programs provides all users with access to all the data.

A "database management system" (DBMS) is a suite of computer software providing the interface between users and a database or databases. Because they are so closely related, the term "database" when used casually often refers to both a DBMS and the data it manipulates.

Outside the world of professional information technology, the term *database* is sometimes used casually to refer to any collection of data (perhaps a spreadsheet, maybe even a card index). This article is concerned only with databases where the size and usage requirements necessitate use of a database management system.[1]

The interactions catered for by most existing DBMSs fall into four main groups:

- **Data definition –** Defining new data structures for a database, removing data structures from the database, modifying the structure of existing data.
- **Update –** Inserting, modifying, and deleting data.
- **Retrieval –** Obtaining information either for end-user queries and reports or for processing by applications.
- **Administration –** Registering and monitoring users, enforcing data security, monitoring performance, maintaining data integrity, dealing with concurrency control, and recovering information if the system fails.

A DBMS is responsible for maintaining the integrity and security of stored data, and for recovering information if the system fails.

Both a database and its DBMS conform to the principles of a particular database model.[2] "Database system" refers collectively to the database model, database management system, and database.[3]

Physically, database servers are dedicated computers that hold the actual databases and run only the DBMS and related software. Database servers are usually multiprocessor computers, with generous memory and RAID disk arrays used for stable storage. RAID is used for recovery of data if any of the disks fail. Hardware database accelerators, connected to one or more servers via a high-speed channel, are also used in large volume transaction processing environments. DBMSs are found at the heart of most database applications. DBMSs may be built around a custom multitasking kernel with built-in networking support, but modern DBMSs typically rely on a standard operating system to provide these functions. [*citation needed*] Since DBMSs comprise a significant economical market, computer and storage vendors often take into account DBMS requirements in their own development plans.[*citation needed*]

Databases and DBMSs can be categorized according to the database model(s) that they support (such as relational or XML), the type(s) of computer they run on (from a server cluster to a mobile phone), the query language(s) used to access the database (such as SQL or XQuery), and their internal engineering, which affects performance, scalability, resilience, and security.

Applications and roles

Most organizations in developed countries today depend on databases for their business operations. Increasingly, databases are not only used to support the internal operations of the organization, but also to underpin its online interactions with customers and suppliers (see Enterprise software). Databases are not used only to hold administrative information, but are often embedded within applications to hold more specialized data: for example engineering data or economic models. Examples of database applications include computerized library systems, flight reservation systems, and computerized parts inventory systems.

Client-server or transactional DBMSs are often complex to maintain high performance, availability and security when many users are querying and updating the database at the same time. Personal, desktop-based database systems tend to be less complex. For example, FileMaker and Microsoft Access come with built-in graphical user interfaces.

General-purpose and special-purpose DBMSs

A DBMS has evolved into a complex software system and its development typically requires thousands of person-years of development effort.[4] Some general-purpose DBMSs such as Adabas, Oracle and DB2 have been undergoing upgrades since the 1970s. General-purpose DBMSs aim to meet the needs of as many applications as possible, which adds to the complexity. However, the fact that their development cost can be spread over a large number of users means that they are often the most cost-effective approach. However, a general-purpose DBMS is not always the optimal solution: in some cases a general-purpose DBMS may introduce unnecessary overhead. Therefore, there are many examples of systems that use special-purpose databases. A common example is an email system: email systems are designed to optimize the handling of email messages, and do not need significant portions of a general-purpose DBMS functionality.

Many databases have application software that accesses the database on behalf of end-users, without exposing the DBMS interface directly. Application programmers may use a wire protocol directly, or more likely through an application programming interface. Database designers and database administrators interact with the DBMS through dedicated interfaces to build and maintain the applications' databases, and thus need some more knowledge and understanding about how DBMSs operate and the DBMSs' external interfaces and tuning parameters.

General-purpose databases are usually developed by one organization or community of programmers, while a different group builds the applications that use it. In many companies, specialized database administrators maintain databases, run reports, and may work on code that runs on the databases themselves (rather than in the client application).

History

Following the technology progress in the areas of processors, computer memory, computer storage and computer networks, the sizes, capabilities, and performance of databases and their respective DBMSs have grown in orders of magnitude. The development of database technology can be divided into three eras based on data model or structure: navigational,[5] SQL/relational, and post-relational.

The two main early navigational data models were the hierarchical model, epitomized by IBM's IMS system, and the CODASYL model (network model), implemented in a number of products such as IDMS.

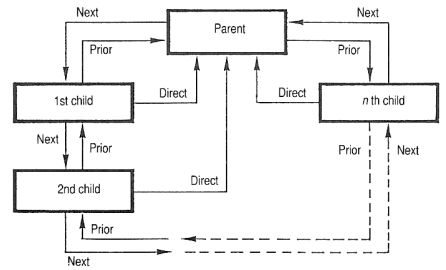
The relational model, first proposed in 1970 by Edgar F. Codd, departed from this tradition by insisting that applications should search for data by content, rather than by following links. The relational model employs sets of ledger-style tables, each used for a different type of entity. Only in the mid-1980s did computing hardware became powerful enough to allow the wide deployment of relational systems (DBMSs plus applications). By the early 1990s, however, relational systems dominated in all large-scale data processing applications, and as of 2014[6] they remain dominant except in niche areas. The dominant database language, standardised SQL for the relational model, has influenced database languages for other data models.[*citation needed*]

Object databases developed in the 1980s to overcome the inconvenience of object-relational impedance mismatch, which led to the coining of the term "post-relational" and also the development of hybrid object-relational databases.

The next generation of post-relational databases in the late 2000s became known as NoSQL databases, introducing fast key-value stores and document-oriented databases. A competing "next generation" known as NewSQL databases attempted new implementations that retained the relational/SQL model while aiming to match the high performance of NoSQL compared to commercially available relational DBMSs.

1960s, navigational DBMS

The introduction of the term *database* coincided with the availability of direct-access storage (disks and drums) from the mid-1960s onwards. The term represented a contrast with the tape-based systems of the past, allowing shared interactive use rather than daily batch processing. The Oxford English dictionary cites a 1962 report by the System Development Corporation of California as the first to use the term "data-base" in a specific technical sense.



A closed chain of records in a navigational database model (e.g. CODASYL), with ***next pointers***, ***prior pointers*** and ***direct pointers*** provided by keys in the various records.

Illustration of a set type using a ***Bachman diagram***

The record set, basic structure of navigational (e.g. CODASYL) databse model. A set consists of one parent record (also called "the owner"), and n child records (also called members records)

Basic structure of navigational CODASYL database model.

As computers grew in speed and capability, a number of general-purpose database systems emerged; by the mid-1960s a number of such systems had come into commercial use. Interest in a standard began to grow, and Charles Bachman, author of one such product, the Integrated Data Store (IDS), founded the "Database Task Group" within CODASYL, the group responsible for the creation and standardization of COBOL. In 1971 theDatabase Task Group delivered their standard, which generally became known as the "CODASYL approach", and soon a number of commercial products based on this approach entered the market.

The CODASYL approach relied on the "manual" navigation of a linked data set which was formed into a large network. Applications could find records by one of three methods:

- use of a primary key (known as a CALC key, typically implemented by hashing)
- navigating relationships (called sets) from one record to another
- scanning all the records in a sequential order.

Later systems added B-Trees to provide alternate access paths. Many CODASYL databases also added a very straightforward query language. However, in the final tally, CODASYL was very complex and required significant training and effort to produce useful applications.

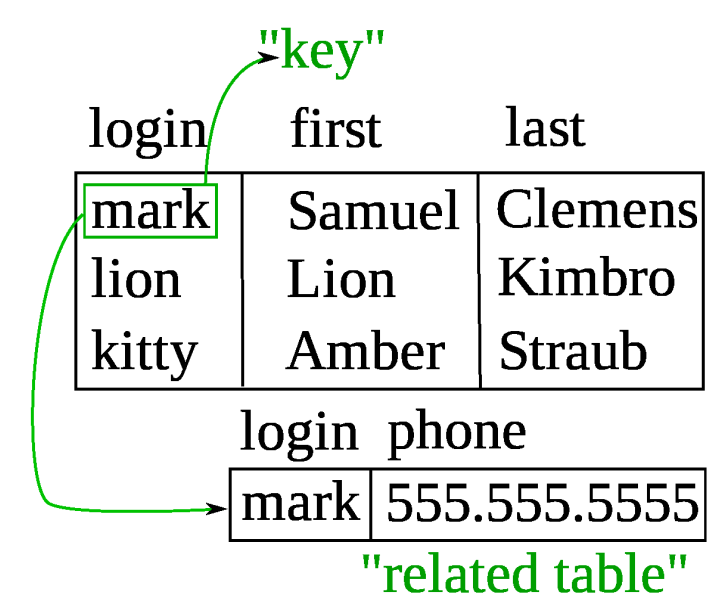
IBM also had their own DBMS system in 1968, known as *IMS*. IMS was a development of software written for the Apollo program on the System/360. IMS was generally similar in concept to CODASYL, but used a strict hierarchy for its model of data navigation instead of CODASYL's network model. Both concepts later became known as navigational databases due to the way data was accessed, and Bachman's 1973 Turing Award presentation was *The Programmer as Navigator*. IMS is classifiedWikipedia:Manual of Style/Words to watch#Unsupported attributions as a hierarchical database. IDMS and Cincom Systems' TOTAL database are classified as network databases. IMS remains in use as of 2014[6].

1970s, relational DBMS

Edgar Codd worked at IBM in San Jose, California, in one of their offshoot offices that was primarily involved in the development of hard disk systems. He was unhappy with the navigational model of the CODASYL approach, notably the lack of a "search" facility. In 1970, he wrote a number of papers that outlined a new approach to database construction that eventually culminated in the groundbreaking *A Relational Model of Data for Large Shared Data Banks*.[6]

In this paper, he described a new system for storing and working with large databases. Instead of records being stored in some sort of linked list of free-form records as in CODASYL, Codd's idea was to use a "table" of fixed-length records, with each table used for a different type of entity. A linked-list system would be very inefficient when storing "sparse" databases where some of the data for any one record could be left empty. The relational model solved this by splitting the data into a series of normalized tables (or *relations*), with optional elements being moved out of the main table to where they would take up room only if needed. Data may be freely inserted, deleted and edited in these tables, with the DBMS doing whatever maintenance needed to present a table view to the application/user.

The relational model also allowed the content of the database to evolve without constant rewriting of links and pointers. The relational part comes from entities referencing other entities in what is known as one-to-many relationship, like a traditional hierarchical model, and many-to-many relationship, like a navigational (network) model. Thus, a relational model can express both hierarchical and navigational models, as well as its native tabular model, allowing for pure or combined modeling in terms of these three models, as the application requires.



In the relational model, related records are linked together with a "key"

For instance, a common use of a database system is to track information about users, their name, login information, various addresses and phone numbers. In the navigational approach all of these data would be placed in a single record, and unused items would simply not be placed in the database. In the relational approach, the data would be *normalized* into a user table, an address table and a phone number table (for instance). Records would be created in these optional tables only if the address or phone numbers were actually provided.

Linking the information back together is the key to this system. In the relational model, some bit of information was used as a "key", uniquely defining a particular record. When information was being collected about a user, information stored in the optional tables would be found by searching for this key. For instance, if the login name of a user is unique, addresses and phone numbers for that user would be recorded with the login name as its key. This simple "re-linking" of related data back into a single collection is something that traditional computer languages are not designed for.

Just as the navigational approach would require programs to loop in order to collect records, the relational approach would require loops to collect information about any *one* record. Codd's solution to the necessary looping was a set-oriented language, a suggestion that would later spawn the ubiquitous SQL. Using a branch of mathematics known as tuple calculus, he demonstrated that such a system could support all the operations of normal databases (inserting, updating etc.) as well as providing a simple system for finding and returning *sets* of data in a single operation.

Codd's paper was picked up by two people at Berkeley, Eugene Wong and Michael Stonebraker. They started a project known as INGRES using funding that had already been allocated for a geographical database project and student programmers to produce code. Beginning in 1973, INGRES delivered its first test products which were generally ready for widespread use in 1979. INGRES was similar to System R in a number of ways, including the

use of a "language" for data access, known as QUEL. Over time, INGRES moved to the emerging SQL standard.

IBM itself did one test implementation of the relational model, PRTV, and a production one, Business System 12, both now discontinued. Honeywell wrote MRDS for Multics, and now there are two new implementations: Alphora Dataphor and Rel. Most other DBMS implementations usually called *relational* are actually SQL DBMSs.

In 1970, the University of Michigan began development of the MICRO Information Management System[7] based on D.L. Childs' Set-Theoretic Data model.[8][9][10] Micro was used to manage very large data sets by the US Department of Labor, the U.S. Environmental Protection Agency, and researchers from the University of Alberta, the University of Michigan, and Wayne State University. It ran on IBM mainframe computers using the Michigan Terminal System.[11] The system remained in production until 1998.

Integrated approach

In the 1970s and 1980s attempts were made to build database systems with integrated hardware and software. The underlying philosophy was that such integration would provide higher performance at lower cost. Examples were IBM System/38, the early offering of Teradata, and the Britton Lee, Inc. database machine.

Another approach to hardware support for database management was ICL's CAFS accelerator, a hardware disk controller with programmable search capabilities. In the long term, these efforts were generally unsuccessful because specialized database machines could not keep pace with the rapid development and progress of general-purpose computers. Thus most database systems nowadays are software systems running on general-purpose hardware, using general-purpose computer data storage. However this idea is still pursued for certain applications by some companies like Netezza and Oracle (Exadata).

Late 1970s, SQL DBMS

IBM started working on a prototype system loosely based on Codd's concepts as *System R* in the early 1970s. The first version was ready in 1974/5, and work then started on multi-table systems in which the data could be split so that all of the data for a record (some of which is optional) did not have to be stored in a single large "chunk". Subsequent multi-user versions were tested by customers in 1978 and 1979, by which time a standardized query language – SQL[*citation needed*] – had been added. Codd's ideas were establishing themselves as both workable and superior to CODASYL, pushing IBM to develop a true production version of System R, known as *SQL/DS*, and, later, *Database 2* (DB2).

Larry Ellison's Oracle started from a different chain, based on IBM's papers on System R, and beat IBM to market when the first version was released in 1978.[*citation needed*]

Stonebraker went on to apply the lessons from INGRES to develop a new database, Postgres, which is now known as PostgreSQL. PostgreSQL is often used for global mission critical applications (the .org and .info domain name registries use it as their primary data store, as do many large companies and financial institutions).

In Sweden, Codd's paper was also read and Mimer SQL was developed from the mid-1970s at Uppsala University. In 1984, this project was consolidated into an independent enterprise. In the early 1980s, Mimer introduced transaction handling for high robustness in applications, an idea that was subsequently implemented on most other DBMSs.

Another data model, the entity-relationship model, emerged in 1976 and gained popularity for database design as it emphasized a more familiar description than the earlier relational model. Later on, entity-relationship constructs were retrofitted as a data modeling construct for the relational model, and the difference between the two have become irrelevant.[*citation needed*]

1980s, on the desktop

The 1980s ushered in the age of desktop computing. The new computers empowered their users with spreadsheets like Lotus 1,2,3 and database software like dBASE. The dBASE product was lightweight and easy for any computer user to understand out of the box. C. Wayne Ratliff the creator of dBASE stated: “dBASE was different from programs like BASIC, C, FORTRAN, and COBOL in that a lot of the dirty work had already been done. The data manipulation is done by dBASE instead of by the user, so the user can concentrate on what he is doing, rather than having to mess with the dirty details of opening, reading, and closing files, and managing space allocation.“ [12] dBASE was one of the top selling software titles in the 1980s and early 1990s.

1980s, object-oriented

The 1980s, along with a rise in object oriented programming, saw a growth in how data in various databases were handled. Programmers and designers began to treat the data in their databases as objects. That is to say that if a person's data were in a database, that person's attributes, such as their address, phone number, and age, were now considered to belong to that person instead of being extraneous data. This allows for relations between data to be relations to objects and their attributes and not to individual fields.[13] The term "object-relational impedance mismatch" described the inconvenience of translating between programmed objects and database tables. Object databases and object-relational databases attempt to solve this problem by providing an object-oriented language (sometimes as extensions to SQL) that programmers can use as alternative to purely relational SQL. On the programming side, libraries known as object-relational mappings (ORMs) attempt to solve the same problem.

2000s, NoSQL and NewSQL

The next generation of post-relational databases in the 2000s became known as NoSQL databases, including fast key-value stores and document-oriented databases. XML databases are a type of structured document-oriented database that allows querying based on XML document attributes.

NoSQL databases are often very fast, do not require fixed table schemas, avoid join operations by storing denormalized data, and are designed to scale horizontally.

In recent years there was a high demand for massively distributed databases with high partition tolerance but according to the CAP theorem it is impossible for a distributed system to simultaneously provide consistency, availability and partition tolerance guarantees. A distributed system can satisfy any two of these guarantees at the same time, but not all three. For that reason many NoSQL databases are using what is called eventual consistency to provide both availability and partition tolerance guarantees with a maximum level of data consistency.

The most popular NoSQL systems include: MongoDB, Couchbase, Riak, memcached, Redis, CouchDB, Hazelcast, Apache Cassandra and HBase. Note that all are open-source software products.

A number of new relational databases continuing use of SQL but aiming for performance comparable to NoSQL are known as NewSQL.

Research

Database technology has been an active research topic since the 1960s, both in academia and in the research and development groups of companies (for example IBM Research). Research activity includes theory and development of prototypes. Notable research topics have included models, the atomic transaction concept and related concurrency control techniques, query languages and query optimization methods, RAID, and more.

The database research area has several dedicated academic journals (for example, ACM Transactions on Database Systems-TODS, Data and Knowledge Engineering-DKE) and annual conferences (e.g., ACM SIGMOD, ACM PODS, VLDB, IEEE ICDE).

Examples

One way to classify databases involves the type of their contents, for example: bibliographic, document-text, statistical, or multimedia objects. Another way is by their application area, for example: accounting, music compositions, movies, banking, manufacturing, or insurance. A third way is by some technical aspect, such as the database structure or interface type. This section lists a few of the adjectives used to characterize different kinds of databases.

- An in-memory database is a database that primarily resides in main memory, but is typically backed-up by non-volatile computer data storage. Main memory databases are faster than disk databases, and so are often used where response time is critical, such as in telecommunications network equipment.SAP HANA platform is a very hot topic for in-memory database. By May 2012, HANA was able to run on servers with 100TB main memory powered by IBM. The co founder of the company claimed that the system was big enough to run the 8 largest SAP customers.
- An active database includes an event-driven architecture which can respond to conditions both inside and outside the database. Possible uses include security monitoring, alerting, statistics gathering and authorization. Many databases provide active database features in the form of database triggers.
- A cloud database relies on cloud technology. Both the database and most of its DBMS reside remotely, "in the cloud", while its applications are both developed by programmers and later maintained and utilized by (application's) end-users through a web browser and Open APIs.
- Data warehouses archive data from operational databases and often from external sources such as market research firms. The warehouse becomes the central source of data for use by managers and other end-users who may not have access to operational data. For example, sales data might be aggregated to weekly totals and converted from internal product codes to use UPCs so that they can be compared with ACNielsen data. Some basic and essential components of data warehousing include retrieving, analyzing, and mining data, transforming, loading and managing data so as to make them available for further use.
- A deductive database combines logic programming with a relational database, for example by using the Datalog language.
- A distributed database is one in which both the data and the DBMS span multiple computers.
- A document-oriented database is designed for storing, retrieving, and managing document-oriented, or semi structured data, information. Document-oriented databases are one of the main categories of NoSQL databases.
- An embedded database system is a DBMS which is tightly integrated with an application software that requires access to stored data in such a way that the DBMS is hidden from the application's end-users and requires little or no ongoing maintenance.[14]
- **End-user databases** consist of data developed by individual end-users. Examples of these are collections of documents, spreadsheets, presentations, multimedia, and other files. Several products exist to support such databases. Some of them are much simpler than full fledged DBMSs, with more elementary DBMS functionality.

- A federated database system comprises several distinct databases, each with its own DBMS. It is handled as a single database by a federated database management system (FDBMS), which transparently integrates multiple autonomous DBMSs, possibly of different types (in which case it would also be a heterogeneous database system), and provides them with an integrated conceptual view.
- Sometimes the term *multi-database* is used as a synonym to federated database, though it may refer to a less integrated (e.g., without an FDBMS and a managed integrated schema) group of databases that cooperate in a single application. In this case typically middleware is used for distribution, which typically includes an atomic commit protocol (ACP), e.g., the two-phase commit protocol, to allow distributed (global) transactions across the participating databases.
- A graph database is a kind of NoSQL database that uses graph structures with nodes, edges, and properties to represent and store information. General graph databases that can store any graph are distinct from specialized graph databases such as triplestores and network databases.
- In a hypertext or hypermedia database, any word or a piece of text representing an object, e.g., another piece of text, an article, a picture, or a film, can be hyperlinked to that object. Hypertext databases are particularly useful for organizing large amounts of disparate information. For example, they are useful for organizing online encyclopedias, where users can conveniently jump around the text. The World Wide Web is thus a large distributed hypertext database.
- A knowledge base (abbreviated **KB**, **kb** or Δ[15]) is a special kind of database for knowledge management, providing the means for the computerized collection, organization, and retrieval of knowledge. Also a collection of data representing problems with their solutions and related experiences.
- A mobile database can be carried on or synchronized from a mobile computing device.
- Operational databases store detailed data about the operations of an organization. They typically process relatively high volumes of updates using transactions. Examples include customer databases that record contact, credit, and demographic information about a business' customers, personnel databases that hold information such as salary, benefits, skills data about employees, enterprise resource planning systems that record details about product components, parts inventory, and financial databases that keep track of the organization's money, accounting and financial dealings.
- A parallel database seeks to improve performance through parallelization for tasks such as loading data, building indexes and evaluating queries.

  The major parallel DBMS architectures which are induced by the underlying hardware architecture are:

  - **Shared memory architecture**, where multiple processors share the main memory space, as well as other data storage.
  - **Shared disk architecture**, where each processing unit (typically consisting of multiple processors) has its own main memory, but all units share the other storage.
  - **Shared nothing architecture**, where each processing unit has its own main memory and other storage.
- Probabilistic databases employ fuzzy logic to draw inferences from imprecise data.
- Real-time databases process transactions fast enough for the result to come back and be acted on right away.
- A spatial database can store the data with multidimensional features. The queries on such data include location based queries, like "Where is the closest hotel in my area?".
- A temporal database has built-in time aspects, for example a temporal data model and a temporal version of SQL. More specifically the temporal aspects usually include valid-time and transaction-time.
- A terminology-oriented database builds upon an object-oriented database, often customized for a specific field.
- An unstructured data database is intended to store in a manageable and protected way diverse objects that do not fit naturally and conveniently in common databases. It may include email messages, documents, journals,

multimedia objects, etc. The name may be misleading since some objects can be highly structured. However, the entire possible object collection does not fit into a predefined structured framework. Most established DBMSs now support unstructured data in various ways, and new dedicated DBMSs are emerging.

Design and modeling

The first task of a database designer is to produce a conceptual data model that reflects the structure of the information to be held in the database. A common approach to this is to develop an entity-relationship model, often with the aid of drawing tools. Another popular approach is the Unified Modeling Language. A successful data model will accurately reflect the possible state of the external world being modeled: for example, if people can have more than one phone number, it will allow this information to be captured. Designing a good conceptual data model requires a good understanding of the application domain; it typically involves asking deep questions about the things of interest to an organisation, like "can a customer also be a supplier?", or "if a product is sold with two different forms of packaging, are those the same product or different products?", or "if a plane flies from New York to Dubai via Frankfurt, is that one flight or two (or maybe even three)?". The answers to these questions establish definitions of the terminology used for entities (customers, products, flights, flight segments) and their relationships and attributes.

Producing the conceptual data model sometimes involves input from business processes, or the analysis of workflow in the organization. This can help to establish what information is needed in the database, and what can be left out. For example, it can help when deciding whether the database needs to hold historic data as well as current data.

Having produced a conceptual data model that users are happy with, the next stage is to translate this into a schema that implements the relevant data structures within the database. This process is often called logical database design, and the output is a logical data model expressed in the form of a schema. Whereas the conceptual data model is (in theory at least) independent of the choice of database technology, the logical data model will be expressed in terms of a particular database model supported by the chosen DBMS. (The terms *data model* and *database model* are often used interchangeably, but in this article we use *data model* for the design of a specific database, and *database model* for the modelling notation used to express that design.)

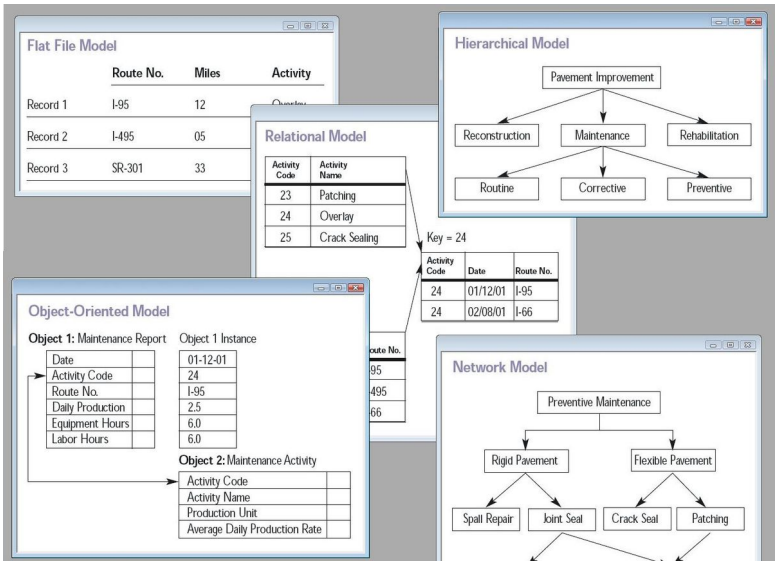
The most popular database model for general-purpose databases is the relational model, or more precisely, the relational model as represented by the SQL language. The process of creating a logical database design using this model uses a methodical approach known as normalization. The goal of normalization is to ensure that each elementary "fact" is only recorded in one place, so that insertions, updates, and deletions automatically maintain consistency.

The final stage of database design is to make the decisions that affect performance, scalability, recovery, security, and the like. This is often called *physical database design*. A key goal during this stage is data independence, meaning that the decisions made for performance optimization purposes should be invisible to end-users and applications. Physical design is driven mainly by performance requirements, and requires a good knowledge of the expected workload and access patterns, and a deep understanding of the features offered by the chosen DBMS.

Another aspect of physical database design is security. It involves both defining access control to database objects as well as defining security levels and methods for the data itself.

Models

A database model is a type of data model that determines the logical structure of a database and fundamentally determines in which manner data can be stored, organized, and manipulated. The most popular example of a database model is the relational model (or the SQL approximation of relational), which uses a table-based format.



Collage of five types of database models.

Common logical data models for databases include:

- Hierarchical database model
- Network model
- Relational model
- Entity–relationship model
  - Enhanced entity–relationship model
- Object model
- Document model
- Entity–attribute–value model
- Star schema

An object-relational database combines the two related structures.

Physical data models include:

- Inverted index
- Flat file

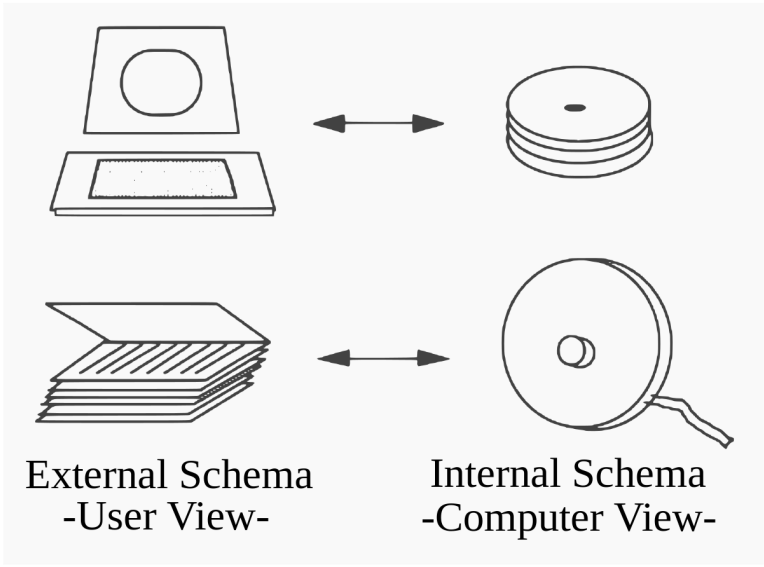
Other models include:

- Associative model
- Multidimensional model
- Multivalue model
- Semantic model
- XML database
- Named graph

External, conceptual, and internal views

A database management system provides three views of the database data:

- The **external level** defines how each group of end-users sees the organization of data in the database. A single database can have any number of views at the external level.
- The **conceptual level** unifies the various external views into a compatible global view. It provides the synthesis of all the external views. It is out of the scope of the various database end-users, and is rather of interest to database application developers and database administrators.
- The **internal level** (or *physical level*) is the internal organization of data inside a DBMS (see Implementation section below). It is concerned with cost, performance, scalability and other operational matters. It deals with storage layout of the data, using storage structures such as indexes to enhance performance. Occasionally it stores data of individual views (materialized views), computed from generic data, if performance justification exists for such redundancy. It balances all the external views' performance requirements, possibly conflicting, in an attempt to optimize overall performance across all activities.



Traditional view of data[16]

While there is typically only one conceptual (or logical) and physical (or internal) view of the data, there can be any number of different external views. This allows users to see database information in a more business-related way rather than from a technical, processing viewpoint. For example, a financial department of a company needs the payment details of all employees as part of the company's expenses, but does not need details about employees that are the interest of the human resources department. Thus different departments need different *views* of the company's database.

The three-level database architecture relates to the concept of *data independence* which was one of the major initial driving forces of the relational model. The idea is that changes made at a certain level do not affect the view at a higher level. For example, changes in the internal level do not affect application programs written using conceptual level interfaces, which reduces the impact of making physical changes to improve performance.

The conceptual view provides a level of indirection between internal and external. On one hand it provides a common view of the database, independent of different external view structures, and on the other hand it abstracts away details of how the data is stored or managed (internal level). In principle every level, and even every external view, can be presented by a different data model. In practice usually a given DBMS uses the same data model for both the external and the conceptual levels (e.g., relational model). The internal level, which is hidden inside the DBMS and depends on its implementation (see Implementation section below), requires a different level of detail and uses its own types of data structure types.

Separating the *external*, *conceptual* and *internal* levels was a major feature of the relational database model implementations that dominate 21st century databases.

Languages

Database languages are special-purpose languages, which do one or more of the following:

- Data definition language – defines data types and the relationships among them
- Data manipulation language – performs tasks such as inserting, updating, or deleting data occurrences
- Query language – allows searching for information and computing derived information

Database languages are specific to a particular data model. Notable examples include:

- SQL combines the roles of data definition, data manipulation, and query in a single language. It was one of the first commercial languages for the relational model, although it departs in some respects from the relational model as described by Codd (for example, the rows and columns of a table can be ordered). SQL became a standard of the American National Standards Institute (ANSI) in 1986, and of the International Organization for Standardization (ISO) in 1987. The standards have been regularly enhanced since and is supported (with varying degrees of conformance) by all mainstream commercial relational DBMSs.
- OQL is an object model language standard (from the Object Data Management Group). It has influenced the design of some of the newer query languages like JDOQL and EJB QL.
- XQuery is a standard XML query language implemented by XML database systems such as MarkLogic and eXist, by relational databases with XML capability such as Oracle and DB2, and also by in-memory XML processors such as Saxon.
- SQL/XML combines XQuery with SQL.

A database language may also incorporate features like:

- DBMS-specific Configuration and storage engine management
- Computations to modify query results, like counting, summing, averaging, sorting, grouping, and cross-referencing
- Constraint enforcement (e.g. in an automotive database, only allowing one engine type per car)
- Application programming interface version of the query language, for programmer convenience

Performance, security, and availability

Because of the critical importance of database technology to the smooth running of an enterprise, database systems include complex mechanisms to deliver the required performance, security, and availability, and allow database administrators to control the use of these features.

Storage

Database storage is the container of the physical materialization of a database. It comprises the *internal* (physical) *level* in the database architecture. It also contains all the information needed (e.g., metadata, "data about the data", and internal data structures) to reconstruct the *conceptual level* and *external level* from the internal level when needed. Putting data into permanent storage is generally the responsibility of the database engine a.k.a. "storage engine". Though typically accessed by a DBMS through the underlying operating system (and often utilizing the operating systems' file systems as intermediates for storage layout), storage properties and configuration setting are extremely important for the efficient operation of the DBMS, and thus are closely maintained by database administrators. A DBMS, while in operation, always has its database residing in several types of storage (e.g., memory and external storage). The database data and the additional needed information, possibly in very large amounts, are coded into bits. Data typically reside in the storage in structures that look completely different from the way the data look in the conceptual and external levels, but in ways that attempt to optimize (the best possible) these levels' reconstruction when needed by users and programs, as well as for computing additional types of needed information from the data (e.g., when querying the database).

Some DBMSs support specifying which character encoding was used to store data, so multiple encodings can be used in the same database.

Various low-level database storage structures are used by the storage engine to serialize the data model so it can be written to the medium of choice. Techniques such as indexing may be used to improve performance. Conventional storage is row-oriented, but there are also column-oriented and correlation databases.

Materialized views

Often storage redundancy is employed to increase performance. A common example is storing *materialized views*, which consist of frequently needed *external views* or query results. Storing such views saves the expensive computing of them each time they are needed. The downsides of materialized views are the overhead incurred when updating them to keep them synchronized with their original updated database data, and the cost of storage redundancy.

Replication

Occasionally a database employs storage redundancy by database objects replication (with one or more copies) to increase data availability (both to improve performance of simultaneous multiple end-user accesses to a same database object, and to provide resiliency in a case of partial failure of a distributed database). Updates of a replicated object need to be synchronized across the object copies. In many cases the entire database is replicated.

Security

Database security deals with all various aspects of protecting the database content, its owners, and its users. It ranges from protection from intentional unauthorized database uses to unintentional database accesses by unauthorized entities (e.g., a person or a computer program).

Database access control deals with controlling who (a person or a certain computer program) is allowed to access what information in the database. The information may comprise specific database objects (e.g., record types, specific records, data structures), certain computations over certain objects (e.g., query types, or specific queries), or utilizing specific access paths to the former (e.g., using specific indexes or other data structures to access information). Database access controls are set by special authorized (by the database owner) personnel that uses dedicated protected security DBMS interfaces.

This may be managed directly on an individual basis, or by the assignment of individuals and privileges to groups, or (in the most elaborate models) through the assignment of individuals and groups to roles which are then granted entitlements. Data security prevents unauthorized users from viewing or updating the database. Using passwords, users are allowed access to the entire database or subsets of it called "subschemas". For example, an employee database can contain all the data about an individual employee, but one group of users may be authorized to view only payroll data, while others are allowed access to only work history and medical data. If the DBMS provides a way to interactively enter and update the database, as well as interrogate it, this capability allows for managing personal databases.

Data security in general deals with protecting specific chunks of data, both physically (i.e., from corruption, or destruction, or removal; e.g., see physical security), or the interpretation of them, or parts of them to meaningful information (e.g., by looking at the strings of bits that they comprise, concluding specific valid credit-card numbers; e.g., see data encryption).

Change and access logging records who accessed which attributes, what was changed, and when it was changed. Logging services allow for a forensic database audit later by keeping a record of access occurrences and changes. Sometimes application-level code is used to record changes rather than leaving this to the database. Monitoring can be set up to attempt to detect security breaches.

Transactions and concurrency

Database transactions can be used to introduce some level of fault tolerance and data integrity after recovery from a crash. A database transaction is a unit of work, typically encapsulating a number of operations over a database (e.g., reading a database object, writing, acquiring lock, etc.), an abstraction supported in database and also other systems. Each transaction has well defined boundaries in terms of which program/code executions are included in that transaction (determined by the transaction's programmer via special transaction commands).

The acronym ACID describes some ideal properties of a database transaction: Atomicity, Consistency, Isolation, and Durability.

Migration

See also section Database migration in article Data migration

A database built with one DBMS is not portable to another DBMS (i.e., the other DBMS cannot run it). However, in some situations it is desirable to move, migrate a database from one DBMS to another. The reasons are primarily economical (different DBMSs may have different total costs of ownership or TCOs), functional, and operational (different DBMSs may have different capabilities). The migration involves the database's transformation from one DBMS type to another. The transformation should maintain (if possible) the database related application (i.e., all related application programs) intact. Thus, the database's conceptual and external architectural levels should be maintained in the transformation. It may be desired that also some aspects of the architecture internal level are maintained. A complex or large database migration may be a complicated and costly (one-time) project by itself, which should be factored into the decision to migrate. This in spite of the fact that tools may exist to help migration between specific DBMSs. Typically a DBMS vendor provides tools to help importing databases from other popular DBMSs.

Building, maintaining, and tuning

After designing a database for an application, the next stage is building the database. Typically an appropriate general-purpose DBMS can be selected to be utilized for this purpose. A DBMS provides the needed user interfaces to be utilized by database administrators to define the needed application's data structures within the DBMS's respective data model. Other user interfaces are used to select needed DBMS parameters (like security related, storage allocation parameters, etc.).

When the database is ready (all its data structures and other needed components are defined) it is typically populated with initial application's data (database initialization, which is typically a distinct project; in many cases using specialized DBMS interfaces that support bulk insertion) before making it operational. In some cases the database becomes operational while empty of application data, and data is accumulated during its operation.

After the database is created, initialised and populated it needs to be maintained. Various database parameters may need changing and the database may need to be tuned (tuning) for better performance; application's data structures may be changed or added, new related application programs may be written to add to the application's functionality, etc. Databases are often confused with spreadsheets such as Microsoft Excel (Microsoft Access is a database management system, Excel is a spreadsheet program). Both can be used to store information, however a database is more efficient and flexible at storing large amounts of data. Below is a simple comparison of spreadsheets and databases.

Spreadsheet strengths	Spreadsheet Weaknesses
Very simple data storage	Data integrity problems, including inaccurate, inconsistent and out of date data and formulas.
Relatively easy to use	Difficult to validate data e.g. an incorrect formula
Require less planning	

Database strengths	Database Weaknesses
Methods for keeping data up to date and consistent	Require more planning and designing
Data is of higher quality than data stored in spreadsheets	Harder to change structure once database is built
Good for storing and organizing information.	Requires more technical knowledge to administrate

Backup and restore

Sometimes it is desired to bring a database back to a previous state (for many reasons, e.g., cases when the database is found corrupted due to a software error, or if it has been updated with erroneous data). To achieve this a **backup** operation is done occasionally or continuously, where each desired database state (i.e., the values of its data and their embedding in database's data structures) is kept within dedicated backup files (many techniques exist to do this effectively). When this state is needed, i.e., when it is decided by a database administrator to bring the database back to this state (e.g., by specifying this state by a desired point in time when the database was in this state), these files are utilized to **restore** that state.

Other

Other DBMS features might include:

- Database logs
- Graphics component for producing graphs and charts, especially in a data warehouse system
- **Query optimizer –** Performs query optimization on every query to choose for it the most efficient *query plan* (a partial order (tree) of operations) to be executed to compute the query result. May be specific to a particular storage engine.
- Tools or hooks for database design, application programming, application program maintenance, database performance analysis and monitoring, database configuration monitoring, DBMS hardware configuration (a DBMS and related database may span computers, networks, and storage units) and related database mapping (especially for a distributed DBMS), storage allocation and database layout monitoring, storage migration, etc.

Database management system

A **database** is an organized collection of data. The data are typically organized to model relevant aspects of reality in a way that supports processes requiring this information. For example, modeling the availability of rooms in hotels in a way that supports finding a hotel with vacancies.

Database management systems (**DBMS**s) are specially designed software applications that interact with the user, other applications, and the database itself to capture and analyze data. A general-purpose DBMS is a software system designed to allow the definition, creation, querying, update, and administration of databases. Well-known DBMSs include MySQL, MariaDB, PostgreSQL, SQLite, Microsoft SQL Server, Oracle, SAP HANA, dBASE, FoxPro, IBM DB2, LibreOffice Base and FileMaker Pro. A database is not generally portable across different DBMSs, but different DBMSs can interoperate by using standards such as SQL and ODBC or JDBC to allow a single application to work with more than one database.

Terminology and overview

Formally, "database" refers to the data themselves and supporting data structures. Databases are created to operate large quantities of information by inputting, storing, retrieving, and managing that information. Databases are set up so that one set of software programs provides all users with access to all the data.

A "database management system" (DBMS) is a suite of computer software providing the interface between users and a database or databases. Because they are so closely related, the term "database" when used casually often refers to both a DBMS and the data it manipulates.

Outside the world of professional information technology, the term *database* is sometimes used casually to refer to any collection of data (perhaps a spreadsheet, maybe even a card index). This article is concerned only with databases where the size and usage requirements necessitate use of a database management system.[1]

The interactions catered for by most existing DBMSs fall into four main groups:

- **Data definition –** Defining new data structures for a database, removing data structures from the database, modifying the structure of existing data.
- **Update –** Inserting, modifying, and deleting data.
- **Retrieval –** Obtaining information either for end-user queries and reports or for processing by applications.
- **Administration –** Registering and monitoring users, enforcing data security, monitoring performance, maintaining data integrity, dealing with concurrency control, and recovering information if the system fails.

A DBMS is responsible for maintaining the integrity and security of stored data, and for recovering information if the system fails.

Both a database and its DBMS conform to the principles of a particular database model.[2] "Database system" refers collectively to the database model, database management system, and database.[3]

Physically, database servers are dedicated computers that hold the actual databases and run only the DBMS and related software. Database servers are usually multiprocessor computers, with generous memory and RAID disk arrays used for stable storage. RAID is used for recovery of data if any of the disks fail. Hardware database accelerators, connected to one or more servers via a high-speed channel, are also used in large volume transaction processing environments. DBMSs are found at the heart of most database applications. DBMSs may be built around a custom multitasking kernel with built-in networking support, but modern DBMSs typically rely on a standard operating system to provide these functions. [*citation needed*] Since DBMSs comprise a significant economical market, computer and storage vendors often take into account DBMS requirements in their own development plans.[*citation needed*]

Databases and DBMSs can be categorized according to the database model(s) that they support (such as relational or XML), the type(s) of computer they run on (from a server cluster to a mobile phone), the query language(s) used to access the database (such as SQL or XQuery), and their internal engineering, which affects performance, scalability, resilience, and security.

Applications and roles

Most organizations in developed countries today depend on databases for their business operations. Increasingly, databases are not only used to support the internal operations of the organization, but also to underpin its online interactions with customers and suppliers (see Enterprise software). Databases are not used only to hold administrative information, but are often embedded within applications to hold more specialized data: for example engineering data or economic models. Examples of database applications include computerized library systems, flight reservation systems, and computerized parts inventory systems.

Client-server or transactional DBMSs are often complex to maintain high performance, availability and security when many users are querying and updating the database at the same time. Personal, desktop-based database systems tend to be less complex. For example, FileMaker and Microsoft Access come with built-in graphical user interfaces.

General-purpose and special-purpose DBMSs

A DBMS has evolved into a complex software system and its development typically requires thousands of person-years of development effort.[4] Some general-purpose DBMSs such as Adabas, Oracle and DB2 have been undergoing upgrades since the 1970s. General-purpose DBMSs aim to meet the needs of as many applications as possible, which adds to the complexity. However, the fact that their development cost can be spread over a large number of users means that they are often the most cost-effective approach. However, a general-purpose DBMS is not always the optimal solution: in some cases a general-purpose DBMS may introduce unnecessary overhead. Therefore, there are many examples of systems that use special-purpose databases. A common example is an email system: email systems are designed to optimize the handling of email messages, and do not need significant portions of a general-purpose DBMS functionality.

Many databases have application software that accesses the database on behalf of end-users, without exposing the DBMS interface directly. Application programmers may use a wire protocol directly, or more likely through an application programming interface. Database designers and database administrators interact with the DBMS through dedicated interfaces to build and maintain the applications' databases, and thus need some more knowledge and understanding about how DBMSs operate and the DBMSs' external interfaces and tuning parameters.

General-purpose databases are usually developed by one organization or community of programmers, while a different group builds the applications that use it. In many companies, specialized database administrators maintain databases, run reports, and may work on code that runs on the databases themselves (rather than in the client application).

History

Following the technology progress in the areas of processors, computer memory, computer storage and computer networks, the sizes, capabilities, and performance of databases and their respective DBMSs have grown in orders of magnitude. The development of database technology can be divided into three eras based on data model or structure: navigational,[5] SQL/relational, and post-relational.

The two main early navigational data models were the hierarchical model, epitomized by IBM's IMS system, and the CODASYL model (network model), implemented in a number of products such as IDMS.

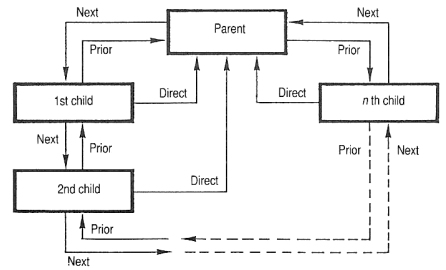
The relational model, first proposed in 1970 by Edgar F. Codd, departed from this tradition by insisting that applications should search for data by content, rather than by following links. The relational model employs sets of ledger-style tables, each used for a different type of entity. Only in the mid-1980s did computing hardware became powerful enough to allow the wide deployment of relational systems (DBMSs plus applications). By the early 1990s, however, relational systems dominated in all large-scale data processing applications, and as of 2014[6] they remain dominant except in niche areas. The dominant database language, standardised SQL for the relational model, has influenced database languages for other data models.[*citation needed*]

Object databases developed in the 1980s to overcome the inconvenience of object-relational impedance mismatch, which led to the coining of the term "post-relational" and also the development of hybrid object-relational databases.

The next generation of post-relational databases in the late 2000s became known as NoSQL databases, introducing fast key-value stores and document-oriented databases. A competing "next generation" known as NewSQL databases attempted new implementations that retained the relational/SQL model while aiming to match the high performance of NoSQL compared to commercially available relational DBMSs.

1960s, navigational DBMS

The introduction of the term *database* coincided with the availability of direct-access storage (disks and drums) from the mid-1960s onwards. The term represented a contrast with the tape-based systems of the past, allowing shared interactive use rather than daily batch processing. The Oxford English dictionary cites a 1962 report by the System Development Corporation of California as the first to use the term "data-base" in a specific technical sense.



A closed chain of records in a navigational database model (e.g. CODASYL), with ***next pointers***, ***prior pointers*** and ***direct pointers*** provided by keys in the various records.

The record set, basic structure of navigational (e.g. CODASYL) databse model. A set consists of one parent record (also called "the owner"), and n child records (also called members records)

Basic structure of navigational CODASYL database model.

As computers grew in speed and capability, a number of general-purpose database systems emerged; by the mid-1960s a number of such systems had come into commercial use. Interest in a standard began to grow, and Charles Bachman, author of one such product, the Integrated Data Store (IDS), founded the "Database Task Group" within CODASYL, the group responsible for the creation and standardization of COBOL. In 1971 theDatabase Task Group delivered their standard, which generally became known as the "CODASYL approach", and soon a number of commercial products based on this approach entered the market.

The CODASYL approach relied on the "manual" navigation of a linked data set which was formed into a large network. Applications could find records by one of three methods:

- use of a primary key (known as a CALC key, typically implemented by hashing)
- navigating relationships (called sets) from one record to another
- scanning all the records in a sequential order.

Later systems added B-Trees to provide alternate access paths. Many CODASYL databases also added a very straightforward query language. However, in the final tally, CODASYL was very complex and required significant training and effort to produce useful applications.

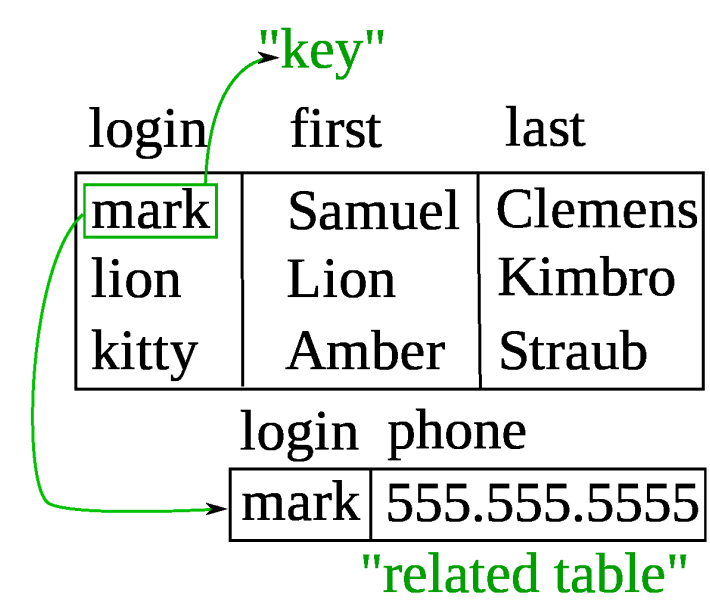
IBM also had their own DBMS system in 1968, known as *IMS*. IMS was a development of software written for the Apollo program on the System/360. IMS was generally similar in concept to CODASYL, but used a strict hierarchy for its model of data navigation instead of CODASYL's network model. Both concepts later became known as navigational databases due to the way data was accessed, and Bachman's 1973 Turing Award presentation was *The Programmer as Navigator*. IMS is classifiedWikipedia:Manual of Style/Words to watch#Unsupported attributions as a hierarchical database. IDMS and Cincom Systems' TOTAL database are classified as network databases. IMS remains in use as of 2014[6].

1970s, relational DBMS

Edgar Codd worked at IBM in San Jose, California, in one of their offshoot offices that was primarily involved in the development of hard disk systems. He was unhappy with the navigational model of the CODASYL approach, notably the lack of a "search" facility. In 1970, he wrote a number of papers that outlined a new approach to database construction that eventually culminated in the groundbreaking *A Relational Model of Data for Large Shared Data Banks*.[6]

In this paper, he described a new system for storing and working with large databases. Instead of records being stored in some sort of linked list of free-form records as in CODASYL, Codd's idea was to use a "table" of fixed-length records, with each table used for a different type of entity. A linked-list system would be very inefficient when storing "sparse" databases where some of the data for any one record could be left empty. The relational model solved this by splitting the data into a series of normalized tables (or *relations*), with optional elements being moved out of the main table to where they would take up room only if needed. Data may be freely inserted, deleted and edited in these tables, with the DBMS doing whatever maintenance needed to present a table view to the application/user.

The relational model also allowed the content of the database to evolve without constant rewriting of links and pointers. The relational part comes from entities referencing other entities in what is known as one-to-many relationship, like a traditional hierarchical model, and many-to-many relationship, like a navigational (network) model. Thus, a relational model can express both hierarchical and navigational models, as well as its native tabular model, allowing for pure or combined modeling in terms of these three models, as the application requires.



In the relational model, related records are linked together with a "key"

For instance, a common use of a database system is to track information about users, their name, login information, various addresses and phone numbers. In the navigational approach all of these data would be placed in a single record, and unused items would simply not be placed in the database. In the relational approach, the data would be *normalized* into a user table, an address table and a phone number table (for instance). Records would be created in these optional tables only if the address or phone numbers were actually provided.

Linking the information back together is the key to this system. In the relational model, some bit of information was used as a "key", uniquely defining a particular record. When information was being collected about a user, information stored in the optional tables would be found by searching for this key. For instance, if the login name of a user is unique, addresses and phone numbers for that user would be recorded with the login name as its key. This simple "re-linking" of related data back into a single collection is something that traditional computer languages are not designed for.

Just as the navigational approach would require programs to loop in order to collect records, the relational approach would require loops to collect information about any *one* record. Codd's solution to the necessary looping was a set-oriented language, a suggestion that would later spawn the ubiquitous SQL. Using a branch of mathematics known as tuple calculus, he demonstrated that such a system could support all the operations of normal databases (inserting, updating etc.) as well as providing a simple system for finding and returning *sets* of data in a single operation.

Codd's paper was picked up by two people at Berkeley, Eugene Wong and Michael Stonebraker. They started a project known as INGRES using funding that had already been allocated for a geographical database project and student programmers to produce code. Beginning in 1973, INGRES delivered its first test products which were generally ready for widespread use in 1979. INGRES was similar to System R in a number of ways, including the

use of a "language" for data access, known as QUEL. Over time, INGRES moved to the emerging SQL standard.

IBM itself did one test implementation of the relational model, PRTV, and a production one, Business System 12, both now discontinued. Honeywell wrote MRDS for Multics, and now there are two new implementations: Alphora Dataphor and Rel. Most other DBMS implementations usually called *relational* are actually SQL DBMSs.

In 1970, the University of Michigan began development of the MICRO Information Management System[7] based on D.L. Childs' Set-Theoretic Data model.[8][9][10] Micro was used to manage very large data sets by the US Department of Labor, the U.S. Environmental Protection Agency, and researchers from the University of Alberta, the University of Michigan, and Wayne State University. It ran on IBM mainframe computers using the Michigan Terminal System.[11] The system remained in production until 1998.

Integrated approach

In the 1970s and 1980s attempts were made to build database systems with integrated hardware and software. The underlying philosophy was that such integration would provide higher performance at lower cost. Examples were IBM System/38, the early offering of Teradata, and the Britton Lee, Inc. database machine.

Another approach to hardware support for database management was ICL's CAFS accelerator, a hardware disk controller with programmable search capabilities. In the long term, these efforts were generally unsuccessful because specialized database machines could not keep pace with the rapid development and progress of general-purpose computers. Thus most database systems nowadays are software systems running on general-purpose hardware, using general-purpose computer data storage. However this idea is still pursued for certain applications by some companies like Netezza and Oracle (Exadata).

Late 1970s, SQL DBMS

IBM started working on a prototype system loosely based on Codd's concepts as *System R* in the early 1970s. The first version was ready in 1974/5, and work then started on multi-table systems in which the data could be split so that all of the data for a record (some of which is optional) did not have to be stored in a single large "chunk". Subsequent multi-user versions were tested by customers in 1978 and 1979, by which time a standardized query language – SQL[*citation needed*] – had been added. Codd's ideas were establishing themselves as both workable and superior to CODASYL, pushing IBM to develop a true production version of System R, known as *SQL/DS*, and, later, *Database 2* (DB2).

Larry Ellison's Oracle started from a different chain, based on IBM's papers on System R, and beat IBM to market when the first version was released in 1978.[*citation needed*]

Stonebraker went on to apply the lessons from INGRES to develop a new database, Postgres, which is now known as PostgreSQL. PostgreSQL is often used for global mission critical applications (the .org and .info domain name registries use it as their primary data store, as do many large companies and financial institutions).

In Sweden, Codd's paper was also read and Mimer SQL was developed from the mid-1970s at Uppsala University. In 1984, this project was consolidated into an independent enterprise. In the early 1980s, Mimer introduced transaction handling for high robustness in applications, an idea that was subsequently implemented on most other DBMSs.

Another data model, the entity-relationship model, emerged in 1976 and gained popularity for database design as it emphasized a more familiar description than the earlier relational model. Later on, entity-relationship constructs were retrofitted as a data modeling construct for the relational model, and the difference between the two have become irrelevant.[*citation needed*]

1980s, on the desktop

The 1980s ushered in the age of desktop computing. The new computers empowered their users with spreadsheets like Lotus 1,2,3 and database software like dBASE. The dBASE product was lightweight and easy for any computer user to understand out of the box. C. Wayne Ratliff the creator of dBASE stated: “dBASE was different from programs like BASIC, C, FORTRAN, and COBOL in that a lot of the dirty work had already been done. The data manipulation is done by dBASE instead of by the user, so the user can concentrate on what he is doing, rather than having to mess with the dirty details of opening, reading, and closing files, and managing space allocation.“ [12] dBASE was one of the top selling software titles in the 1980s and early 1990s.

1980s, object-oriented

The 1980s, along with a rise in object oriented programming, saw a growth in how data in various databases were handled. Programmers and designers began to treat the data in their databases as objects. That is to say that if a person's data were in a database, that person's attributes, such as their address, phone number, and age, were now considered to belong to that person instead of being extraneous data. This allows for relations between data to be relations to objects and their attributes and not to individual fields.[13] The term "object-relational impedance mismatch" described the inconvenience of translating between programmed objects and database tables. Object databases and object-relational databases attempt to solve this problem by providing an object-oriented language (sometimes as extensions to SQL) that programmers can use as alternative to purely relational SQL. On the programming side, libraries known as object-relational mappings (ORMs) attempt to solve the same problem.

2000s, NoSQL and NewSQL

The next generation of post-relational databases in the 2000s became known as NoSQL databases, including fast key-value stores and document-oriented databases. XML databases are a type of structured document-oriented database that allows querying based on XML document attributes.

NoSQL databases are often very fast, do not require fixed table schemas, avoid join operations by storing denormalized data, and are designed to scale horizontally.

In recent years there was a high demand for massively distributed databases with high partition tolerance but according to the CAP theorem it is impossible for a distributed system to simultaneously provide consistency, availability and partition tolerance guarantees. A distributed system can satisfy any two of these guarantees at the same time, but not all three. For that reason many NoSQL databases are using what is called eventual consistency to provide both availability and partition tolerance guarantees with a maximum level of data consistency.

The most popular NoSQL systems include: MongoDB, Couchbase, Riak, memcached, Redis, CouchDB, Hazelcast, Apache Cassandra and HBase. Note that all are open-source software products.

A number of new relational databases continuing use of SQL but aiming for performance comparable to NoSQL are known as NewSQL.

Research

Database technology has been an active research topic since the 1960s, both in academia and in the research and development groups of companies (for example IBM Research). Research activity includes theory and development of prototypes. Notable research topics have included models, the atomic transaction concept and related concurrency control techniques, query languages and query optimization methods, RAID, and more.

The database research area has several dedicated academic journals (for example, ACM Transactions on Database Systems-TODS, Data and Knowledge Engineering-DKE) and annual conferences (e.g., ACM SIGMOD, ACM PODS, VLDB, IEEE ICDE).

Examples

One way to classify databases involves the type of their contents, for example: bibliographic, document-text, statistical, or multimedia objects. Another way is by their application area, for example: accounting, music compositions, movies, banking, manufacturing, or insurance. A third way is by some technical aspect, such as the database structure or interface type. This section lists a few of the adjectives used to characterize different kinds of databases.

- An in-memory database is a database that primarily resides in main memory, but is typically backed-up by non-volatile computer data storage. Main memory databases are faster than disk databases, and so are often used where response time is critical, such as in telecommunications network equipment.SAP HANA platform is a very hot topic for in-memory database. By May 2012, HANA was able to run on servers with 100TB main memory powered by IBM. The co founder of the company claimed that the system was big enough to run the 8 largest SAP customers.
- An active database includes an event-driven architecture which can respond to conditions both inside and outside the database. Possible uses include security monitoring, alerting, statistics gathering and authorization. Many databases provide active database features in the form of database triggers.
- A cloud database relies on cloud technology. Both the database and most of its DBMS reside remotely, "in the cloud", while its applications are both developed by programmers and later maintained and utilized by (application's) end-users through a web browser and Open APIs.
- Data warehouses archive data from operational databases and often from external sources such as market research firms. The warehouse becomes the central source of data for use by managers and other end-users who may not have access to operational data. For example, sales data might be aggregated to weekly totals and converted from internal product codes to use UPCs so that they can be compared with ACNielsen data. Some basic and essential components of data warehousing include retrieving, analyzing, and mining data, transforming, loading and managing data so as to make them available for further use.
- A deductive database combines logic programming with a relational database, for example by using the Datalog language.
- A distributed database is one in which both the data and the DBMS span multiple computers.
- A document-oriented database is designed for storing, retrieving, and managing document-oriented, or semi structured data, information. Document-oriented databases are one of the main categories of NoSQL databases.
- An embedded database system is a DBMS which is tightly integrated with an application software that requires access to stored data in such a way that the DBMS is hidden from the application's end-users and requires little or no ongoing maintenance.[14]
- **End-user databases** consist of data developed by individual end-users. Examples of these are collections of documents, spreadsheets, presentations, multimedia, and other files. Several products exist to support such databases. Some of them are much simpler than full fledged DBMSs, with more elementary DBMS functionality.

- A federated database system comprises several distinct databases, each with its own DBMS. It is handled as a single database by a federated database management system (FDBMS), which transparently integrates multiple autonomous DBMSs, possibly of different types (in which case it would also be a heterogeneous database system), and provides them with an integrated conceptual view.
- Sometimes the term *multi-database* is used as a synonym to federated database, though it may refer to a less integrated (e.g., without an FDBMS and a managed integrated schema) group of databases that cooperate in a single application. In this case typically middleware is used for distribution, which typically includes an atomic commit protocol (ACP), e.g., the two-phase commit protocol, to allow distributed (global) transactions across the participating databases.
- A graph database is a kind of NoSQL database that uses graph structures with nodes, edges, and properties to represent and store information. General graph databases that can store any graph are distinct from specialized graph databases such as triplestores and network databases.
- In a hypertext or hypermedia database, any word or a piece of text representing an object, e.g., another piece of text, an article, a picture, or a film, can be hyperlinked to that object. Hypertext databases are particularly useful for organizing large amounts of disparate information. For example, they are useful for organizing online encyclopedias, where users can conveniently jump around the text. The World Wide Web is thus a large distributed hypertext database.
- A knowledge base (abbreviated **KB**, **kb** or Δ[15]) is a special kind of database for knowledge management, providing the means for the computerized collection, organization, and retrieval of knowledge. Also a collection of data representing problems with their solutions and related experiences.
- A mobile database can be carried on or synchronized from a mobile computing device.
- Operational databases store detailed data about the operations of an organization. They typically process relatively high volumes of updates using transactions. Examples include customer databases that record contact, credit, and demographic information about a business' customers, personnel databases that hold information such as salary, benefits, skills data about employees, enterprise resource planning systems that record details about product components, parts inventory, and financial databases that keep track of the organization's money, accounting and financial dealings.
- A parallel database seeks to improve performance through parallelization for tasks such as loading data, building indexes and evaluating queries.

  The major parallel DBMS architectures which are induced by the underlying hardware architecture are:

  - **Shared memory architecture**, where multiple processors share the main memory space, as well as other data storage.
  - **Shared disk architecture**, where each processing unit (typically consisting of multiple processors) has its own main memory, but all units share the other storage.
  - **Shared nothing architecture**, where each processing unit has its own main memory and other storage.
- Probabilistic databases employ fuzzy logic to draw inferences from imprecise data.
- Real-time databases process transactions fast enough for the result to come back and be acted on right away.
- A spatial database can store the data with multidimensional features. The queries on such data include location based queries, like "Where is the closest hotel in my area?".
- A temporal database has built-in time aspects, for example a temporal data model and a temporal version of SQL. More specifically the temporal aspects usually include valid-time and transaction-time.
- A terminology-oriented database builds upon an object-oriented database, often customized for a specific field.
- An unstructured data database is intended to store in a manageable and protected way diverse objects that do not fit naturally and conveniently in common databases. It may include email messages, documents, journals,

multimedia objects, etc. The name may be misleading since some objects can be highly structured. However, the entire possible object collection does not fit into a predefined structured framework. Most established DBMSs now support unstructured data in various ways, and new dedicated DBMSs are emerging.

Design and modeling

The first task of a database designer is to produce a conceptual data model that reflects the structure of the information to be held in the database. A common approach to this is to develop an entity-relationship model, often with the aid of drawing tools. Another popular approach is the Unified Modeling Language. A successful data model will accurately reflect the possible state of the external world being modeled: for example, if people can have more than one phone number, it will allow this information to be captured. Designing a good conceptual data model requires a good understanding of the application domain; it typically involves asking deep questions about the things of interest to an organisation, like "can a customer also be a supplier?", or "if a product is sold with two different forms of packaging, are those the same product or different products?", or "if a plane flies from New York to Dubai via Frankfurt, is that one flight or two (or maybe even three)?". The answers to these questions establish definitions of the terminology used for entities (customers, products, flights, flight segments) and their relationships and attributes.

Producing the conceptual data model sometimes involves input from business processes, or the analysis of workflow in the organization. This can help to establish what information is needed in the database, and what can be left out. For example, it can help when deciding whether the database needs to hold historic data as well as current data.

Having produced a conceptual data model that users are happy with, the next stage is to translate this into a schema that implements the relevant data structures within the database. This process is often called logical database design, and the output is a logical data model expressed in the form of a schema. Whereas the conceptual data model is (in theory at least) independent of the choice of database technology, the logical data model will be expressed in terms of a particular database model supported by the chosen DBMS. (The terms *data model* and *database model* are often used interchangeably, but in this article we use *data model* for the design of a specific database, and *database model* for the modelling notation used to express that design.)

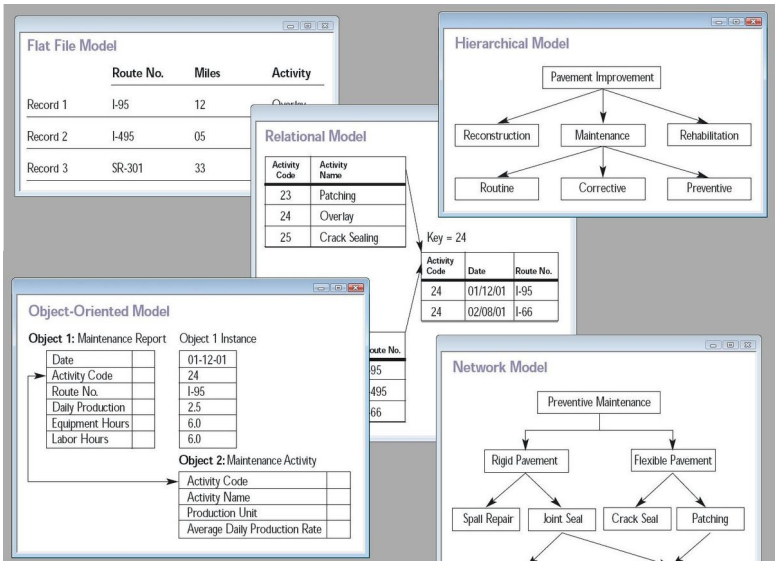
The most popular database model for general-purpose databases is the relational model, or more precisely, the relational model as represented by the SQL language. The process of creating a logical database design using this model uses a methodical approach known as normalization. The goal of normalization is to ensure that each elementary "fact" is only recorded in one place, so that insertions, updates, and deletions automatically maintain consistency.

The final stage of database design is to make the decisions that affect performance, scalability, recovery, security, and the like. This is often called *physical database design*. A key goal during this stage is data independence, meaning that the decisions made for performance optimization purposes should be invisible to end-users and applications. Physical design is driven mainly by performance requirements, and requires a good knowledge of the expected workload and access patterns, and a deep understanding of the features offered by the chosen DBMS.

Another aspect of physical database design is security. It involves both defining access control to database objects as well as defining security levels and methods for the data itself.

Models

A database model is a type of data model that determines the logical structure of a database and fundamentally determines in which manner data can be stored, organized, and manipulated. The most popular example of a database model is the relational model (or the SQL approximation of relational), which uses a table-based format.



Collage of five types of database models.

Common logical data models for databases include:

- Hierarchical database model
- Network model
- Relational model
- Entity–relationship model
  - Enhanced entity–relationship model
- Object model
- Document model
- Entity–attribute–value model
- Star schema

An object-relational database combines the two related structures.

Physical data models include:

- Inverted index
- Flat file

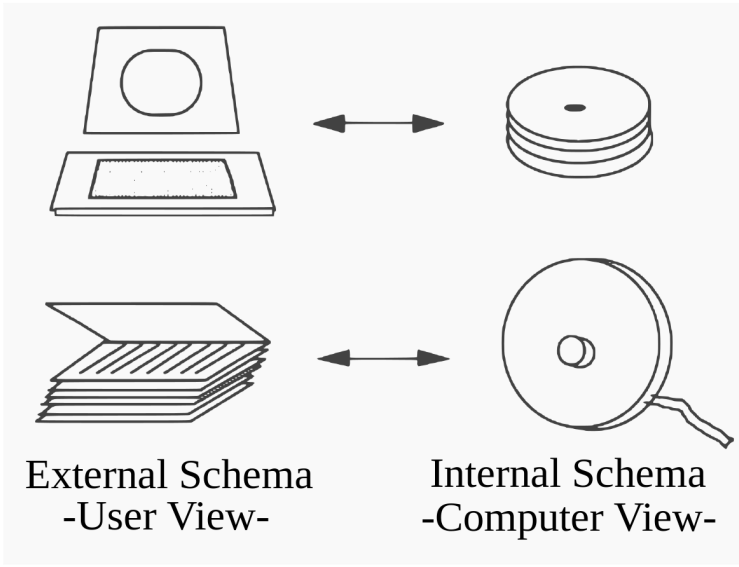
Other models include:

- Associative model
- Multidimensional model
- Multivalue model
- Semantic model
- XML database
- Named graph

External, conceptual, and internal views

A database management system provides three views of the database data:

- The **external level** defines how each group of end-users sees the organization of data in the database. A single database can have any number of views at the external level.
- The **conceptual level** unifies the various external views into a compatible global view. It provides the synthesis of all the external views. It is out of the scope of the various database end-users, and is rather of interest to database application developers and database administrators.
- The **internal level** (or *physical level*) is the internal organization of data inside a DBMS (see Implementation section below). It is concerned with cost, performance, scalability and other operational matters. It deals with storage layout of the data, using storage structures such as indexes to enhance performance. Occasionally it stores data of individual views (materialized views), computed from generic data, if performance justification exists for such redundancy. It balances all the external views' performance requirements, possibly conflicting, in an attempt to optimize overall performance across all activities.



Traditional view of data[16]

While there is typically only one conceptual (or logical) and physical (or internal) view of the data, there can be any number of different external views. This allows users to see database information in a more business-related way rather than from a technical, processing viewpoint. For example, a financial department of a company needs the payment details of all employees as part of the company's expenses, but does not need details about employees that are the interest of the human resources department. Thus different departments need different *views* of the company's database.

The three-level database architecture relates to the concept of *data independence* which was one of the major initial driving forces of the relational model. The idea is that changes made at a certain level do not affect the view at a higher level. For example, changes in the internal level do not affect application programs written using conceptual level interfaces, which reduces the impact of making physical changes to improve performance.

The conceptual view provides a level of indirection between internal and external. On one hand it provides a common view of the database, independent of different external view structures, and on the other hand it abstracts away details of how the data is stored or managed (internal level). In principle every level, and even every external view, can be presented by a different data model. In practice usually a given DBMS uses the same data model for both the external and the conceptual levels (e.g., relational model). The internal level, which is hidden inside the DBMS and depends on its implementation (see Implementation section below), requires a different level of detail and uses its own types of data structure types.

Separating the *external*, *conceptual* and *internal* levels was a major feature of the relational database model implementations that dominate 21st century databases.

Languages

Database languages are special-purpose languages, which do one or more of the following:

- Data definition language – defines data types and the relationships among them
- Data manipulation language – performs tasks such as inserting, updating, or deleting data occurrences
- Query language – allows searching for information and computing derived information

Database languages are specific to a particular data model. Notable examples include:

- SQL combines the roles of data definition, data manipulation, and query in a single language. It was one of the first commercial languages for the relational model, although it departs in some respects from the relational model as described by Codd (for example, the rows and columns of a table can be ordered). SQL became a standard of the American National Standards Institute (ANSI) in 1986, and of the International Organization for Standardization (ISO) in 1987. The standards have been regularly enhanced since and is supported (with varying degrees of conformance) by all mainstream commercial relational DBMSs.
- OQL is an object model language standard (from the Object Data Management Group). It has influenced the design of some of the newer query languages like JDOQL and EJB QL.
- XQuery is a standard XML query language implemented by XML database systems such as MarkLogic and eXist, by relational databases with XML capability such as Oracle and DB2, and also by in-memory XML processors such as Saxon.
- SQL/XML combines XQuery with SQL.

A database language may also incorporate features like:

- DBMS-specific Configuration and storage engine management
- Computations to modify query results, like counting, summing, averaging, sorting, grouping, and cross-referencing
- Constraint enforcement (e.g. in an automotive database, only allowing one engine type per car)
- Application programming interface version of the query language, for programmer convenience

Performance, security, and availability

Because of the critical importance of database technology to the smooth running of an enterprise, database systems include complex mechanisms to deliver the required performance, security, and availability, and allow database administrators to control the use of these features.

Storage

Database storage is the container of the physical materialization of a database. It comprises the *internal* (physical) *level* in the database architecture. It also contains all the information needed (e.g., metadata, "data about the data", and internal data structures) to reconstruct the *conceptual level* and *external level* from the internal level when needed. Putting data into permanent storage is generally the responsibility of the database engine a.k.a. "storage engine". Though typically accessed by a DBMS through the underlying operating system (and often utilizing the operating systems' file systems as intermediates for storage layout), storage properties and configuration setting are extremely important for the efficient operation of the DBMS, and thus are closely maintained by database administrators. A DBMS, while in operation, always has its database residing in several types of storage (e.g., memory and external storage). The database data and the additional needed information, possibly in very large amounts, are coded into bits. Data typically reside in the storage in structures that look completely different from the way the data look in the conceptual and external levels, but in ways that attempt to optimize (the best possible) these levels' reconstruction when needed by users and programs, as well as for computing additional types of needed information from the data (e.g., when querying the database).

Some DBMSs support specifying which character encoding was used to store data, so multiple encodings can be used in the same database.

Various low-level database storage structures are used by the storage engine to serialize the data model so it can be written to the medium of choice. Techniques such as indexing may be used to improve performance. Conventional storage is row-oriented, but there are also column-oriented and correlation databases.

Materialized views

Often storage redundancy is employed to increase performance. A common example is storing *materialized views*, which consist of frequently needed *external views* or query results. Storing such views saves the expensive computing of them each time they are needed. The downsides of materialized views are the overhead incurred when updating them to keep them synchronized with their original updated database data, and the cost of storage redundancy.

Replication

Occasionally a database employs storage redundancy by database objects replication (with one or more copies) to increase data availability (both to improve performance of simultaneous multiple end-user accesses to a same database object, and to provide resiliency in a case of partial failure of a distributed database). Updates of a replicated object need to be synchronized across the object copies. In many cases the entire database is replicated.

Security

Database security deals with all various aspects of protecting the database content, its owners, and its users. It ranges from protection from intentional unauthorized database uses to unintentional database accesses by unauthorized entities (e.g., a person or a computer program).

Database access control deals with controlling who (a person or a certain computer program) is allowed to access what information in the database. The information may comprise specific database objects (e.g., record types, specific records, data structures), certain computations over certain objects (e.g., query types, or specific queries), or utilizing specific access paths to the former (e.g., using specific indexes or other data structures to access information). Database access controls are set by special authorized (by the database owner) personnel that uses dedicated protected security DBMS interfaces.

This may be managed directly on an individual basis, or by the assignment of individuals and privileges to groups, or (in the most elaborate models) through the assignment of individuals and groups to roles which are then granted entitlements. Data security prevents unauthorized users from viewing or updating the database. Using passwords, users are allowed access to the entire database or subsets of it called "subschemas". For example, an employee database can contain all the data about an individual employee, but one group of users may be authorized to view only payroll data, while others are allowed access to only work history and medical data. If the DBMS provides a way to interactively enter and update the database, as well as interrogate it, this capability allows for managing personal databases.

Data security in general deals with protecting specific chunks of data, both physically (i.e., from corruption, or destruction, or removal; e.g., see physical security), or the interpretation of them, or parts of them to meaningful information (e.g., by looking at the strings of bits that they comprise, concluding specific valid credit-card numbers; e.g., see data encryption).

Change and access logging records who accessed which attributes, what was changed, and when it was changed. Logging services allow for a forensic database audit later by keeping a record of access occurrences and changes. Sometimes application-level code is used to record changes rather than leaving this to the database. Monitoring can be set up to attempt to detect security breaches.

Transactions and concurrency

Database transactions can be used to introduce some level of fault tolerance and data integrity after recovery from a crash. A database transaction is a unit of work, typically encapsulating a number of operations over a database (e.g., reading a database object, writing, acquiring lock, etc.), an abstraction supported in database and also other systems. Each transaction has well defined boundaries in terms of which program/code executions are included in that transaction (determined by the transaction's programmer via special transaction commands).

The acronym ACID describes some ideal properties of a database transaction: Atomicity, Consistency, Isolation, and Durability.

Migration

See also section Database migration in article Data migration

A database built with one DBMS is not portable to another DBMS (i.e., the other DBMS cannot run it). However, in some situations it is desirable to move, migrate a database from one DBMS to another. The reasons are primarily economical (different DBMSs may have different total costs of ownership or TCOs), functional, and operational (different DBMSs may have different capabilities). The migration involves the database's transformation from one DBMS type to another. The transformation should maintain (if possible) the database related application (i.e., all related application programs) intact. Thus, the database's conceptual and external architectural levels should be maintained in the transformation. It may be desired that also some aspects of the architecture internal level are maintained. A complex or large database migration may be a complicated and costly (one-time) project by itself, which should be factored into the decision to migrate. This in spite of the fact that tools may exist to help migration between specific DBMSs. Typically a DBMS vendor provides tools to help importing databases from other popular DBMSs.

Building, maintaining, and tuning

After designing a database for an application, the next stage is building the database. Typically an appropriate general-purpose DBMS can be selected to be utilized for this purpose. A DBMS provides the needed user interfaces to be utilized by database administrators to define the needed application's data structures within the DBMS's respective data model. Other user interfaces are used to select needed DBMS parameters (like security related, storage allocation parameters, etc.).

When the database is ready (all its data structures and other needed components are defined) it is typically populated with initial application's data (database initialization, which is typically a distinct project; in many cases using specialized DBMS interfaces that support bulk insertion) before making it operational. In some cases the database becomes operational while empty of application data, and data is accumulated during its operation.

After the database is created, initialised and populated it needs to be maintained. Various database parameters may need changing and the database may need to be tuned (tuning) for better performance; application's data structures may be changed or added, new related application programs may be written to add to the application's functionality, etc. Databases are often confused with spreadsheets such as Microsoft Excel (Microsoft Access is a database management system, Excel is a spreadsheet program). Both can be used to store information, however a database is more efficient and flexible at storing large amounts of data. Below is a simple comparison of spreadsheets and databases.

Spreadsheet strengths	Spreadsheet Weaknesses
Very simple data storage	Data integrity problems, including inaccurate, inconsistent and out of date data and formulas.
Relatively easy to use	Difficult to validate data e.g. an incorrect formula
Require less planning	

Database strengths	Database Weaknesses
Methods for keeping data up to date and consistent	Require more planning and designing
Data is of higher quality than data stored in spreadsheets	Harder to change structure once database is built
Good for storing and organizing information.	Requires more technical knowledge to administrate

Backup and restore

Sometimes it is desired to bring a database back to a previous state (for many reasons, e.g., cases when the database is found corrupted due to a software error, or if it has been updated with erroneous data). To achieve this a **backup** operation is done occasionally or continuously, where each desired database state (i.e., the values of its data and their embedding in database's data structures) is kept within dedicated backup files (many techniques exist to do this effectively). When this state is needed, i.e., when it is decided by a database administrator to bring the database back to this state (e.g., by specifying this state by a desired point in time when the database was in this state), these files are utilized to **restore** that state.

Other

Other DBMS features might include:

- Database logs
- Graphics component for producing graphs and charts, especially in a data warehouse system
- **Query optimizer –** Performs query optimization on every query to choose for it the most efficient *query plan* (a partial order (tree) of operations) to be executed to compute the query result. May be specific to a particular storage engine.
- Tools or hooks for database design, application programming, application program maintenance, database performance analysis and monitoring, database configuration monitoring, DBMS hardware configuration (a DBMS and related database may span computers, networks, and storage units) and related database mapping (especially for a distributed DBMS), storage allocation and database layout monitoring, storage migration, etc.

Types of DBMS

There are four main types of database management systems (DBMS) and these are based upon their management of database structures. In other words, the **types of DBMS** are entirely dependent upon how the database is structured by that particular DBMS.

Hierarchical DBMS

A DBMS is said to be hierarchical if the relationships among data in the database are established in such a way that one data item is present as the subordinate of another one or a sub unit. Here subordinate means that items have "parent-child" relationships among them. Direct relationships exist between any two records that are stored consecutively. The data structure "tree" is followed by the DBMS to structure the database. No backward movement is possible/allowed in the hierarchical database.

The hierarchical data model was developed by IBM in 1968 and introduced in information management systems. This model is like a structure of a tree with the records forming the nodes and fields forming the branches of the tree. In the hierarchical model, records are linked in the form of an organization chart. A tree structure may establish one-to-many relationship.....

Network DBMS

A DBMS is said to be a Network DBMS if the relationships among data in the database are of type many-to-many. The relationships among many-to-many appears in the form of a network. Thus the structure of a network database is extremely complicated because of these many-to-many relationships in which one record can be used as a key of the entire database. A network database is structured in the form of a graph that is also a data structure. Though the structure of such a DBMS is highly complicated however it has two basic elements i.e. records and sets to designate many-to-many relationships. Mainly high-level languages such as Pascal, C++, COBOL and FORTRAN etc. were used to implement the records and set structures.

Relational DBMS

A DBMS is said to be a Relational DBMS or RDBMS if the database relationships are treated in the form of a table. There are three keys on relational DBMS: relation, domain and attributes. A network means it contains a fundamental constructs sets or records sets contains one to many relationship,records contains fields statical table that is composed of rows and columns is used to organize the database and its structure and is actually a two dimension array in the computer memory. A number of RDBMSs are available, some popular examples are Oracle, Sybase, Ingress, Informix, Microsoft SQL Server, and Microsoft Access.

Object-oriented DBMS

Able to handle many new data types, including graphics, photographs, audio, and video, object-oriented databases represent a significant advance over their other database cousins. Hierarchical and network databases are all designed to handle structured data; that is, data that fits nicely into fields, rows, and columns. They are useful for handling small snippets of information such as names, addresses, zip codes, product numbers, and any kind of statistic or number you can think of. On the other hand, an object-oriented database can be used to store data from a variety of media sources, such as photographs and text, and produce work, as output, in a multimedia format.[1]

- Object-oriented databases use small, reusable chunks of software called objects. The objects themselves are stored in the object-oriented database. Each object consists of two elements: 1) a piece of data (e.g., sound, video, text, or graphics), and 2) the instructions, or software programs called methods, for what to do with the data. Part two

of this definition requires a little more explanation. The instructions contained within the object are used to do something with the data in the object. For example, test scores would be within the object as would the instructions for calculating average test score.

- Object-oriented databases have two disadvantages. First, they are more costly to develop. Second, most organizations are reluctant to abandon or convert from those databases that they have already invested money in developing and implementing. However, the benefits to object-oriented databases are compelling. The ability to mix and match reusable objects provides incredible multimedia capability. Healthcare organizations, for example, can store, track, and recall CAT scans, X-rays, electrocardiograms and many other forms of crucial data.

Data store

A **data store** is a data repository of a set of integrated objects. These objects are modeled using classes defined in database schemas. Data store includes not only data repositories like databases, it is a more general concept that includes also flat files that can store data.

Some data stores do represent data in only one schema, while other data stores use several schemas for this task. An example are RDBMS-based data stores like MySQL or PostgreSQL.

Types

Data stores can be of different types, including:

- Paper files
- Simple files like a spreadsheet
- File systems
- Databases
  - Relational databases are the most common type of database in the 2000s. Examples include MySQL, PostgreSQL, Microsoft SQL Server, and Oracle Database.
  - Object-oriented databases, like Caché or ConceptBase. They can save objects of an object-oriented design.
- Distributed data stores, like Apache Cassandra, Druid (open-source data store) or Dynamo
- Directory services
- VMware uses "datastore" to refer to a file that stores a virtual machine[1]

[1] http://pubs.vmware.com/vi3/sdk/ReferenceGuide/vim.Datastore.html

Technical Information Project

The **Technical Information Project** (TIP) was an early database project. TIP included over 25,000 records and was used to explore bibliographic coupling between works.

Developed by Meyer Mike Kessler at MIT around 1964, some of the innovations in TIP included the use of wild cards, and boolean searching.

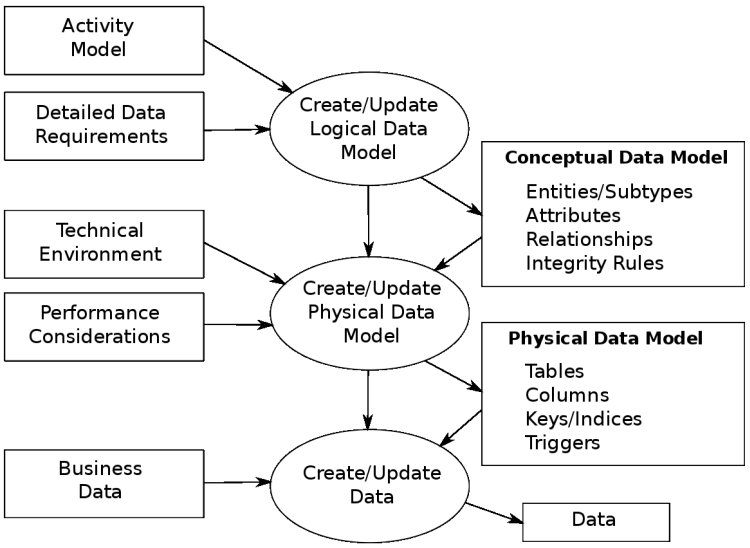
Introduction to Data Modeling

Data modeling

Data modeling in software engineering is the process of creating a data model for an information system by applying formal data modeling techniques.



The data modeling process. The figure illustrates the way data models are developed and used today. A conceptual data model is developed based on the data requirements for the application that is being developed, perhaps in the context of an activity model. The data model will normally consist of entity types, attributes, relationships, integrity rules, and the definitions of those objects. This is then used as the start point for interface or database design.

Overview

Data modeling is a process used to define and analyze data requirements needed to support the business processes within the scope of corresponding information systems in organizations. Therefore, the process of data modeling involves professional data modelers working closely with business stakeholders, as well as potential users of the information system.

There are three different types of data models produced while progressing from requirements to the actual database to be used for the information system.[1] The data requirements are initially recorded as a conceptual data model which is essentially a set of technology independent specifications about the data and is used to discuss initial requirements with the business stakeholders. The conceptual model is then translated into a logical data model, which documents structures of the data that can be implemented in databases. Implementation of one conceptual data model may require multiple logical data models. The last step in data modeling is transforming the logical data model to a physical data model that organizes the data into tables, and accounts for access, performance and storage details. Data modeling defines not just data elements, but also their structures and the relationships between them.[2]

Data modeling techniques and methodologies are used to model data in a standard, consistent, predictable manner in order to manage it as a resource. The use of data modeling standards is strongly recommended for all projects requiring a standard means of defining and analyzing data within an organization, e.g., using data modeling:

- to assist business analysts, programmers, testers, manual writers, IT package selectors, engineers, managers, related organizations and clients to understand and use an agreed semi-formal model the concepts of the organization and how they relate to one another
- to manage data as a resource
- for the integration of information systems
- for designing databases/data warehouses (aka data repositories)

Data modeling may be performed during various types of projects and in multiple phases of projects. Data models are progressive; there is no such thing as the final data model for a business or application. Instead a data model should be considered a living document that will change in response to a changing business. The data models should ideally be stored in a repository so that they can be retrieved, expanded, and edited over time. Whitten et al. (2004) determined two types of data modeling:

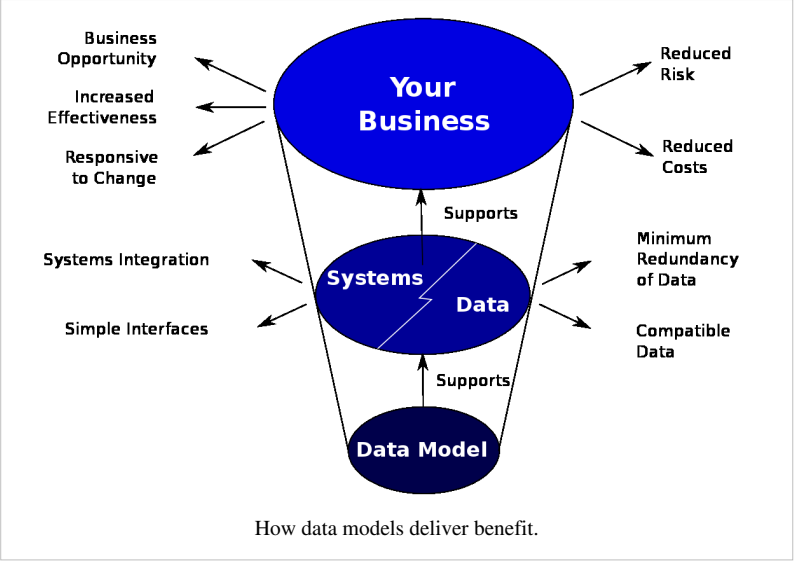
- Strategic data modeling: This is part of the creation of an information systems strategy, which defines an overall vision and architecture for information systems is defined. Information engineering is a methodology that embraces this approach.
- Data modeling during systems analysis: In systems analysis logical data models are created as part of the development of new databases.

Data modeling is also used as a technique for detailing business requirements for specific databases. It is sometimes called *database modeling* because a data model is eventually implemented in a database.[]

Data modeling topics

Data models

Data models provide a structure for data used within information systems by providing specific definition and format. If a data model is used consistently across systems then compatibility of data can be achieved. If the same data structures are used to store and access data then different applications can share data seamlessly. The results of this are indicated in the diagram. However, systems and interfaces often cost more than they should, to build, operate, and maintain. They may also constrain the business rather than support it. This may occur when the quality of the data models implemented in systems and interfaces is poor.[]



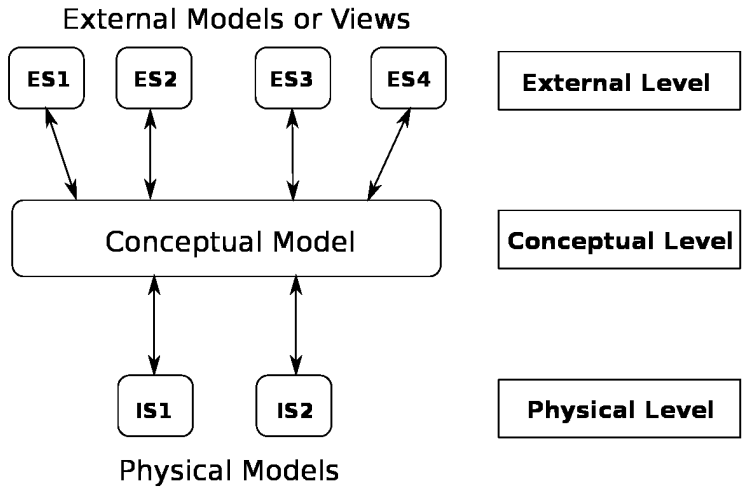
How data models deliver benefit.

- Business rules, specific to how things are done in a particular place, are often fixed in the structure of a data model. This means that small changes in the way business is conducted lead to large changes in computer systems and interfaces. So, business rules need to be implemented in a flexible way that does not result in complicated dependencies, rather the data model should be flexible enough so that changes in the business can be implemented within the data model in a relatively quick and efficient way.
- Entity types are often not identified, or are identified incorrectly. This can lead to replication of data, data structure and functionality, together with the attendant costs of that duplication in development and maintenance.Therefore, data definitions should be made as explicit and easy to understand as possible to minimize misinterpretation and duplication.
- Data models for different systems are arbitrarily different. The result of this is that complex interfaces are required between systems that share data. These interfaces can account for between 25-70% of the cost of current systems. Required interfaces should be considered inherently while designing a data model, as a data model on its own would not be usable without interfaces within different systems.

- Data cannot be shared electronically with customers and suppliers, because the structure and meaning of data has not been standardised. To obtain optimal value from an implemented data model, it is very important to define standards that will ensure that data models will both meet business needs and be consistent.

Conceptual, logical and physical schemas

In 1975 ANSI described three kinds of data-model *instance*:[3]



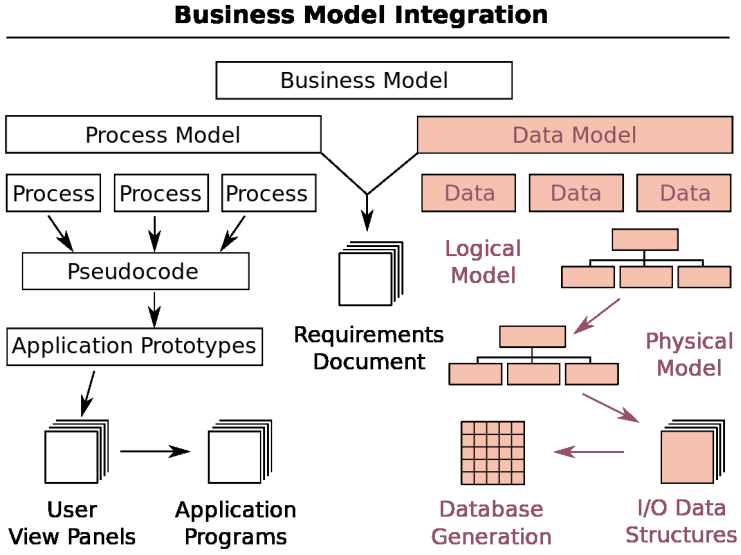
The ANSI/SPARC three level architecture. This shows that a data model can be an external model (or view), a conceptual model, or a physical model. This is not the only way to look at data models, but it is a useful way, particularly when comparing models.

- Conceptual schema: describes the semantics of a domain (the scope of the model). For example, it may be a model of the interest area of an organization or of an industry. This consists of entity classes, representing kinds of things of significance in the domain, and relationships assertions about associations between pairs of entity classes. A conceptual schema specifies the kinds of facts or propositions that can be expressed using the model. In that sense, it defines the allowed expressions in an artificial "language" with a scope that is limited by the scope of the model. Simply described, a conceptual schema is the first step in organizing the data requirements.
- Logical schema: describes the structure of some domain of information. This consists of descriptions of (for example) tables, columns, object-oriented classes, and XML tags. The logical schema and conceptual schema are sometimes implemented as one and the same.
- Physical schema: describes the physical means used to store data. This is concerned with partitions, CPUs, tablespaces, and the like.

According to ANSI, this approach allows the three perspectives to be relatively independent of each other. Storage technology can change without affecting either the logical or the conceptual schema. The table/column structure can change without (necessarily) affecting the conceptual schema. In each case, of course, the structures must remain consistent across all schemas of the same data model.

Data modeling process

In the context of business process integration (see figure), data modeling complements business process modeling, and ultimately results in database generation.



Data modeling in the context of Business Process Integration.[4]

The process of designing a database involves producing the previously described three types of schemas - conceptual, logical, and physical. The database design documented in these schemas are converted through a Data Definition Language, which can then be used to generate a database. A fully attributed data model contains detailed attributes (descriptions) for every entity within it. The term "database design" can describe many different parts of the design of an overall database system. Principally, and most correctly, it can be thought of as the logical design of the base data structures used to store the data. In the relational model these are the tables and views. In an object database the entities and relationships map directly to object classes and named relationships. However, the term "database design" could also be used to apply to the overall process of designing, not just the base data structures, but also the forms and queries used as part of the overall database application within the Database Management System or DBMS.

In the process, system interfaces account for 25% to 70% of the development and support costs of current systems. The primary reason for this cost is that these systems do not share a common data model. If data models are developed on a system by system basis, then not only is the same analysis repeated in overlapping areas, but further analysis must be performed to create the interfaces between them. Most systems within an organization contain the same basic data, redeveloped for a specific purpose. Therefore, an efficiently designed basic data model can minimize rework with minimal modifications for the purposes of different systems within the organization

Modeling methodologies

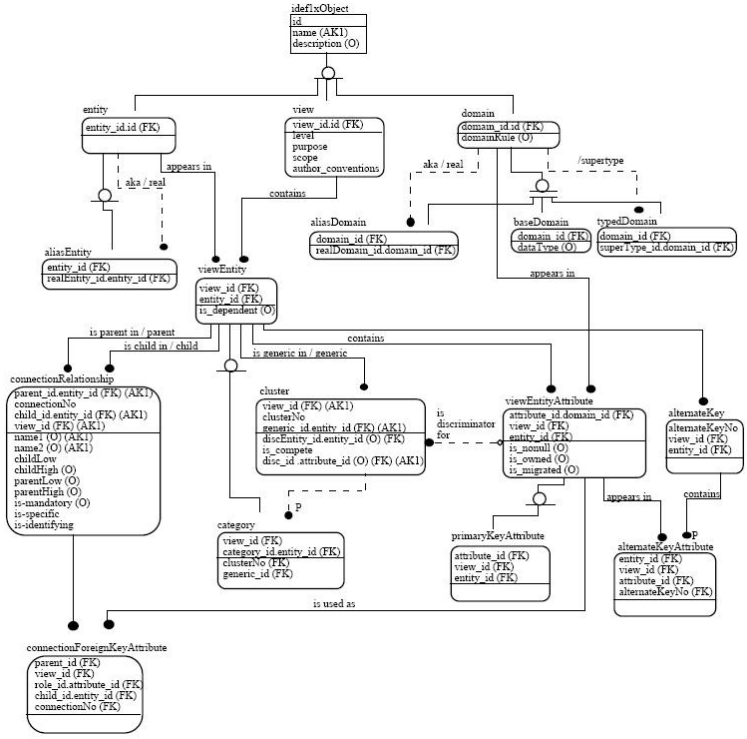
Data models represent information areas of interest. While there are many ways to create data models, according to Len Silverston (1997)[5] only two modeling methodologies stand out, top-down and bottom-up:

- Bottom-up models or View Integration models are often the result of a reengineering effort. They usually start with existing data structures forms, fields on application screens, or reports. These models are usually physical, application-specific, and incomplete from an enterprise perspective. They may not promote data sharing, especially if they are built without reference to other parts of the organization.
- Top-down logical data models, on the other hand, are created in an abstract way by getting information from people who know the subject area. A system may not implement all the entities in a logical model, but the model serves as a reference point or template.

Sometimes models are created in a mixture of the two methods: by considering the data needs and structure of an application and by consistently referencing a subject-area model. Unfortunately, in many environments the distinction between a logical data model and a physical data model is blurred. In addition, some CASE tools don't make a distinction between logical and physical data models.

Entity relationship diagrams

There are several notations for data modeling. The actual model is frequently called "Entity relationship model", because it depicts data in terms of the entities and relationships described in the data. An entity-relationship model (ERM) is an abstract conceptual representation of structured data. Entity-relationship modeling is a relational schema database modeling method, used in software engineering to produce a type of conceptual data model (or semantic data model) of a system, often a relational database, and its requirements in a top-down fashion.



Example of an IDEF1X Entity relationship diagrams used to model IDEF1X itself. The name of the view is mm. The domain hierarchy and constraints are also given. The constraints are expressed as sentences in the formal theory of the meta model.[6]

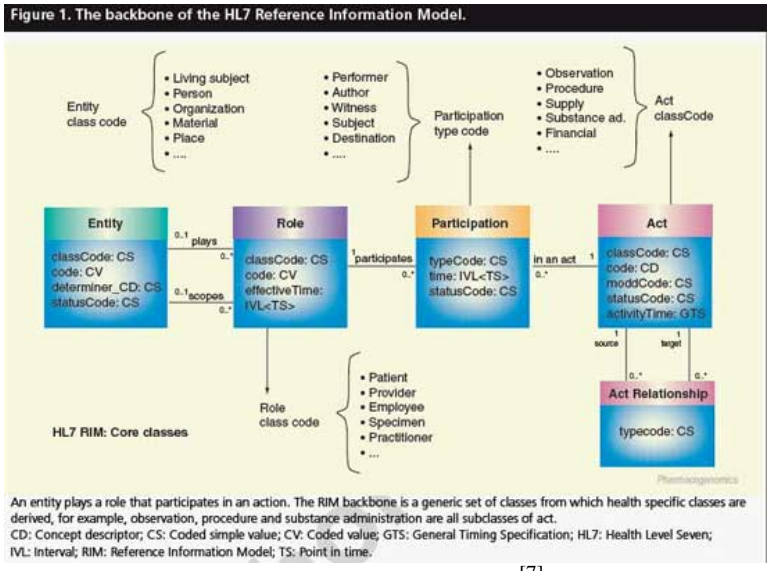
These models are being used in the first stage of information system design during the requirements analysis to describe information needs or the type of information that is to be stored in a database. The data modeling technique can be used to describe any ontology (i.e. an overview and classifications of used terms and their relationships) for a certain universe of discourse i.e. area of interest.

Several techniques have been developed for the design of data models. While these methodologies guide data modelers in their work, two different people using the same methodology will often come up with very different results. Most notable are:

- Bachman diagrams
- Barker's Notation
- Chen's Notation
- Data Vault Modeling
- Extended Backus–Naur form
- IDEF1X
- Object-relational mapping
- Object-Role Modeling
- Relational Model
- Relational Model/Tasmania

Generic data modeling

Generic data models are generalizations of conventional data models. They define standardized general relation types, together with the kinds of things that may be related by such a relation type. The definition of generic data model is similar to the definition of a natural language. For example, a generic data model may define relation types such as a 'classification relation', being a binary relation between an individual thing and a kind of thing (a class) and a 'part-whole relation', being a binary relation between two things, one with the role of part, the other with the role of whole, regardless the kind of things that are related.



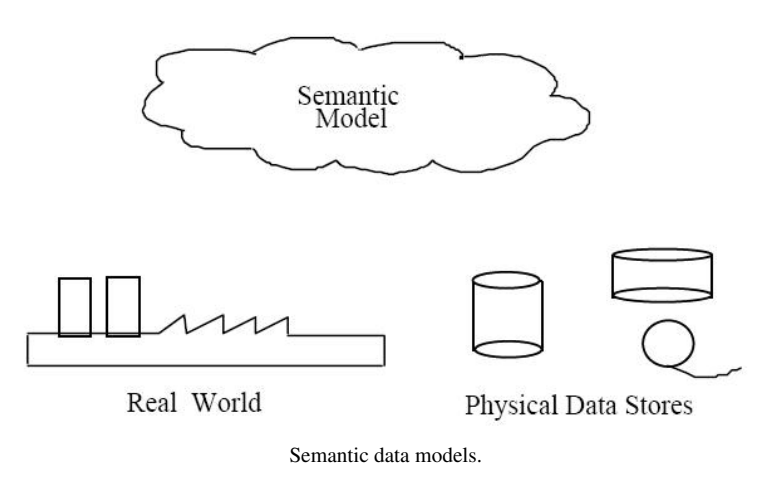
Example of a Generic data model.[7]

Given an extensible list of classes, this allows the classification of any individual thing and to specify part-whole relations for any individual object. By standardization of an extensible list of relation types, a generic data model enables the expression of an unlimited number of kinds of facts and will approach the capabilities of natural languages. Conventional data models, on the other hand, have a fixed and limited domain scope, because the instantiation (usage) of such a model only allows expressions of kinds of facts that are predefined in the model.

Semantic data modeling

The logical data structure of a DBMS, whether hierarchical, network, or relational, cannot totally satisfy the requirements for a conceptual definition of data because it is limited in scope and biased toward the implementation strategy employed by the DBMS.

Therefore, the need to define data from a conceptual view has led to the development of semantic data modeling techniques. That is, techniques to define the meaning of data within the context of its interrelationships with other data. As illustrated in the figure the real world, in terms of resources, ideas, events, etc., are symbolically defined within physical data stores. A semantic data model is an abstraction which defines how the stored symbols relate to the real world. Thus, the model must be a true representation of the real world.



Semantic data models.

A semantic data model can be used to serve many purposes, such as:

- planning of data resources
- building of shareable databases

- evaluation of vendor software
- integration of existing databases

The overall goal of semantic data models is to capture more meaning of data by integrating relational concepts with more powerful abstraction concepts known from the Artificial Intelligence field. The idea is to provide high level modeling primitives as integral part of a data model in order to facilitate the representation of real world situations.[8]

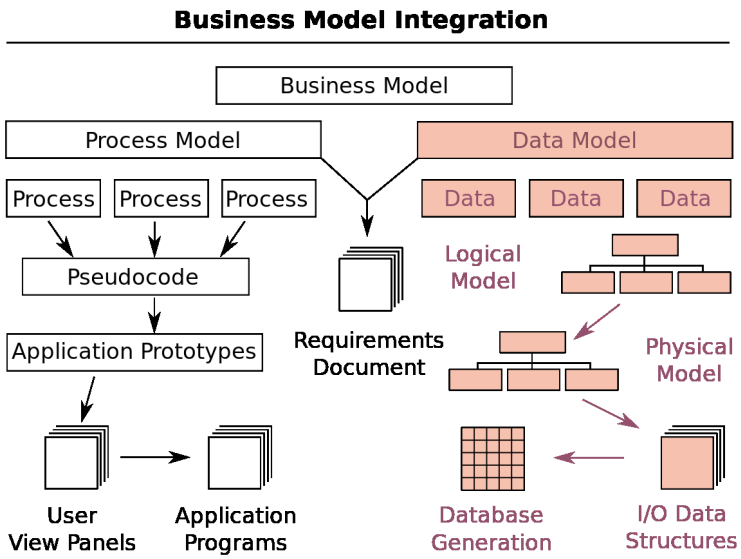
Data model

In software engineering, the term **data model** is used in two related senses. In the sense covered by this article, it is a description of the objects represented by a computer system together with their properties and relationships; these are typically "real world" objects such as products, suppliers, customers, and orders. In the second sense, covered by the article database model, it means a collection of concepts and rules used in defining data models: for example the relational model uses relations and tuples, while the network model uses records, sets, and fields.

Data models are often used as an aid to communication between the business people defining the requirements for a computer system and the technical people defining the design in response to those requirements. They are used to show the data needed and created by business processes.

According to Hoberman (2009), "A data model is a wayfinding tool for both business and IT professionals, which uses a set of symbols and text to precisely explain a subset of real information to improve communication within the organization and thereby lead to a more flexible and stable application environment."[2]

A data model explicitly determines the structure of data. Data models are specified in a data modeling notation, which is often graphical in form.[3]



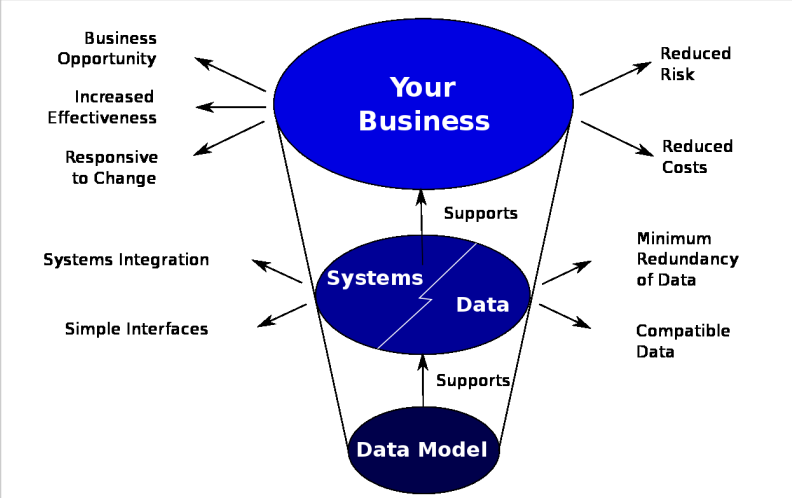
Overview of data modeling context: Data model is based on Data, Data relationship, Data semantic and Data constraint. A data model provides the details of information to be stored, and is of primary use when the final product is the generation of computer software code for an application or the preparation of a functional specification to aid a computer software make-or-buy decision. The figure is an example of the interaction between process and data models.[1]

A data model can be sometimes referred to as a data structure, especially in the context of programming languages. Data models are often complemented by function models, especially in the context of enterprise models.

Overview

Managing large quantities of structured and unstructured data is a primary function of information systems. Data models describe structured data for storage in data management systems such as relational databases. They typically do not describe unstructured data, such as word processing documents, email messages, pictures, digital audio, and video.

The role of data models



How data models deliver benefit.[4]

The main aim of data models is to support the development of information systems by providing the definition and format of data. According to West and Fowler (1999) "if this is done consistently across systems then compatibility of data can be achieved. If the same data structures are used to store and access data then different applications can share data. The results of this are indicated above. However, systems and interfaces often cost more than they should, to build, operate, and maintain. They may also constrain the business rather than support it. A major cause is that the quality of the data models implemented in systems and interfaces is poor".

- "Business rules, specific to how things are done in a particular place, are often fixed in the structure of a data model. This means that small changes in the way business is conducted lead to large changes in computer systems and interfaces".
- "Entity types are often not identified, or incorrectly identified. This can lead to replication of data, data structure, and functionality, together with the attendant costs of that duplication in development and maintenance".
- "Data models for different systems are arbitrarily different. The result of this is that complex interfaces are required between systems that share data. These interfaces can account for between 25-70% of the cost of current systems".
- "Data cannot be shared electronically with customers and suppliers, because the structure and meaning of data has not been standardised. For example, engineering design data and drawings for process plant are still sometimes exchanged on paper".

The reason for these problems is a lack of standards that will ensure that data models will both meet business needs and be consistent. According to Hoberman (2009), "A data model is a wayfinding tool for both business and IT professionals, which uses a set of symbols and text to precisely explain a subset of real information to improve communication within the organization and thereby lead to a more flexible and stable application environment."[2]

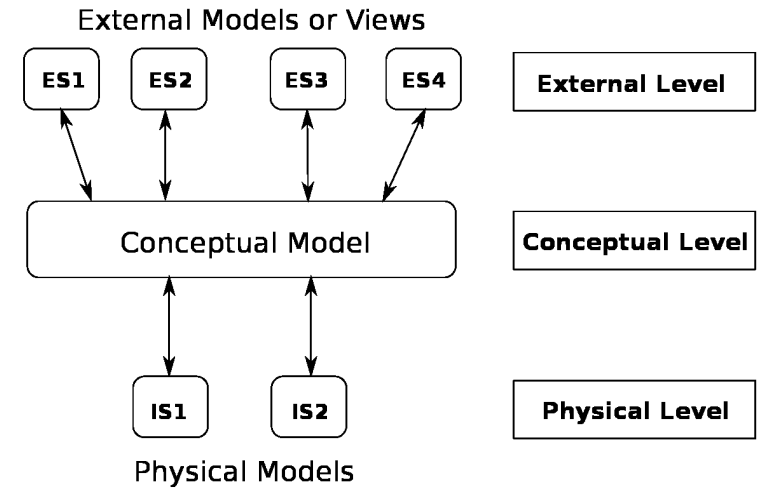
A data model explicitly determines the structure of data or structured data. Typical applications of data models include database models, design of information systems, and enabling exchange of data. Usually data models are specified in a data modeling language.[3]

Communication and precision are the two key benefits that make a data model important to applications that use and exchange data. A data model is the medium which project team members from different backgrounds and with different levels of experience can communicate with one another. Precision means that the terms and rules on a data model can be interpreted only one way and are not ambiguous.[2]

A data model can be sometimes referred to as a data structure, especially in the context of programming languages. Data models are often complemented by function models, especially in the context of enterprise models.

Three perspectives

A data model *instance* may be one of three kinds according to ANSI in 1975:[5]



The ANSI/SPARC three level architecture. This shows that a data model can be an external model (or view), a conceptual model, or a physical model. This is not the only way to look at data models, but it is a useful way, particularly when comparing models.

- Conceptual data model : describes the semantics of a domain, being the scope of the model. For example, it may be a model of the interest area of an organization or industry. This consists of entity classes, representing kinds of things of significance in the domain, and relationships assertions about associations between pairs of entity classes. A conceptual schema specifies the kinds of facts or propositions that can be expressed using the model. In that sense, it defines the allowed expressions in an artificial 'language' with a scope that is limited by the scope of the model. The use of conceptual schema has evolved to become a powerful communication tool with business users. Often called a subject area model (SAM) or high-level data model (HDM), this model is used to communicate core data concepts, rules, and definitions to a business user as part of an overall application development or enterprise initiative. The number of objects should be very small and focused on key concepts. Try to limit this model to one page, although for extremely large organizations or complex projects, the model might span two or more pages.[6]
- Logical data model : describes the semantics, as represented by a particular data manipulation technology. This consists of descriptions of tables and columns, object oriented classes, and XML tags, among other things.
- Physical data model : describes the physical means by which data are stored. This is concerned with partitions, CPUs, tablespaces, and the like.

The significance of this approach, according to ANSI, is that it allows the three perspectives to be relatively independent of each other. Storage technology can change without affecting either the logical or the conceptual model. The table/column structure can change without (necessarily) affecting the conceptual model. In each case, of course, the structures must remain consistent with the other model. The table/column structure may be different from a direct translation of the entity classes and attributes, but it must ultimately carry out the objectives of the conceptual entity class structure. Early phases of many software development projects emphasize the design of a conceptual data model. Such a design can be detailed into a logical data model. In later stages, this model may be translated into physical data model. However, it is also possible to implement a conceptual model directly.

History

One of the earliest pioneering works in modelling information systems was done by Young and Kent (1958),[7][8] who argued for "a precise and abstract way of specifying the informational and time characteristics of a data processing problem". They wanted to create "a notation that should enable the analyst to organize the problem around any piece of hardware". Their work was a first effort to create an abstract specification and invariant basis for designing different alternative implementations using different hardware components. A next step in IS modelling was taken by CODASYL, an IT industry consortium formed in 1959, who essentially aimed at the same thing as Young and Kent: the development of "a proper structure for machine independent problem definition language, at the system level of data processing". This led to the development of a specific IS information algebra.

In the 1960s data modeling gained more significance with the initiation of the management information system (MIS) concept. According to Leondes (2002), "during that time, the information system provided the data and information for management purposes. The first generation database system, called Integrated Data Store (IDS), was designed by Charles Bachman at General Electric. Two famous database models, the network data model and the hierarchical data model, were proposed during this period of time".[9] Towards the end of the 1960s Edgar F. Codd worked out his theories of data arrangement, and proposed the relational model for database management based on first-order predicate logic.[10]

In the 1970s entity relationship modeling emerged as a new type of conceptual data modeling, originally proposed in 1976 by Peter Chen. Entity relationship models were being used in the first stage of information system design during the requirements analysis to describe information needs or the type of information that is to be stored in a database. This technique can describe any ontology, i.e., an overview and classification of concepts and their relationships, for a certain area of interest.

In the 1970s G.M. Nijssen developed "Natural Language Information Analysis Method" (NIAM) method, and developed this in the 1980s in cooperation with Terry Halpin into Object-Role Modeling (ORM).

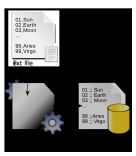
Bill Kent, in his 1978 book *Data and Reality* compared a data model to a map of a territory, emphasizing that in the real world, "highways are not painted red, rivers don't have county lines running down the middle, and you can't see contour lines on a mountain". In contrast to other researchers who tried to create models that were mathematically clean and elegant, Kent emphasized the essential messiness of the real world, and the task of the data modeller to create order out of chaos without excessively distorting the truth.

In the 1980s according to Jan L. Harrington (2000) "the development of the object-oriented paradigm brought about a fundamental change in the way we look at data and the procedures that operate on data. Traditionally, data and procedures have been stored separately: the data and their relationship in a database, the procedures in an application program. Object orientation, however, combined an entity's procedure with its data."[11]

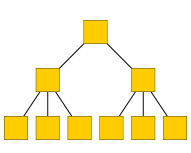
Types of data models

Database model

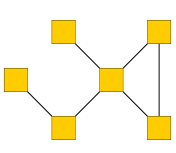
A database model is a specification describing how a database is structured and used. Several such models have been suggested. Common models include:



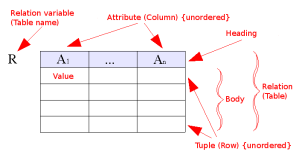
Flat model



Hierarchical model

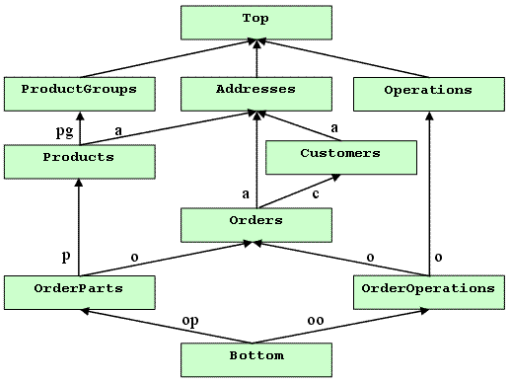


Network model

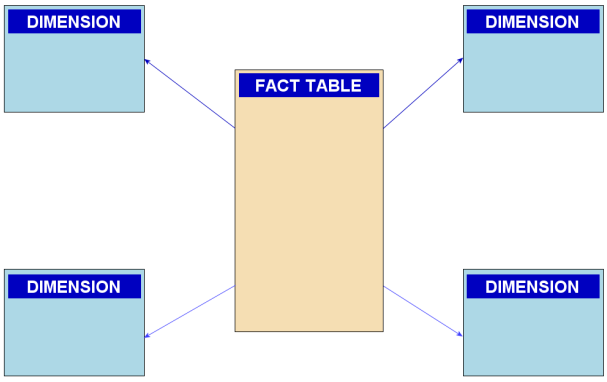


Relational model

- Flat model: This may not strictly qualify as a data model. The flat (or table) model consists of a single, two-dimensional array of data elements, where all members of a given column are assumed to be similar values, and all members of a row are assumed to be related to one another.
- Hierarchical model: In this model data is organized into a tree-like structure, implying a single upward link in each record to describe the nesting, and a sort field to keep the records in a particular order in each same-level list.
- Network model: This model organizes data using two fundamental constructs, called records and sets. Records contain fields, and sets define one-to-many relationships between records: one owner, many members.
- Relational model: is a database model based on first-order predicate logic. Its core idea is to describe a database as a collection of predicates over a finite set of predicate variables, describing constraints on the possible values and combinations of values.



Concept-oriented model

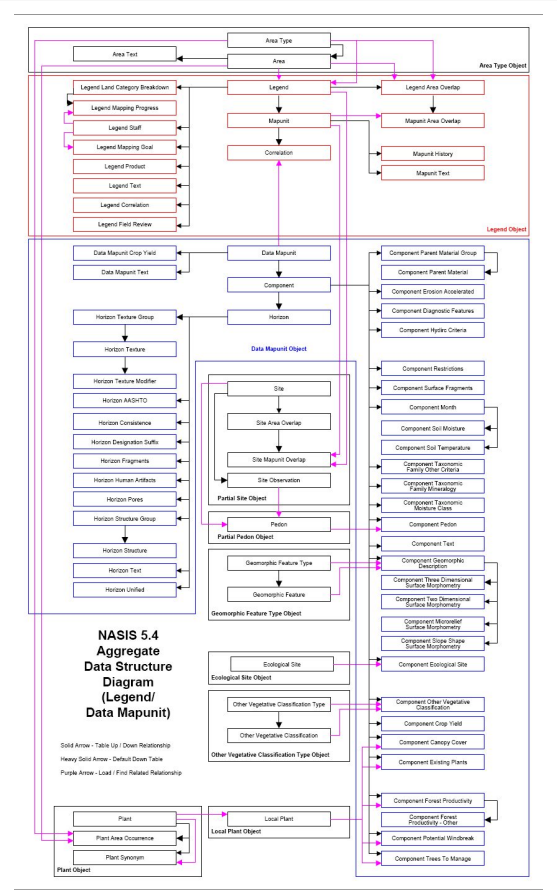


Star schema

- Object-relational model: Similar to a relational database model, but objects, classes and inheritance are directly supported in database schemas and in the query language.
- Star schema is the simplest style of data warehouse schema. The star schema consists of a few "fact tables" (possibly only one, justifying the name) referencing any number of "dimension tables". The star schema is considered an important special case of the snowflake schema.

Data Structure Diagram

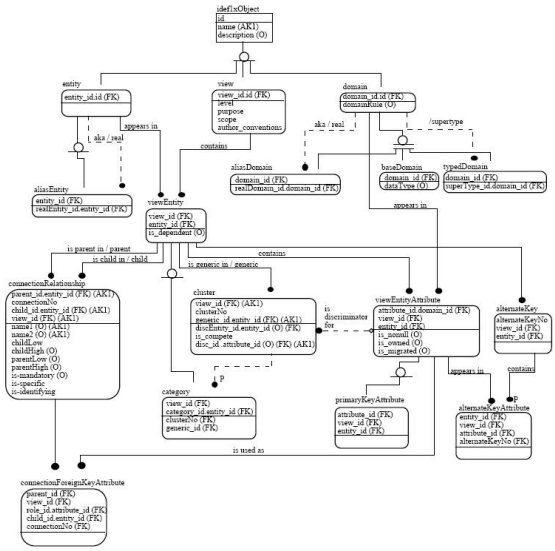
A data structure diagram (DSD) is a diagram and data model used to describe conceptual data models by providing graphical notations which document entities and their relationships, and the constraints that bind them. The basic graphic elements of DSDs are boxes, representing entities, and arrows, representing relationships. Data structure diagrams are most useful for documenting complex data entities.



Example of a Data Structure Diagram.

Data structure diagrams are an extension of the entity-relationship model (ER model). In DSDs, attributes are specified inside the entity boxes rather than outside of them, while relationships are drawn as boxes composed of attributes which specify the constraints that bind entities together. The E-R model, while robust, doesn't provide a way to specify the constraints between relationships, and becomes visually cumbersome when representing entities with several attributes. DSDs differ from the ER model in that the ER model focuses on the relationships between different entities, whereas DSDs focus on the relationships of the elements within an entity and enable users to fully see the links and relationships between each entity.

There are several styles for representing data structure diagrams, with the notable difference in the manner of defining cardinality. The choices are between arrow heads, inverted arrow heads (crow's feet), or numerical representation of the cardinality.



Example of an IDEF1X Entity relationship diagrams used to model IDEF1X itself.[12]

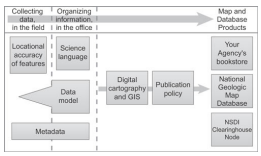
Entity-relationship model

An entity-relationship model (ERM) is an abstract conceptual data model (or semantic data model) used in software engineering to represent structured data. There are several notations used for ERMs.

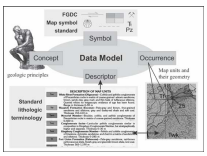
Geographic data model

A data model in Geographic information systems is a mathematical construct for representing geographic objects or surfaces as data. For example,

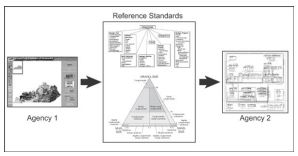
- the vector data model represents geography as collections of points, lines, and polygons;
- the raster data model represent geography as cell matrixes that store numeric values;
- and the Triangulated irregular network (TIN) data model represents geography as sets of contiguous, nonoverlapping triangles.[13]



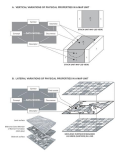
Groups relate to process of making a map[1]



NGMDB data model applications[2]



NGMDB databases linked together[3]



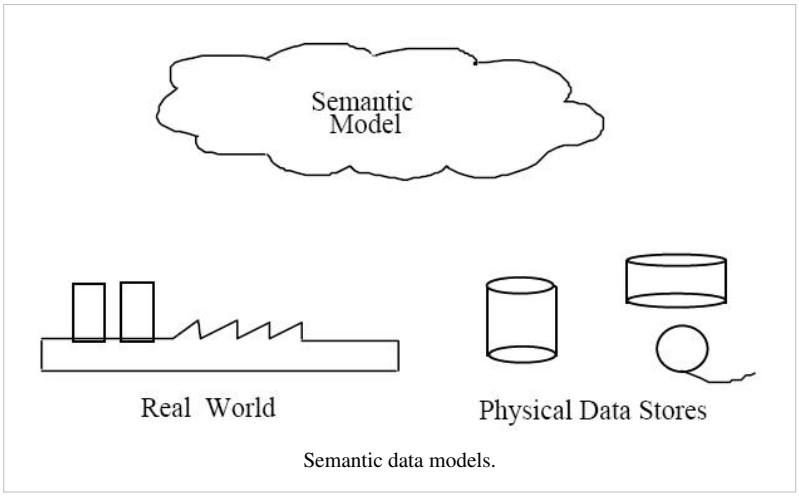
Representing 3D map information[4]

Generic data model

Generic data models are generalizations of conventional data models. They define standardised general relation types, together with the kinds of things that may be related by such a relation type. Generic data models are developed as an approach to solve some shortcomings of conventional data models. For example, different modelers usually produce different conventional data models of the same domain. This can lead to difficulty in bringing the models of different people together and is an obstacle for data exchange and data integration. Invariably, however, this difference is attributable to different levels of abstraction in the models and differences in the kinds of facts that can be instantiated (the semantic expression capabilities of the models). The modelers need to communicate and agree on certain elements which are to be rendered more concretely, in order to make the differences less significant.

Semantic data model

A semantic data model in software engineering is a technique to define the meaning of data within the context of its interrelationships with other data. A semantic data model is an abstraction which defines how the stored symbols relate to the real world. A semantic data model is sometimes called a conceptual data model.



Semantic data models.

The logical data structure of a database management system (DBMS), whether hierarchical, network, or relational, cannot totally satisfy the requirements for a conceptual definition of data because it is limited in scope and biased toward the implementation strategy employed by the DBMS. Therefore, the need to define data from a conceptual view has led to the development of semantic data modeling techniques. That is, techniques to define the meaning of data within the context of its interrelationships with other data. As illustrated in the figure. The real world, in terms of resources, ideas, events, etc., are symbolically defined within physical data stores. A semantic data model is an abstraction which defines how the stored symbols relate to the real world. Thus, the model must be a true representation of the real world.

Data model topics

Data architecture

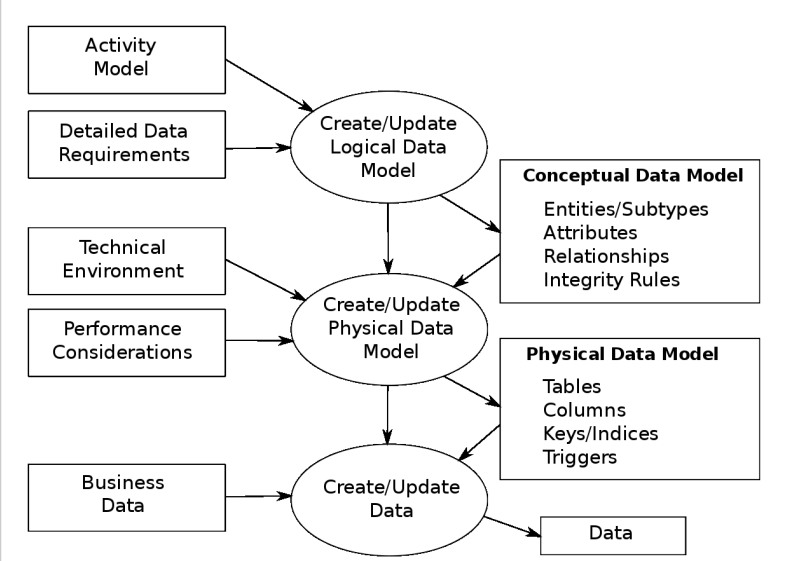
Data architecture is the design of data for use in defining the target state and the subsequent planning needed to hit the target state. It is usually one of several architecture domains that form the pillars of an enterprise architecture or solution architecture.

A data architecture describes the data structures used by a business and/or its applications. There are descriptions of data in storage and data in motion; descriptions of data stores, data groups and data items; and mappings of those data artifacts to data qualities, applications, locations etc.

Essential to realizing the target state, Data architecture describes how data is processed, stored, and utilized in a given system. It provides criteria for data processing operations that make it possible to design data flows and also control the flow of data in the system.

Data modeling

Data modeling in software engineering is the process of creating a data model by applying formal data model descriptions using data modeling techniques. Data modeling is a technique for defining business requirements for a database. It is sometimes called *database modeling* because a data model is eventually implemented in a database.[14]



The data modeling process.

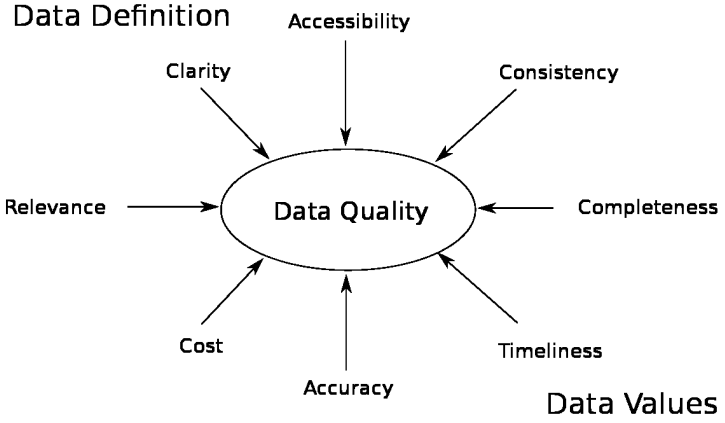
The figure illustrates the way data models are developed and used today. A conceptual data model is developed based on the data requirements for the application that is being developed, perhaps in the context of an activity model. The data model will normally consist of entity types, attributes, relationships, integrity rules, and the definitions of those objects. This is then used as the start point for interface or database design.

Data properties

Some important properties of data for which requirements need to be met are:

- definition-related properties
  - *relevance*: the usefulness of the data in the context of your business.
  - *clarity*: the availability of a clear and shared definition for the data.
  - *consistency*: the compatibility of the same type of data from different sources.

- content-related properties
  - *timeliness*: the availability of data at the time required and how up to date that data is.
  - *accuracy*: how close to the truth the data is.
- properties related to both definition and content
  - *completeness*: how much of the required data is available.
  - *accessibility*: where, how, and to whom the data is available or not available (e.g. security).



Some important properties of data.

- *cost*: the cost incurred in obtaining the data, and making it available for use.

Data organization

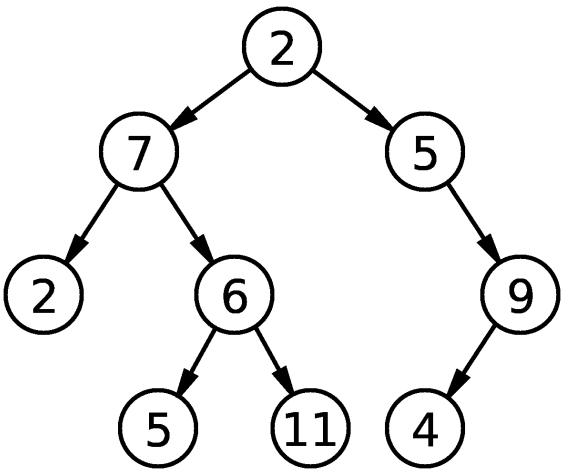
Another kind of data model describes how to organize data using a database management system or other data management technology. It describes, for example, relational tables and columns or object-oriented classes and attributes. Such a data model is sometimes referred to as the *physical data model*, but in the original ANSI three schema architecture, it is called "logical". In that architecture, the physical model describes the storage media (cylinders, tracks, and tablespaces). Ideally, this model is derived from the more conceptual data model described above. It may differ, however, to account for constraints like processing capacity and usage patterns.

While *data analysis* is a common term for data modeling, the activity actually has more in common with the ideas and methods of *synthesis* (inferring general concepts from particular instances) than it does with *analysis* (identifying component concepts from more general ones). {*Presumably we call ourselves systems analysts because no one can say systems synthesists.*} Data modeling strives to bring the data structures of interest together into a cohesive, inseparable, whole by eliminating unnecessary data redundancies and by relating data structures with relationships.

A different approach is to use adaptive systems such as artificial neural networks that can autonomously create implicit models of data.

Data structure

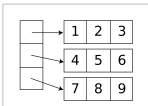
A data structure is a way of storing data in a computer so that it can be used efficiently. It is an organization of mathematical and logical concepts of data. Often a carefully chosen data structure will allow the most efficient algorithm to be used. The choice of the data structure often begins from the choice of an abstract data type.



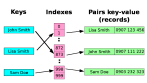
A binary tree, a simple type of branching linked data structure.

A data model describes the structure of the data within a given domain and, by implication, the underlying structure of that domain itself. This means that a data model in fact specifies a dedicated *grammar* for a dedicated artificial language for that domain. A data model represents classes of entities (kinds of things) about which a company wishes to hold information, the attributes of that information, and relationships among those entities and (often implicit) relationships among those attributes. The model describes the organization of the data to some extent irrespective of how data might be represented in a computer system.

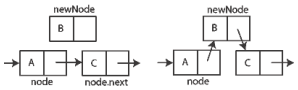
The entities represented by a data model can be the tangible entities, but models that include such concrete entity classes tend to change over time. Robust data models often identify abstractions of such entities. For example, a data model might include an entity class called "Person", representing all the people who interact with an organization. Such an abstract entity class is typically more appropriate than ones called "Vendor" or "Employee", which identify specific roles played by those people.



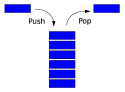
Array



Hash table



Linked list



Stack (data structure)

Data model theory

The term data model can have two meanings:[15]

1. A data model *theory*, i.e. a formal description of how data may be structured and accessed.
2. A data model *instance*, i.e. applying a data model *theory* to create a practical data model *instance* for some particular application.

A data model theory has three main components:

- The structural part: a collection of data structures which are used to create databases representing the entities or objects modeled by the database.
- The integrity part: a collection of rules governing the constraints placed on these data structures to ensure structural integrity.
- The manipulation part: a collection of operators which can be applied to the data structures, to update and query the data contained in the database.

For example, in the relational model, the structural part is based on a modified concept of the mathematical relation; the integrity part is expressed in first-order logic and the manipulation part is expressed using the relational algebra, tuple calculus and domain calculus.

A data model instance is created by applying a data model theory. This is typically done to solve some business enterprise requirement. Business requirements are normally captured by a semantic logical data model. This is transformed into a physical data model instance from which is generated a physical database. For example, a data modeler may use a data modeling tool to create an entity-relationship model of the corporate data repository of some business enterprise. This model is transformed into a relational model, which in turn generates a relational database.

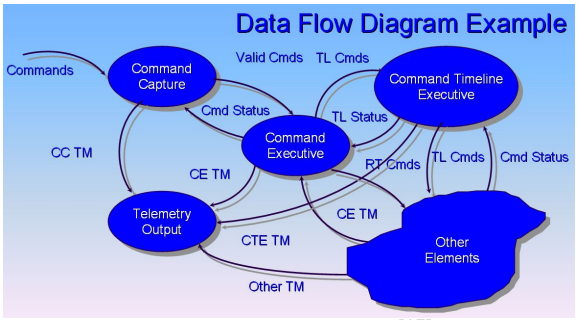
Patterns

Patterns[16] are common data modeling structures that occur in many data models.

Related models

Data flow diagram

A data flow diagram (DFD) is a graphical representation of the "flow" of data through an information system. It differs from the flowchart as it shows the *data* flow instead of the *control* flow of the program. A data flow diagram can also be used for the visualization of data processing (structured design). Data flow diagrams were invented by Larry Constantine, the original developer of structured design,[18] based on Martin and Estrin's "data flow graph" model of computation.

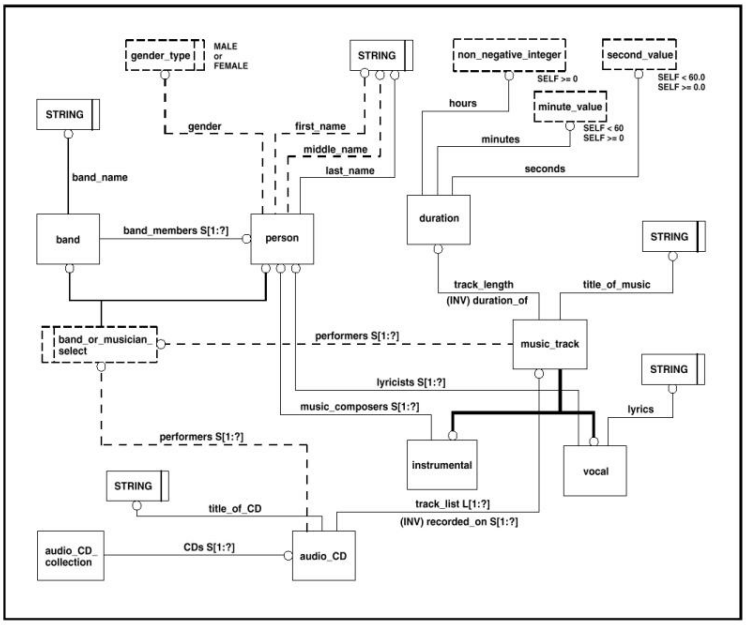


Data Flow Diagram example.[17]

It is common practice to draw a context-level Data flow diagram first which shows the interaction between the system and outside entities. The **DFD** is designed to show how a system is divided into smaller portions and to highlight the flow of data between those parts. This context-level Data flow diagram is then "exploded" to show more detail of the system being modeled

Information model

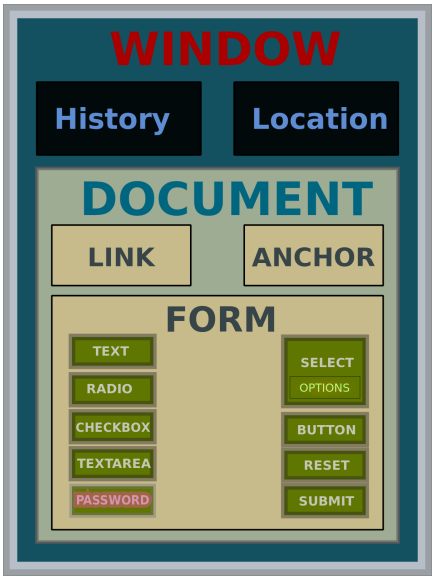
An Information model is not a type of data model, but more or less an alternative model. Within the field of software engineering both a data model and an information model can be abstract, formal representations of entity types that includes their properties, relationships and the operations that can be performed on them. The entity types in the model may be kinds of real-world objects, such as devices in a network, or they may themselves be abstract, such as for the entities used in a billing system. Typically, they are used to model a constrained domain that can be described by a closed set of entity types, properties, relationships and operations.



Example of an EXPRESS G Information model.

According to Lee (1999) an information model is a representation of concepts, relationships, constraints, rules, and operations to specify data semantics for a chosen domain of discourse. It can provide sharable, stable, and organized structure of information requirements for the domain context.[] More in general the term *information model* is used for models of individual things, such as facilities, buildings, process plants, etc. In those cases the concept is specialised to Facility Information Model, Building Information Model, Plant Information Model, etc. Such an information model is an integration of a model of the facility with the data and documents about the facility.

An information model provides formalism to the description of a problem domain without constraining how that description is mapped to an actual implementation in software. There may be many mappings of the information model. Such mappings are called data models, irrespective of whether they are object models (e.g. using UML), entity relationship models or XML schemas.



Document Object Model, a standard object model for representing HTML or XML.

Object model

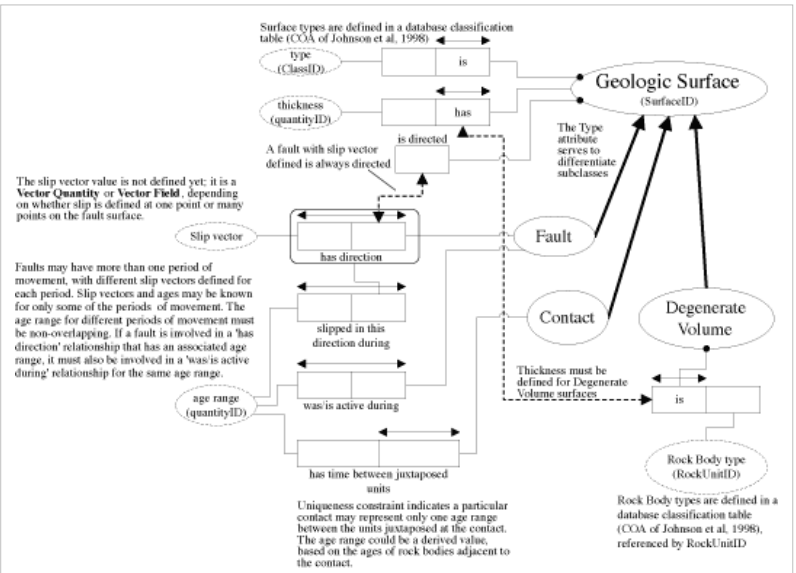
An object model in computer science is a collection of objects or classes through which a program can examine and manipulate some specific parts of its world. In other words, the object-oriented interface to some service or system. Such an interface is said to be the *object model of* the represented service or system. For example, the Document Object Model (DOM) [19] is a collection of objects that represent a page in a web browser, used by script programs to examine and dynamically change the page. There is a Microsoft Excel object model[20] for controlling Microsoft Excel from another program, and the ASCOM Telescope Driver is an object model for controlling an astronomical telescope.

In computing the term *object model* has a distinct second meaning of the general properties of objects in a specific computer programming language, technology, notation or methodology that uses them. For example, the *Java object model*, the *COM object model*, or *the object model of OMT*. Such object models are usually defined using concepts such as class, message, inheritance, polymorphism, and encapsulation. There is an extensive literature on formalized object models as a subset of the formal semantics of programming languages.

Object-Role Model

Object-Role Modeling (ORM) is a method for conceptual modeling, and can be used as a tool for information and rules analysis.[22]

Object-Role Modeling is a fact-oriented method for performing systems analysis at the conceptual level. The quality of a database application depends critically on its design. To help ensure correctness, clarity, adaptability and productivity, information systems are best specified first at the conceptual level, using concepts and language that people can readily understand.



Example of the application of Object-Role Modeling in a "Schema for Geologic Surface", Stephen M. Richard (1999).[21]

The conceptual design may include data, process and behavioral perspectives, and the actual DBMS used to implement the design might be based on one of many logical data models (relational, hierarchic, network, object-oriented etc.).[23]

Unified Modeling Language models

The Unified Modeling Language (UML) is a standardized general-purpose modeling language in the field of software engineering. It is a graphical language for visualizing, specifying, constructing, and documenting the artifacts of a software-intensive system. The Unified Modeling Language offers a standard way to write a system's blueprints, including:[24]

- Conceptual things such as business processes and system functions
- Concrete things such as programming language statements, database schemas, and
- Reusable software components.

UML offers a mix of functional models, data models, and database models.

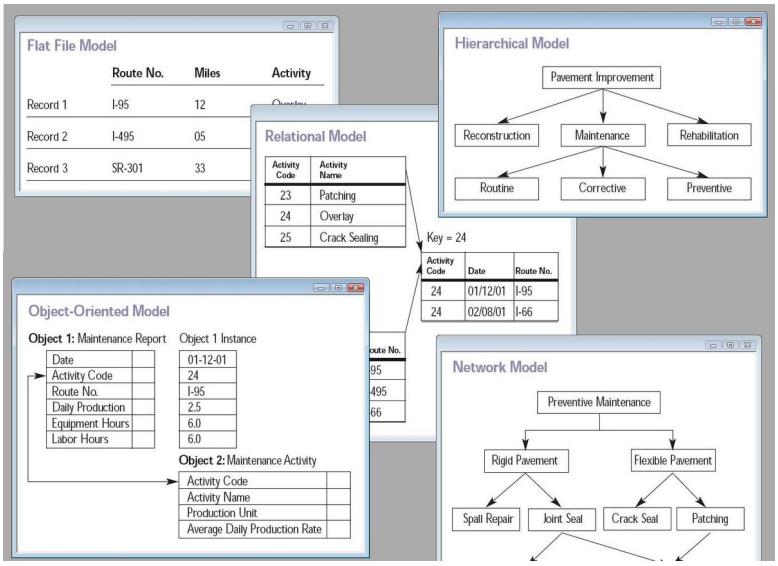
Database model

A **database model** is a type of data model that determines the logical structure of a database and fundamentally determines in which manner data can be stored, organized, and manipulated. The most popular example of a database model is the relational model, which uses a table-based format.



Collage of five types of database models.

Common logical data models for databases include:

- Hierarchical database model
- Network model
- Relational model
- Entity–relationship model
  - Enhanced entity–relationship model
- Object model
- Document model
- Entity–attribute–value model
- Star schema

An object-relational database combines the two related structures.

Physical data models include:

- Inverted index
- Flat file

Other models include:

- Associative model
- Multidimensional model
- Multivalue model
- Semantic model
- XML database
- Named graph
- Triplestore

Relationships and functions

A given database management system may provide one or more of the five models. The optimal structure depends on the natural organization of the application's data, and on the application's requirements, which include transaction rate (speed), reliability, maintainability, scalability, and cost. Most database management systems are built around one particular data model, although it is possible for products to offer support for more than one model.

Various physical data models can implement any given logical model. Most database software will offer the user some level of control in tuning the physical implementation, since the choices that are made have a significant effect on performance.

A model is not just a way of structuring data: it also defines a set of operations that can be performed on the data. The relational model, for example, defines operations such as select (project) and join. Although these operations may not be explicit in a particular query language, they provide the foundation on which a query language is built.

Flat model

The flat (or table) model consists of a single, two-dimensional array of data elements, where all members of a given column are assumed to be similar values, and all members of a row are assumed to be related to one another. For instance, columns for name and password that might be used as a part of a system security database. Each row would have the specific password associated with an individual user. Columns of the table often have a type associated with them, defining them as character data, date or time information, integers, or floating point numbers. This tabular format is a precursor to the relational model.

Flat File Model

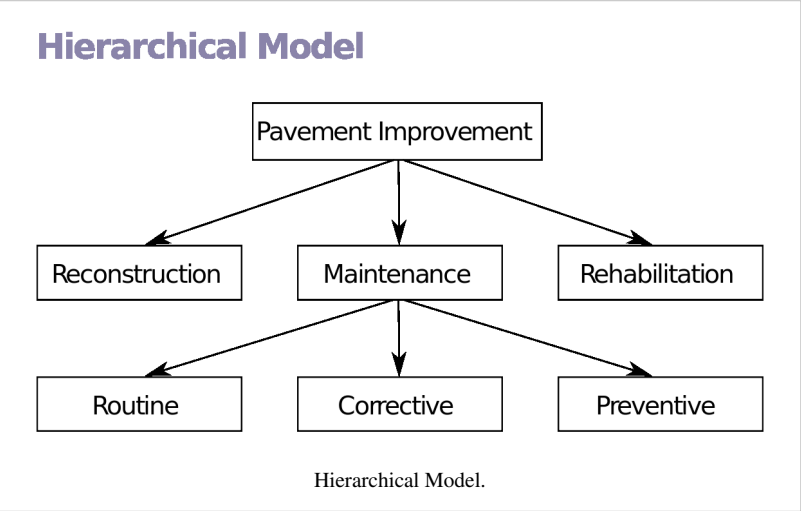
	Route No.	Miles	Activity
Record 1	I-95	12	Overlay
Record 2	I-495	05	Patching
Record 3	SR-301	33	Crack seal

Flat File Model.

Early data models

These models were popular in the 1960s, 1970s, but nowadays can be found primarily in old legacy systems. They are characterized primarily by being navigational with strong connections between their logical and physical representations, and deficiencies in data independence.

Hierarchical model

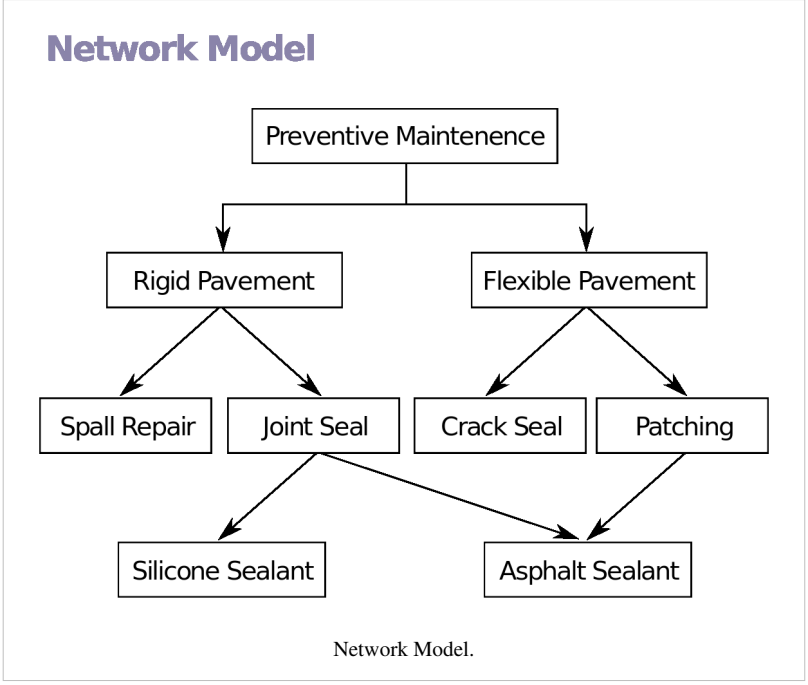


Hierarchical Model.

In a hierarchical model, data is organized into a tree-like structure, implying a single parent for each record. A sort field keeps sibling records in a particular order. Hierarchical structures were widely used in the early mainframe database management systems, such as the Information Management System (IMS) by IBM, and now describe the structure of XML documents. This structure allows one one-to-many relationship between two types of data. This structure is very efficient to describe many relationships in the real world; recipes, table of contents, ordering of paragraphs/verses, any nested and sorted information.

This hierarchy is used as the physical order of records in storage. Record access is done by navigating through the data structure using pointers combined with sequential accessing. Because of this, the hierarchical structure is inefficient for certain database operations when a full path (as opposed to upward link and sort field) is not also included for each record. Such limitations have been compensated for in later IMS versions by additional logical hierarchies imposed on the base physical hierarchy.

Network model



Network Model.

The network model expands upon the hierarchical structure, allowing many-to-many relationships in a tree-like structure that allows multiple parents. It was the most popular before being replaced by the relational model, and is defined by the CODASYL specification.

The network model organizes data using two fundamental concepts, called *records* and *sets*. Records contain fields (which may be organized hierarchically, as in the programming language COBOL). Sets (not to be confused with mathematical sets) define one-to-many[1] relationships between records: one owner, many members. A record may be an owner in any number of sets, and a member in any number of sets.

A set consists of circular linked lists where one record type, the set owner or parent, appears once in each circle, and a second record type, the subordinate or child, may appear multiple times in each circle. In this way a hierarchy may be established between any two record types, e.g., type A is the owner of B. At the same time another set may be defined where B is the owner of A. Thus all the sets comprise a general directed graph (ownership defines a direction), or *network* construct. Access to records is either sequential (usually in each record type) or by navigation in the circular linked lists.

The network model is able to represent redundancy in data more efficiently than in the hierarchical model, and there can be more than one path from an ancestor node to a descendant. The operations of the network model are navigational in style: a program maintains a current position, and navigates from one record to another by following the relationships in which the record participates. Records can also be located by supplying key values.

Although it is not an essential feature of the model, network databases generally implement the set relationships by means of pointers that directly address the location of a record on disk. This gives excellent retrieval performance, at the expense of operations such as database loading and reorganization.

Popular DBMS products that utilized it were Cincom Systems' Total and Cullinet's IDMS. IDMS gained a considerable customer base; in the 1980s, it adopted the relational model and SQL in addition to its original tools and languages.

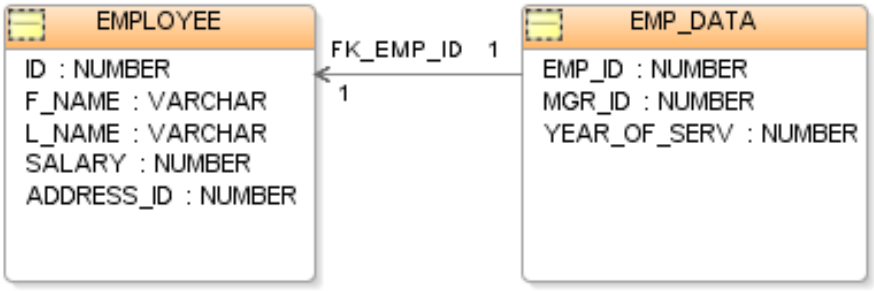
Most object databases (invented in the 1990s) use the navigational concept to provide fast navigation across networks of objects, generally using object identifiers as "smart" pointers to related objects. Objectivity/DB, for instance, implements named one-to-one, one-to-many, many-to-one, and many-to-many named relationships that can cross databases. Many object databases also support SQL, combining the strengths of both models.

Inverted file model

In an *inverted file* or *inverted index*, the contents of the data are used as keys in a lookup table, and the values in the table are pointers to the location of each instance of a given content item. This is also the logical structure of contemporary database indexes, which might only use the contents from a particular columns in the lookup table. The *inverted file data model* can put indexes in a second set of files next to existing flat database files, in order to efficiently directly access needed records in these files.

Notable for using this data model is the ADABAS DBMS of Software AG, introduced in 1970. ADABAS has gained considerable customer base and exists and supported until today. In the 1980s it has adopted the relational model and SQL in addition to its original tools and languages.

Relational model



The relational model was introduced by E.F. Codd in 1970[2] as a way to make database management systems more independent of any particular application. It is a mathematical model defined in terms of predicate logic and set theory, and systems implementing it have been used by mainframe, midrange and microcomputer systems.

The products that are generally referred to as relational databases in fact implement a model that is only an approximation to the mathematical model defined by Codd. Three key terms are used extensively in relational database models: *relations*, *attributes*, and *domains*. A relation is a table with columns and rows. The named columns of the relation are called attributes, and the domain is the set of values the attributes are allowed to take.

The basic data structure of the relational model is the table, where information about a particular entity (say, an employee) is represented in rows (also called tuples) and columns. Thus, the "relation" in "relational database" refers to the various tables in the database; a relation is a set of tuples. The columns enumerate the various attributes of the entity (the employee's name, address or phone number, for example), and a row is an actual instance of the entity (a specific employee) that is represented by the relation. As a result, each tuple of the employee table represents various attributes of a single employee.

All relations (and, thus, tables) in a relational database have to adhere to some basic rules to qualify as relations. First, the ordering of columns is immaterial in a table. Second, there can't be identical tuples or rows in a table. And third, each tuple will contain a single value for each of its attributes.

A relational database contains multiple tables, each similar to the one in the "flat" database model. One of the strengths of the relational model is that, in principle, any value occurring in two different records (belonging to the same table or to different tables), implies a relationship among those two records. Yet, in order to enforce explicit integrity constraints, relationships between records in tables can also be defined explicitly, by identifying or non-identifying parent-child relationships characterized by assigning cardinality (1:1, (0)1:M, M:M). Tables can also have a designated single attribute or a set of attributes that can act as a "key", which can be used to uniquely identify each tuple in the table.

A key that can be used to uniquely identify a row in a table is called a primary key. Keys are commonly used to join or combine data from two or more tables. For example, an *Employee* table may contain a column named *Location* which contains a value that matches the key of a *Location* table. Keys are also critical in the creation of indexes, which facilitate fast retrieval of data from large tables. Any column can be a key, or multiple columns can be

grouped together into a compound key. It is not necessary to define all the keys in advance; a column can be used as a key even if it was not originally intended to be one.

A key that has an external, real-world meaning (such as a person's name, a book's ISBN, or a car's serial number) is sometimes called a "natural" key. If no natural key is suitable (think of the many people named *Brown*), an arbitrary or surrogate key can be assigned (such as by giving employees ID numbers). In practice, most databases have both generated and natural keys, because generated keys can be used internally to create links between rows that cannot break, while natural keys can be used, less reliably, for searches and for integration with other databases. (For example, records in two independently developed databases could be matched up by social security number, except when the social security numbers are incorrect, missing, or have changed.)

The most common query language used with the relational model is the Structured Query Language (SQL).

Dimensional model

The dimensional model is a specialized adaptation of the relational model used to represent data in data warehouses in a way that data can be easily summarized using online analytical processing, or OLAP queries. In the dimensional model, a database schema consists of a single large table of facts that are described using dimensions and measures. A dimension provides the context of a fact (such as who participated, when and where it happened, and its type) and is used in queries to group related facts together. Dimensions tend to be discrete and are often hierarchical; for example, the location might include the building, state, and country. A measure is a quantity describing the fact, such as revenue. It is important that measures can be meaningfully aggregated—for example, the revenue from different locations can be added together.

In an OLAP query, dimensions are chosen and the facts are grouped and aggregated together to create a summary.

The dimensional model is often implemented on top of the relational model using a star schema, consisting of one highly normalized table containing the facts, and surrounding denormalized tables containing each dimension. An alternative physical implementation, called a snowflake schema, normalizes multi-level hierarchies within a dimension into multiple tables.

A data warehouse can contain multiple dimensional schemas that share dimension tables, allowing them to be used together. Coming up with a standard set of dimensions is an important part of dimensional modeling.

Its high performance has made the dimensional model the most popular database structure for OLAP.

Post-relational database models

Products offering a more general data model than the relational model are sometimes classified as *post-relational*.[3] Alternate terms include "hybrid database", "Object-enhanced RDBMS" and others. The data model in such products incorporates relations but is not constrained by E.F. Codd's Information Principle, which requires that

> all information in the database must be cast explicitly in terms of values in relations and in no other way

Some of these extensions to the relational model integrate concepts from technologies that pre-date the relational model. For example, they allow representation of a directed graph with trees on the nodes. The German company *sones* implements this concept in its GraphDB.

Some post-relational products extend relational systems with non-relational features. Others arrived in much the same place by adding relational features to pre-relational systems. Paradoxically, this allows products that are historically pre-relational, such as PICK and MUMPS, to make a plausible claim to be post-relational.

The resource space model (RSM) is a non-relational data model based on multi-dimensional classification.

Graph model

Graph databases allow even more general structure than a network database; any node may be connected to any other node.

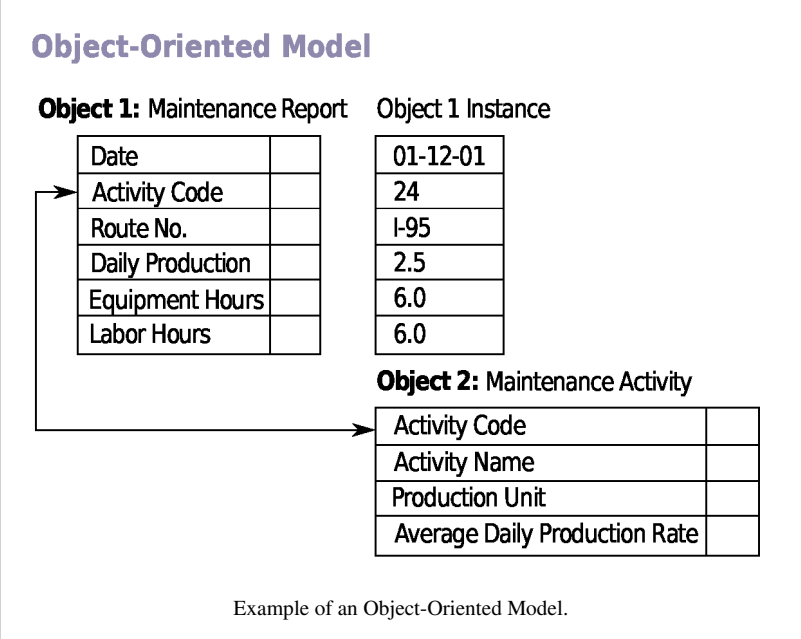
Multivalue model

Multivalue databases are "lumpy" data, in that they can store exactly the same way as relational databases, but they also permit a level of depth which the relational model can only approximate using sub-tables. This is nearly identical to the way XML expresses data, where a given field/attribute can have multiple right answers at the same time. Multivalue can be thought of as a compressed form of XML.

An example is an invoice, which in either multivalue or relational data could be seen as (A) Invoice Header Table - one entry per invoice, and (B) Invoice Detail Table - one entry per line item. In the multivalue model, we have the option of storing the data as on table, with an embedded table to represent the detail: (A) Invoice Table - one entry per invoice, no other tables needed.

The advantage is that the atomicity of the Invoice (conceptual) and the Invoice (data representation) are one-to-one. This also results in fewer reads, less referential integrity issues, and a dramatic decrease in the hardware needed to support a given transaction volume.

Object-oriented database models



Example of an Object-Oriented Model.

In the 1990s, the object-oriented programming paradigm was applied to database technology, creating a new database model known as object databases. This aims to avoid the object-relational impedance mismatch - the overhead of converting information between its representation in the database (for example as rows in tables) and its representation in the application program (typically as objects). Even further, the type system used in a particular application can be defined directly in the database, allowing the database to enforce the same data integrity invariants. Object databases also introduce the key ideas of object programming, such as encapsulation and polymorphism, into the world of databases.

A variety of these ways have been tried Wikipedia:Manual of Style/Words to watch#Unsupported attributionsfor storing objects in a database. SomeWikipedia:Avoid weasel words products have approached the problem from the application programming end, by making the objects manipulated by the program persistent. This typically requires the addition of some kind of query language, since conventional programming languages do not have the ability to find objects based on their information content. OthersWikipedia:Avoid weasel words have attacked the problem from the database end, by defining an object-oriented data model for the database, and defining a database programming language that allows full programming capabilities as well as traditional query facilities.

Object databases suffered because of a lack of standardization: although standards were defined by ODMG, they were never implemented well enough to ensure interoperability between products. Nevertheless, object databases

have been used successfully in many applications: usually specialized applications such as engineering databases or molecular biology databases rather than mainstream commercial data processing. However, object database ideas were picked up by the relational vendors and influenced extensions made to these products and indeed to the SQL language.

An alternative to translating between objects and relational databases is to use an object-relational mapping (ORM) library.

Database design

Database design is the process of producing a detailed data model of a database. This logical data model contains all the needed logical and physical design choices and physical storage parameters needed to generate a design in a Data Definition Language, which can then be used to create a database. A fully attributed data model contains detailed attributes for each entity.

The term database design can be used to describe many different parts of the design of an overall database system. Principally, and most correctly, it can be thought of as the logical design of the base data structures used to store the data. In the relational model these are the tables and views. In an object database the entities and relationships map directly to object classes and named relationships. However, the term database design could also be used to apply to the overall process of designing, not just the base data structures, but also the forms and queries used as part of the overall database application within the database management system (DBMS).[1]

The process of doing database design generally consists of a number of steps which will be carried out by the database designer. Usually, the designer must:

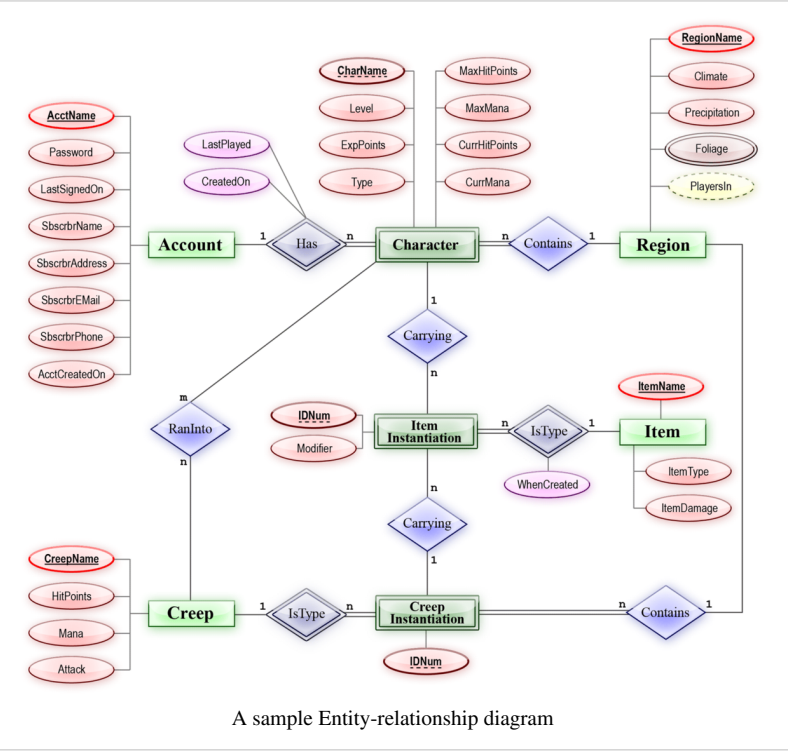
- Determine the relationships between the different data elements.
- Superimpose a logical structure upon the data on the basis of these relationships.[2]

ER diagram (entity-relationship model)

Database designs also include ER (Entity-relationship model) diagrams. An ER diagram is a diagram that helps to design databases in an efficient way.

Attributes in ER diagrams are usually modeled as an oval with the name of the attribute, linked to the entity or relationship that contains the attribute.

Within the relational model the final step can generally be broken down into two further steps, that of determining the grouping of information within the system, generally determining what are the basic objects about which information is being stored, and then determining the relationships between these groups of information, or objects. This step is not necessary with an Object database.



A sample Entity-relationship diagram

Design process[3]

1. **Determine the purpose of the database** - This helps prepare for the remaining steps.
2. **Find and organize the information required** - Gather all of the types of information to record in the database, such as product name and order number.
3. **Divide the information into tables** - Divide information items into major entities or subjects, such as Products or Orders. Each subject then becomes a table.
4. **Turn information items into columns** - Decide what information needs to be stored in each table. Each item becomes a field, and is displayed as a column in the table. For example, an Employees table might include fields such as Last Name and Hire Date.
5. **Specify primary keys** - Choose each table's primary key. The primary key is a column, or a set of columns, that is used to uniquely identify each row. An example might be Product ID or Order ID.
6. **Set up the table relationships** - Look at each table and decide how the data in one table is related to the data in other tables. Add fields to tables or create new tables to clarify the relationships, as necessary.
7. **Refine the design** - Analyze the design for errors. Create tables and add a few records of sample data. Check if results come from the tables as expected. Make adjustments to the design, as needed.
8. **Apply the normalization rules** - Apply the data normalization rules to see if tables are structured correctly. Make adjustments to the tables

Determining data to be stored

In a majority of cases, a person who is doing the design of a database is a person with expertise in the area of database design, rather than expertise in the domain from which the data to be stored is drawn e.g. financial information, biological information etc. Therefore the data to be stored in the database must be determined in cooperation with a person who does have expertise in that domain, and who is aware of what data must be stored within the system.

This process is one which is generally considered part of requirements analysis, and requires skill on the part of the database designer to elicit the needed information from those with the domain knowledge. This is because those with the necessary domain knowledge frequently cannot express clearly what their system requirements for the database are as they are unaccustomed to thinking in terms of the discrete data elements which must be stored. Data to be stored can be determined by Requirement Specification.[4]

Normalization

In the field of relational database design, **normalization** is a systematic way of ensuring that a database structure is suitable for general-purpose querying and free of certain undesirable characteristics—insertion, update, and deletion anomalies—that could lead to a loss of data integrity.

A standard piece of database design guidance is that the designer should create a fully normalized design; selective denormalization can subsequently be performed, but only for performance reasons. However, some modeling disciplines, such as the dimensional modeling approach to data warehouse design, explicitly recommend non-normalized designs, i.e. designs that in large part do not adhere to 3NF. Normalization consists of normal forms that are 1NF,2NF,3NF,BOYCE-CODD NF (3.5NF),4NF and 5NF

Types of Database design

Conceptual schema

Once a database designer is aware of the data which is to be stored within the database, they must then determine where dependency is within the data. Sometimes when data is changed you can be changing other data that is not visible. For example, in a list of names and addresses, assuming a situation where multiple people can have the same address, but one person cannot have more than one address, the address is dependent upon the name. When provided a name and the list the address can be uniquely determined; however, the inverse does not hold - when given an address and the list, a name cannot be uniquely determined because multiple people can reside at an address. Because an address is determined by a name, an address is considered dependent on a name.

(NOTE: A common misconception is that the relational model is so called because of the stating of relationships between data elements therein. This is not true. The relational model is so named because it is based upon the mathematical structures known as relations.)

Logically structuring data

Once the relationships and dependencies amongst the various pieces of information have been determined, it is possible to arrange the data into a logical structure which can then be mapped into the storage objects supported by the database management system. In the case of relational databases the storage objects are tables which store data in rows and columns.

Each table may represent an implementation of either a logical object or a relationship joining one or more instances of one or more logical objects. Relationships between tables may then be stored as links connecting child tables with parents. Since complex logical relationships are themselves tables they will probably have links to more than one parent.

In an Object database the storage objects correspond directly to the objects used by the Object-oriented programming language used to write the applications that will manage and access the data. The relationships may be defined as attributes of the object classes involved or as methods that operate on the object classes.

Schema Refinement

The Schema Refinement of the database specifies that how the data is Normalized and reduce the Data Insufficiency and Conflicts also.

Physical design

The physical design of the database specifies the physical configuration of the database on the storage media. This includes detailed specification of data elements, data types, indexing options and other parameters residing in the DBMS data dictionary. It is the detailed design of a system that includes modules & the database's hardware & software specifications of the system.

Conceptual schema

This is a high-level description of a business informational needs. It typically includes only the main concepts and the main relationship among them. Typically this is a first-cut model, with insufficient detail to build an actual database.[1]

Overview

A **conceptual schema** or **conceptual data model** is a map of concepts and their relationships used for databases. This describes the semantics of an organization and represents a series of assertions about its nature. Specifically, it describes the things of significance to an organization (*entity classes*), about which it is inclined to collect information, and characteristics of (*attributes*) and associations between pairs of those things of significance (*relationships*).

Because a conceptual schema represents the semantics of an organization, and not a database design, it may exist on various levels of abstraction. The original ANSI four-schema architecture began with the set of *external schemas* that each represent one person's view of the world around him or her. These are consolidated into a single *conceptual schema* that is the superset of all of those external views. A data model can be as concrete as each person's perspective, but this tends to make it inflexible. If that person's world changes, the model must change. Conceptual data models take a more abstract perspective, identifying the fundamental things, of which the things an individual deals with are just examples.

The model does allow for what is called inheritance in object oriented terms. The set of instances of an entity class may be subdivided into entity classes in their own right. Thus, each instance of a *sub-type* entity class is also an instance of the entity class's *super-type*. Each instance of the super-type entity class, then is also an instance of one of the sub-type entity classes.

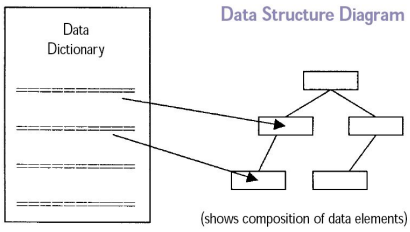
Super-type/sub-type relationships may be *exclusive* or not. A methodology may require that each instance of a super-type may *only* be an instance of *one* sub-type. Similarly, a super-type/sub-type relationship may be *exhaustive* or not. It is exhaustive if the methodology requires that each instance of a super-type *must be* an instance of a sub-type.

Example relationships

- Each PERSON may be *the vendor in* one or more ORDERS..
- Each ORDER must be *from* one and only one PERSON.
- PERSON is *a sub-type of* PARTY. (Meaning that every instance of PERSON is also an instance of PARTY.)
- Each EMPLOYEE may have a *supervisor* who is also an EMPLOYEE.

Data structure diagram

A data structure diagram (DSD) is a data model or diagram used to describe conceptual data models by providing graphical notations which document entities and their relationships, and the constraints that bind them.



Data Structure Diagram.

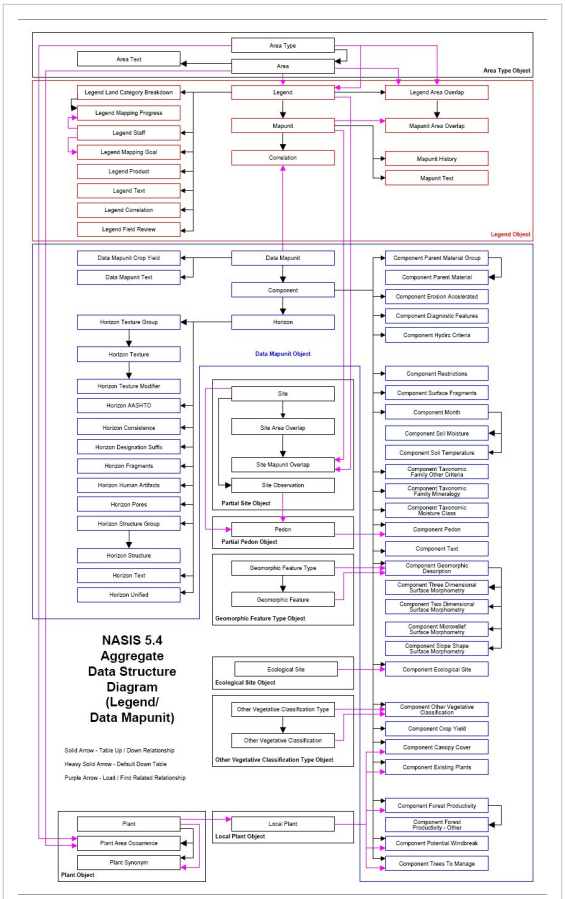
Data structure diagram

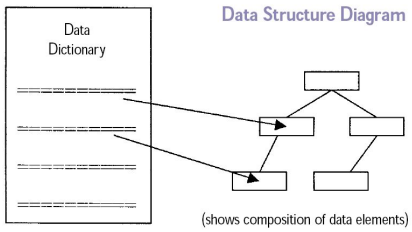
Data Structure Diagram (DSD) is a diagram of the conceptual data model which documents the entities and their relationships, as well as the constraints that connect to them.

The basic graphic notation elements of DSDs are boxes which represent entities.The arrow symbol represents relationships. Data structure diagrams are most useful for documenting complex data entities.



Example of a Data Structure Diagram.

Overview



Data Structure Diagram.

Data Structure Diagram is a diagram type that is used to depict the structure of data elements in the data dictionary. The data structure diagram is a graphical alternative to the composition specifications within such data dictionary entries.[1]

The data structure diagrams is a predecessor of the entity-relationship model (E-R model). In DSDs, attributes are specified inside the entity boxes rather than outside of them, while relationships are drawn as boxes composed of attributes which specify the constraints that bind entities together. DSDs differ from the E-R model in that the E-R model focuses on the relationships between different entities, whereas DSDs focus on the relationships of the elements within an entity.

There are several styles for representing data structure diagrams, with the notable difference in the manner of defining cardinality. The choices are between arrow heads, inverted arrow heads (crow's feet), or numerical representation of the cardinality.

Bachman diagram

A Bachman diagram is a certain type of data structure diagram,[2] and is used to design the data with a network or relational "logical" model, separating the data model from the way the data is stored in the system. The model is named after database pioneer Charles Bachman, and mostly used in computer software design.

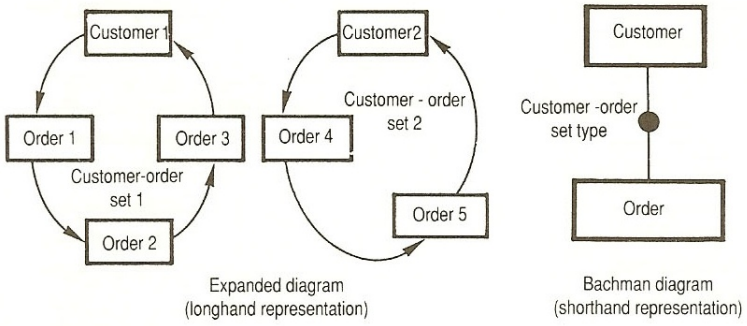


Illustration of set type using a Bachman diagram.

In a relational model, a relation is the cohesion of attributes that are fully and not transitive functional dependent[*clarify*] of every key in that relation. The coupling between the relations is based on accordant attributes. For every relation, a rectangle has to be drawn and every coupling is illustrated by a line that connects the relations. On the edge of each line, arrows indicate the cardinality. We have 1-to-n, 1-to-1 and n-to-n. The latter has to be avoided and must be replaced by two 1-to-n couplings.

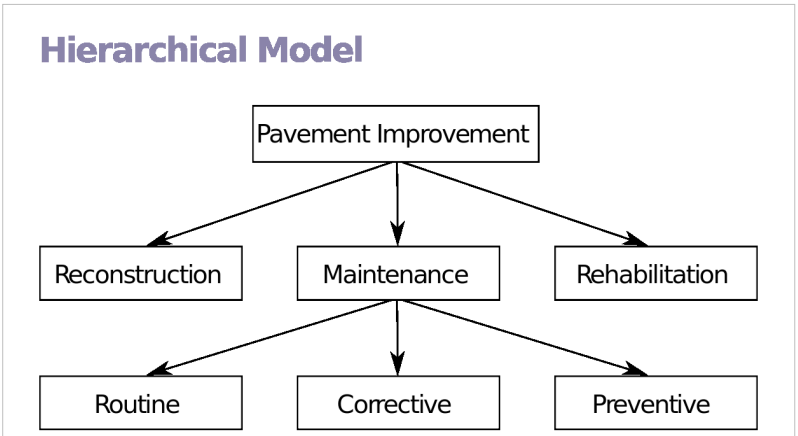
Hierarchical database model

Hierarchical model redirects here. For the statistics usage, see hierarchical linear modeling or hierarchical Bayesian model.

A **hierarchical database model** is a data model in which the data is organized into a tree-like structure. The structure allows representing information using parent/child relationships: each parent can have many children, but each child has only one parent (also known as a **1-to-many relationship**). All attributes of a specific record are listed under an entity type.

In a database an entity type is the equivalent of a table. Each individual record is represented as a row, and each attribute as a column. Entity types are related to each other using *1:N* mappings, also known as one-to-many relationships. This model is recognized as the first database model created by IBM in the 1960s.

Currently the most widely used hierarchical databases are IMS developed by IBM and Windows Registry by Microsoft.



Example of a hierarchical model

History

The hierarchical structure was used in early mainframe DBMS. Records' relationships form a treelike model. This structure is simple but inflexible because the relationship is confined to a one-to-many relationship. The IBM Information Management System (IMS) and the RDM Mobile are examples of a hierarchical database system with multiple hierarchies over the same data. RDM Mobile is a newly designed embedded database for a mobile computer system.[*citation needed*]

The hierarchical data model lost traction as Codd's relational model became the de facto standard used by virtually all mainstream database management systems. A relational-database implementation of a hierarchical model was first discussed in published form in 1992[1] (see also nested set model). Hierarchical data organization schemes resurfaced with the advent of XML in the late 1990s (see also XML database). The hierarchical structure is used primarily today for storing geographic information and file systems.[*citation needed*] Currently the most widely used hierarchical databases are IMS and Windows Registry by Microsoft.[*citation needed*]

Examples of hierarchical data represented as relational tables

An organization could store employee information in a table that contains attributes/columns such as employee number, first name, last name, and Department number. The organization provides each employee with computer hardware as needed, but computer equipment may only be used by the employee to which it is assigned. The organization could store the computer hardware information in a separate table that includes each part's serial number, type, and the employee that uses it. The tables might look like this:

EmpNo	First Name	Last Name	Dept. Num
100	Sally	Baker	10-L
101	Jack	Douglas	10-L
102	Sarah	Schultz	20-B
103	David	Drachmeier	20-B

Serial Num	Type	User EmpNo
3009734-4	Computer	100
3-23-283742	Monitor	100
2-22-723423	Monitor	100
232342	Printer	100

In this model, the employee data table represents the "parent" part of the hierarchy, while the computer table represents the "child" part of the hierarchy. In contrast to tree structures usually found in computer software algorithms, in this model the children point to the parents. As shown, each employee may possess several pieces of computer equipment, but each individual piece of computer equipment may have only one employee owner.

Consider the following structure:

EmpNo	Designation	ReportsTo
10	Director	
20	Senior Manager	10
30	Typist	20
40	Programmer	20

In this, the "child" is the same type as the "parent". The hierarchy stating EmpNo 10 is boss of 20, and 30 and 40 each report to 20 is represented by the "ReportsTo" column. In Relational database terms, the ReportsTo column is a foreign key referencing the EmpNo column. If the "child" data type were different, it would be in a different table, but there would still be a foreign key referencing the EmpNo column of the employees table.

This simple model is commonly known as the adjacency list model, and was introduced by Dr. Edgar F. Codd after initial criticisms surfaced that the relational model could not model hierarchical data.

The Windows Registry is a hierarchical database that stores configuration settings and options on Microsoft Windows operating systems.

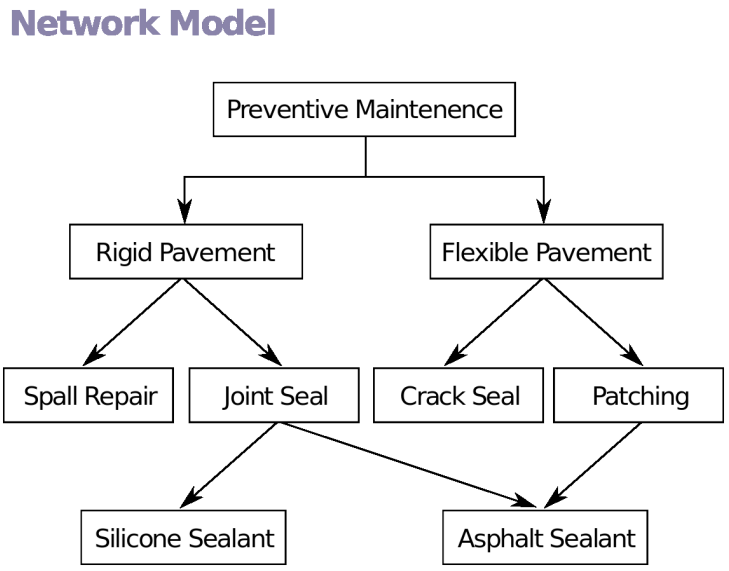
Network model

The **network model** is a database model conceived as a flexible way of representing objects and their relationships. Its distinguishing feature is that the schema, viewed as a graph in which object types are nodes and relationship types are arcs, is not restricted to being a hierarchy or lattice.



Example of a Network Model.

Overview

While the hierarchical database model structures data as a tree of records, with each record having one parent record and many children, the network model allows each record to have multiple parent and child records, forming a generalized graph structure. This property applies at two levels: the schema is a generalized graph of record types connected by relationship types (called "set types" in CODASYL), and the database itself is a generalized graph of record occurrences connected by relationships (CODASYL "sets"). Cycles are permitted at both levels. The chief argument in favour of the network model, in comparison to the hierarchic model, was that it allowed a more natural modeling of relationships between entities. Although the model was widely implemented and used, it failed to become dominant for two main reasons. Firstly, IBM chose to stick to the hierarchical model with semi-network extensions in their established products such as IMS and DL/I. Secondly, it was eventually displaced by the relational model, which offered a higher-level, more declarative interface. Until the early 1980s the performance benefits of the low-level navigational interfaces offered by hierarchical and network databases were persuasive for many large-scale applications, but as hardware became faster, the extra productivity and flexibility of the relational model led to the gradual obsolescence of the network model in corporate enterprise usage.

Database systems

Some well-known database systems that use the network model include:

- Integrated Data Store (IDS)
- IDMS (Integrated Database Management System)
- RDM Embedded
- RDM Server
- TurboIMAGE
- Univac DMS-1100

History

The network model's original inventor was Charles Bachman, and it was developed into a standard specification published in 1969 by the Conference on Data Systems Languages (CODASYL) Consortium. This was followed by a second publication in 1971, which became the basis for most implementations. Subsequent work continued into the early 1980s, culminating in an ISO specification, but this had little influence on products.

Navigational database

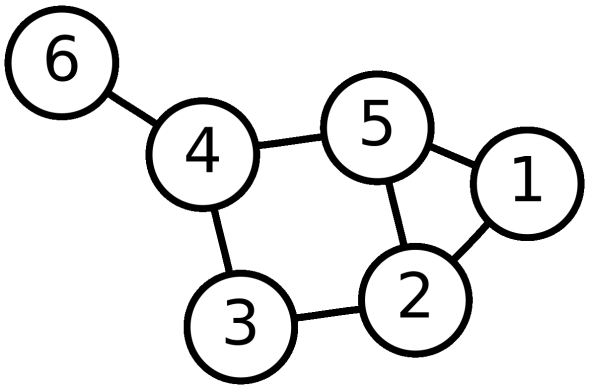
A **navigational database** is a type of database in which records or objects are found primarily by following references from other objects. Navigational interfaces are usually procedural, though some modern systems like XPath can be considered to be simultaneously navigational and declarative.

Navigational access is traditionally associated with the network model and hierarchical model of database interfaces, and some have even acquired set-oriented features. Navigational techniques use "pointers" and "paths" to navigate among data records (also known as "nodes"). This is in contrast to the relational model (implemented in relational databases), which strives to use "declarative" or logic programming techniques that ask the system for *what* to fetch instead of *how* to navigate to it.

For example, to give directions to a house, the navigational approach would resemble something like "Get on highway 25 for 8 miles, turn onto Horse Road, left at the red barn, then stop at the 3rd house down the road", whereas the declarative approach would resemble "Visit the green house(s) within the following coordinates...."

Hierarchical models are also considered navigational because one "goes" up (to parent), down (to leaves), and there are "paths", such as the familiar file/folder paths in hierarchical file systems. In general, navigational systems will use combinations of paths and prepositions such as "next", "previous", "first", "last", "up", "down", "owner", etc.

"Paths" are often formed by concatenation of node names or node addresses. Example:



Sample database nodes: A labeled graph on 6 vertices and 7 edges. (Numbers are used for illustration purposes only. In practice more meaningful names are often used. Other potential attributes are not shown.)

```
Node6.Node4.Node5.Node1
```

Or

```
Node6/Node4/Node5/Node1
```

If there is no link between given nodes, then an error condition is usually triggered with a message such as "Invalid Path". The path "Node6.Node2.Node1" would be invalid in most systems because there is no direct link between Node 6 and Node 2.

The usage of the term "navigational" allegedly is derived from a statement by Charles Bachman in which he describes the "programmer as navigator" while accessing his favored type of database.

Except for hierarchical file systems (which some consider a form of database), navigational techniques fell out of favor by the 1980s. However, object oriented programming and XML have kindled a renewed, but controversial interest in navigational techniques.

Critics of navigational techniques view them as "unstructured spaghetti messes", and liken them to the "goto" of pre-structured programming. In other words, they are allegedly to data organization what goto's were to behavior flow. In this view, relational techniques provide improved discipline and consistency to data organization and usage because of its roots in set theory and predicate calculus.

Some also suggest that navigational database engines are easier to build and take up less memory (RAM) than relational equivalents. However, the existence of relational or relational-based products of the late 1980s that possessed small engines (by today's standards) because they didn't use SQL suggest this is not necessarily the case. Whatever the reason, navigational techniques are still the preferred way to handle smaller-scale structures.

A current example of navigational structuring can be found in the Document Object Model (DOM) often used in web browsers and closely associated with JavaScript. The DOM "engine" is essentially a light-weight navigational database. The World Wide Web itself and Wikipedia could potentially be considered forms of navigational databases, though they focus on human-readable text rather than data (on a large scale, the Web is a network model and on smaller or local scales, such as domain and URL partitioning, it uses hierarchies). In contrast, the Linked Data facet of the Semantic Web is specifically concerned with network-scale machine-readable data, and follows precisely the 'follow your nose' paradigm implied by the navigational idea.

A new kind of navigational databases has recently emerged, the Graph databases. This category of databases is often included as one of the four family of the NoSQL databases.

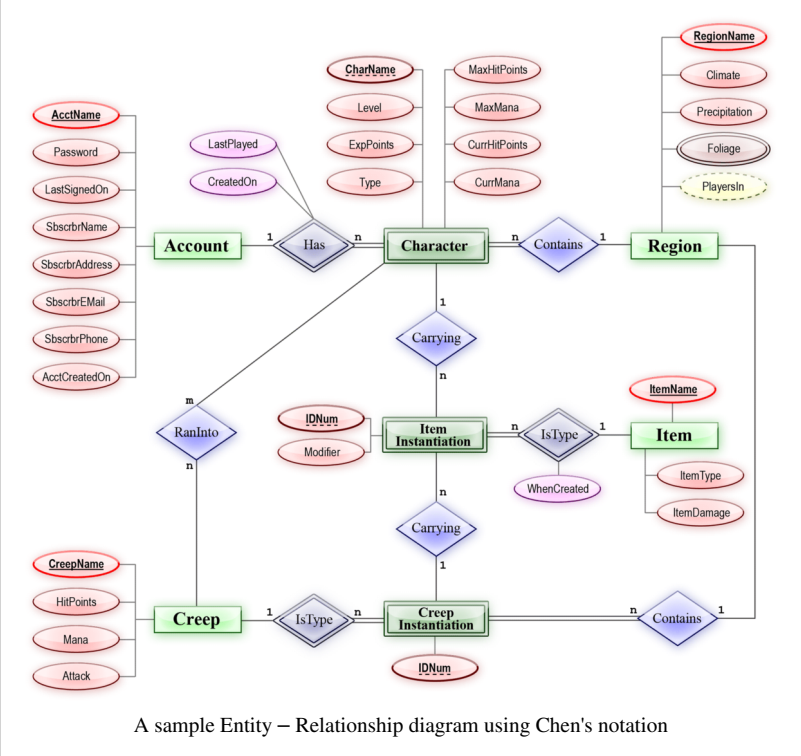
ERD

Entity-relationship model

In software engineering, an **entity–relationship model** (**ER model**) is a data model for describing the data or information aspects of a business domain or its process requirements, in an abstract way that lends itself to ultimately being implemented in a database such as a relational database. The main components of ER models are *entities* (things) and the *relationships* that can exist among them. This article refers to the techniques proposed in Peter Chen's 1976 paper.[1] However, variants of the idea existed previously,[2] and have been devised subsequently such as supertype and subtype data entities[3] and commonality relationships.



A sample Entity – Relationship diagram using Chen's notation

Overview

An ER model is an abstract way of describing a database. In the case of a relational database, which stores data in tables, some of the data in these tables point to data in other tables - for instance, your entry in the database could point to several entries for each of the phone numbers that are yours. The ER model would say that you are an entity, and each phone number is an entity, and the relationship between you and the phone numbers is 'has a phone number'. Diagrams created to design these entities and relationships are called entity–relationship diagrams or ER diagrams.

Using the three schema approach to software engineering, there are three levels of ER models that may be developed.

Conceptual data model

> This is the highest level ER model in that it contains the least granular detail but establishes the overall scope of what is to be included within the model set. The conceptual ER model normally defines master reference data entities that are commonly used by the organization. Developing an enterprise-wide conceptual ER model is useful to support documenting the data architecture for an organization.
>
> A conceptual ER model may be used as the foundation for one or more *logical data models* (see below). The purpose of the conceptual ER model is then to establish structural metadata commonality for the master data entities between the set of logical ER models. The conceptual data model may be used to form commonality relationships between ER models as a basis for data model integration.

Logical data model

A logical ER model does not require a conceptual ER model, especially if the scope of the logical ER model includes only the development of a distinct information system. The logical ER model contains more detail than the conceptual ER model. In addition to master data entities, operational and transactional data entities are now defined. The details of each data entity are developed and the entity relationships between these data entities are established. The logical ER model is however developed independent of technology into which it will be implemented.

Physical data model

One or more physical ER models may be developed from each logical ER model. The physical ER model is normally developed to be instantiated as a database. Therefore, each physical ER model must contain enough detail to produce a database and each physical ER model is technology dependent since each database management system is somewhat different.

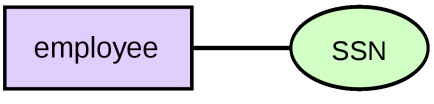
The physical model is normally forward engineered to instantiate the structural metadata into a database management system as relational database objects such as database tables, database indexes such as unique key indexes, and database constraints such as a foreign key constraint or a commonality constraint. The ER model is also normally used to design modifications to the relational database objects and to maintain the structural metadata of the database.

The first stage of information system design uses these models during the requirements analysis to describe information needs or the type of information that is to be stored in a database. The data modeling technique can be used to describe any ontology (i.e. an overview and classifications of used terms and their relationships) for a certain area of interest. In the case of the design of an information system that is based on a database, the conceptual data model is, at a later stage (usually called logical design), mapped to a logical data model, such as the relational model; this in turn is mapped to a physical model during physical design. Note that sometimes, both of these phases are referred to as "physical design". It is also used in database management system.

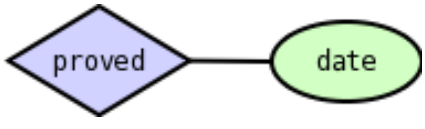
Entity–relationship modelling

An entity may be defined as a thing which is recognized as being capable of an independent existence and which can be uniquely identified. An entity is an abstraction from the complexities of a domain. When we speak of an entity, we normally speak of some aspect of the real world which can be distinguished from other aspects of the real world.[4]

Two related entities



An entity with an attribute



A relationship with an attribute

An entity may be a physical object such as a house or a car, an event such as a house sale or a car service, or a concept such as a customer transaction or order. Although the term entity is the one most commonly used, following Chen we should really distinguish between an entity and an entity-type. An entity-type is a category. An entity, strictly speaking, is an instance of a given entity-type. There are usually many instances of an entity-type. Because the term entity-type is somewhat cumbersome, most people tend to use the term entity as a synonym for this term.

Entities can be thought of as nouns. Examples: a computer, an employee, a song, a mathematical theorem.

A relationship captures how entities are related to one another. Relationships can be thought of as verbs, linking two or more nouns. Examples: an *owns* relationship between a company and a computer, a *supervises* relationship between an employee and a department, a *performs* relationship between an artist and a song, a *proved* relationship between a mathematician and a theorem.

Primary key

The model's linguistic aspect described above is utilized in the declarative database query language ERROL, which mimics natural language constructs. ERROL's semantics and implementation are based on reshaped relational algebra (RRA), a relational algebra which is adapted to the entity–relationship model and captures its linguistic aspect.

Entities and relationships can both have attributes. Examples: an *employee* entity might have a *Social Security Number* (SSN) attribute; the *proved* relationship may have a *date* attribute.

Every entity (unless it is a weak entity) must have a minimal set of uniquely identifying attributes, which is called the entity's primary key.

Entity–relationship diagrams don't show single entities or single instances of relations. Rather, they show entity sets and relationship sets. Example: a particular *song* is an entity. The collection of all songs in a database is an entity set. The *eaten* relationship between a child and her lunch is a single relationship. The set of all such child-lunch relationships in a database is a relationship set. In other words, a relationship set corresponds to a relation in mathematics, while a relationship corresponds to a member of the relation.

Certain cardinality constraints on relationship sets may be indicated as well.

Mapping natural language

Chen proposed the following "rules of thumb" for mapping natural language descriptions into ER diagrams:[5]

English grammar structure	ER structure
Common noun	Entity type
Proper noun	Entity
Transitive verb	Relationship type
Intransitive verb	Attribute type
Adjective	Attribute for entity
Adverb	Attribute for relationship

Physical view show how data is actually stored.

Relationships, roles and cardinalities

In Chen's original paper he gives an example of a relationship and its roles. He describes a relationship "marriage" and its two roles "husband" and "wife".

A person plays the role of husband in a marriage (relationship) and another person plays the role of wife in the (same) marriage. These words are nouns. That is no surprise; naming things requires a noun.

However as is quite usual with new ideas, many eagerly appropriated the new terminology but then applied it to their own old ideas. Thus the lines, arrows and crows-feet of their diagrams owed more to the earlier Bachman diagrams than to Chen's relationship diamonds. And they similarly misunderstood other important concepts.[*citation needed*]

In particular, it became fashionable (now almost to the point of exclusivity) to "name" relationships and roles as verbs or phrases.

Role naming

It has also become prevalent to name roles with phrases e.g. is-the-owner-of and is-owned-by etc. Correct nouns in this case are "owner" and "possession". Thus "person plays the role of owner" and "car plays the role of possession" rather than "person plays the role of is-the-owner-of" etc.

The use of nouns has direct benefit when generating physical implementations from semantic models. When a person has two relationships with car then it is possible to very simply generate names such as "owner_person" and "driver_person" which are immediately meaningful.[6]

Cardinalities

Modifications to the original specification can be beneficial. Chen described look-across cardinalities. As an aside, the Barker-Ellis notation, used in Oracle Designer, uses same-side for minimum cardinality (analogous to optionality) and role, but look-across for maximum cardinality (the crows foot).Wikipedia:Please clarify

In Merise,[7] Elmasri & Navathe[8] and others[9] there is a preference for same-side for roles and both minimum and maximum cardinalities. Recent researchers (Feinerer,[10] Dullea et al.[11]) have shown that this is more coherent when applied to n-ary relationships of order > 2.

In Dullea et al. one reads "A 'look across' notation such as used in the UML does not effectively represent the semantics of participation constraints imposed on relationships where the degree is higher than binary."

In Feinerer it says "Problems arise if we operate under the look-across semantics as used for UML associations. Hartmann[12] investigates this situation and shows how and why different transformations fail." *(Although the "reduction" mentioned is spurious as the two diagrams 3.4 and 3.5 are in fact the same)* and also "As we will see on the next few pages, the look-across interpretation introduces several difficulties which prevent the extension of simple mechanisms from binary to n-ary associations."

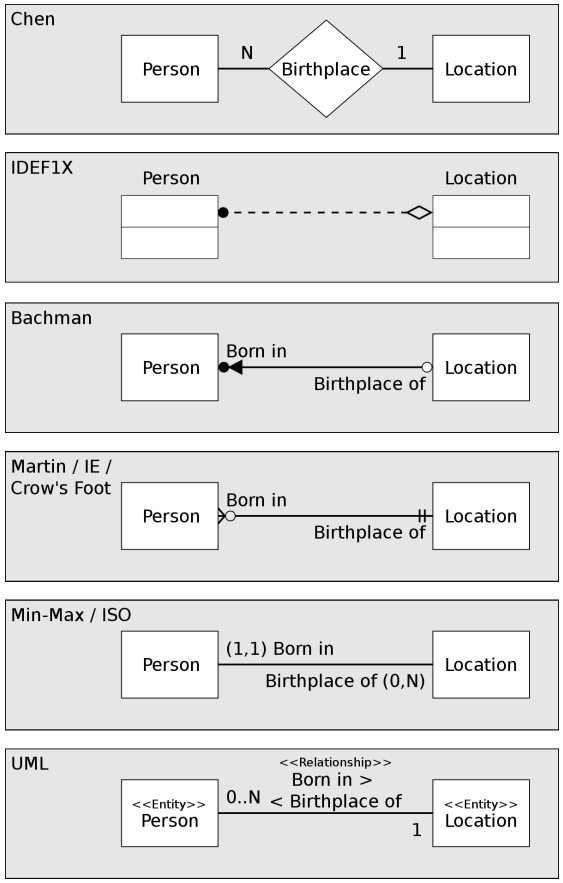
Chen's notation for entity–relationship modeling uses rectangles to represent entity sets, and diamonds to represent relationships appropriate for first-class objects: they can have attributes and relationships of their own. If an entity set participates in a relationship set, they are connected with a line.

Attributes are drawn as ovals and are connected with a line to exactly one entity or relationship set.

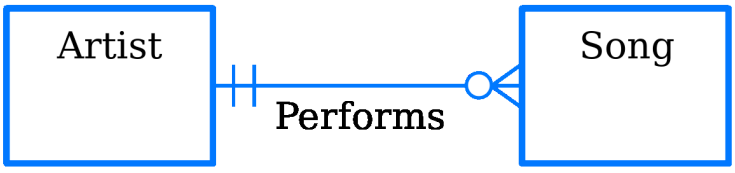
Cardinality constraints are expressed as follows:

- a double line indicates a *participation constraint*, totality or surjectivity: all entities in the entity set must participate in *at least one* relationship in the relationship set;
- an arrow from entity set to relationship set indicates a key constraint, i.e. injectivity: each entity of the entity set can participate in *at most one* relationship in the relationship set;
- a thick line indicates both, i.e. bijectivity: each entity in the entity set is involved in *exactly one* relationship.
- an underlined name of an attribute indicates that it is a key: two different entities or relationships with this attribute always have different values for this attribute.

Attributes are often omitted as they can clutter up a diagram; other diagram techniques often list entity attributes within the rectangles drawn for entity sets.



Various methods of representing the same one to many relationship. In each case, the diagram shows the relationship between a person and a place of birth: each person must have been born at one, and only one, location, but each location may have had zero or more people born at it.



Two related entities shown using Crow's Foot notation. In this example, an optional relationship is shown between Artist and Song; the symbols closest to the song entity represents "zero, one, or many", whereas a song has "one and only one" Artist. The former is therefore read as, an Artist (can) perform(s) "zero, one, or many" song(s).

Related diagramming convention techniques:

- Bachman notation
- Barker's Notation
- EXPRESS
- IDEF1X[13]
- Martin notation
- (min, max)-notation of Jean-Raymond Abrial in 1974

- UML class diagrams
- Merise
- Object-Role Modeling

Crow's Foot Notation

Crow's Foot notation is used in Barker's Notation, SSADM and Information Engineering. Crow's Foot diagrams represent entities as boxes, and relationships as lines between the boxes. Different shapes at the ends of these lines represent the cardinality of the relationship.

Crow's Foot notation was used in the consultancy practice CACI. Many of the consultants at CACI (including Richard Barker) subsequently moved to Oracle UK, where they developed the early versions of Oracle's CASE tools, introducing the notation to a wider audience. The following tools use Crow's Foot notation: ARIS, System Architect, Visio, PowerDesigner, Toad Data Modeler, DeZign for Databases, Devgems Data Modeler, OmniGraffle, MySQL Workbench and SQL Developer Data Modeler. CA's ICASE tool, CA Gen aka Information Engineering Facility also uses this notation. Historically XA Systems Silverrun-LDM (logical data model) also supported this notation.

ER diagramming tools

There are many ER diagramming tools. Free software ER diagramming tools that can interpret and generate ER models and SQL and do database analysis are MySQL Workbench (formerly DBDesigner), and Open ModelSphere (open-source). A freeware ER tool that can generate database and application layer code (webservices) is the RISE Editor. SQL Power Architect while proprietary also has a free community edition.

Proprietary ER diagramming tools are Avolution, ER/Studio, ERwin, DeZign for Databases, MagicDraw, MEGA International, ModelRight, Navicat Data Modeler, OmniGraffle, Oracle Designer, PowerDesigner, Prosa Structured Analysis Tool, Rational Rose, Software Ideas Modeler, Sparx Enterprise Architect, SQLyog, System Architect, Toad Data Modeler, and Visual Paradigm.

Free software diagram tools just draw the shapes without having any knowledge of what they mean, nor do they generate SQL. These include Creately, yEd, LucidChart, Calligra Flow, and Dia.

ER and semantic modelling

Peter Chen, the father of ER modelling said in his seminal paper:

> "*The entity-relationship model adopts the more natural view that the real world consists of entities and relationships. It incorporates some of the important semantic information about the real world.*"

He is here in accord with philosophic and theoretical traditions from the time of the Ancient Greek philosophers: Socrates, Plato and Aristotle (428 BC) through to modern epistemology, semiotics and logic of Peirce, Frege and Russell. Plato himself associates knowledge with the apprehension of unchanging Forms (The forms, according to Socrates, are roughly speaking archetypes or abstract representations of the many types of things, and properties) and their relationships to one another. In his original 1976 article Chen explicitly contrasts entity–relationship diagrams with record modelling techniques:

> "*The data structure diagram is a representation of the organisation of records and is not an exact representation of entities and relationships.*"

Several other authors also support his program:[14][15][16][17][18]

A semantic model is a model of concepts, it is sometimes called a "platform independent model". It is an intensional model. At the latest since Carnap, it is well known that:[19]

> *"...the full meaning of a concept is constituted by two aspects, its intension and its extension. The first part comprises the embedding of a concept in the world of concepts as a whole, i.e. the totality of all relations to*

other concepts. The second part establishes the referential meaning of the concept, i.e. its counterpart in the real or in a possible world".

An extensional model is one which maps to the elements of a particular methodology or technology, and is thus a "platform specific model". The UML specification explicitly states that associations in class models are extensional and this is in fact self-evident by considering the extensive array of additional "adornments" provided by the specification over and above those provided by any of the prior candidate "semantic modelling languages"."UML as a Data Modeling Notation, Part 2" [20]

Limitations

- ER models assume information content that can readily be represented in a relational database. They describe only a relational structure for this information.
- They are inadequate for systems in which the information cannot readily be represented in relational form, such as with semi-structured data.
- For many systems, possible changes to information contained are nontrivial and important enough to warrant explicit specification.
- SomeWikipedia:Avoid weasel words authors have extended ER modeling with constructs to represent change, an approach supported by the original author;[21] an example is Anchor Modeling. An alternative is to model change separately, using a process modeling technique. Additional techniques can be used for other aspects of systems. For instance, ER models roughly correspond to just 1 of the 14 different modeling techniques offered by UML.
- ER modeling is aimed at specifying information from scratch. This suits the design of new, standalone information systems, but is of less help in integrating pre-existing information sources that already define their own data representations in detail.
- Even where it is suitable in principle, ER modeling is rarely used as a separate activity. One reason for this is today's abundance of tools to support diagramming and other design support directly on relational database management systems. These tools can readily extract database diagrams that are very close to ER diagrams from existing databases, and they provide alternative views on the information contained in such diagrams.
- In a survey, Brodie and Liu[22] could not find a single instance of entity–relationship modeling inside a sample of ten Fortune 100 companies. Badia and Lemire[23] blame this lack of use on the lack of guidance but also on the lack of benefits, such as lack of support for data integration.
- The enhanced entity–relationship model (EER modeling) introduces several concepts which are not present in ER modeling, which are closely related to object-oriented design, like is-a relationships.
- For modelling temporal databases, numerous ER extensions have been considered.[24] Similarly, the ER model was found unsuitable for multidimensional databases (used in OLAP applications); no dominant conceptual model has emerged in this field yet, although they generally revolve around the concept of OLAP cube (also known as *data cube* within the field).

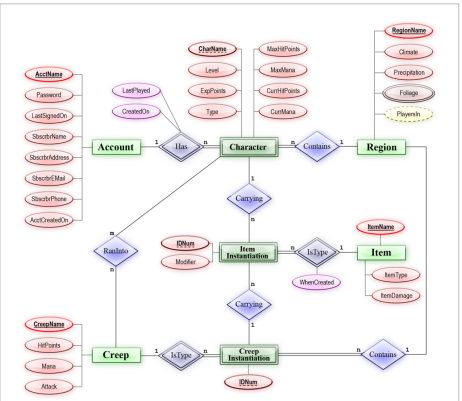
Has-a

In database design and object oriented program architecture, **has-a** is a relationship where one object (often called the composited object) "belongs" to (is a part or member of) another object (called the composite type), and behaves according to the rules of ownership. In simple words, **has-a** relationship in an object is called a member field of an object. Multiple **has-a** relationships will combine to form a possessive hierarchy. This is contrasted with an Is-a relationship which constitutes a different kind of hierarchy (subtyping). The decision whether the most logical relationship for an object and its subordinate is not always clearly *has-a* or *is-a*. Confusion over such decisions have necessitated the creation of these metalinguistic terms. A good example of the *has-a* relationship is containers in the C++ STL.

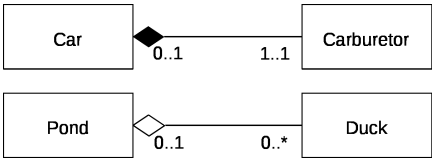
Examples

In databases has-a relationships are usually represented in an Entity-relationship model. As you can see by the diagram on the right an account can have multiple characters. This shows that account has a "has-a" relationship with character.

In object-oriented programming this relationship can be represented with a Unified Modeling Language diagram. This has-a relationship is also known as composition. As you can see from the diagram on the right a car "has-a " carburetor, or a car is "composed of" a carburetor. When the diamond is coloured black it signifies composition, i.e. the object on the side closest to the diamond is made up of or contains the other object. While the white diamond signifies aggregation, which means that the object closest to the diamond can have or possess the other object.



ER Model



Misuses of composition and aggregation

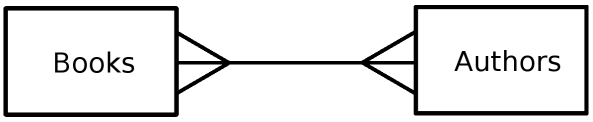
Another way to distinguish between composition and aggregation in modeling the real world, is to consider the relative lifetime of the contained object. For example, if a Car object contains a Chassis object, a Chassis will most likely not be replaced during the lifetime of the Car. It will have the same lifetime as the car itself; so the relationship is one of composition. On the other hand, if the Car object contains a set of Tire objects, these Tire objects may wear out and get replaced several times. Or if the Car becomes unusable, some Tires may be salvaged and assigned to another Car. At any rate, the Tire objects have different lifetimes than the Car object; therefore the relationship is one of aggregation.

The diagram on the right shows a very common misuse of the aggregation concept. It is nowadays common to see almost every relationship in a UML model marked as an aggregation. However it makes no sense to say that "a pond is an aggregation of ducks". The diagram is also incorrect in its example of composition. A carburetor is not necessarily dependent on the car for existence. It could be on a shelf somewhere. The car is an aggregate of its parts. An order-line on the other hand lives and dies with the order. It is therefore correct to say that the order is a composition of order-lines.

If one were to make a C++ software Class to implement the relationships described above, the Car object would contain a complete Chassis object in a data member. This Chassis object would be instantiated in the constructor of the Car class (or defined as the data type of the data member and its properties assigned in the constructor.) And since it would be a wholly contained data member of the Car class, the Chassis object would no longer exist if a Car class object was to be deleted.

On the other hand, the Car class data members that point to Tire objects would most likely be C++ pointers. Tire objects could be instantiated and deleted externally, or even assigned to data members of a different Car object. Tire objects would have an independent lifetime separate from when the Car object was deleted.

Many-to-many (data model)



An Author can write several Books, and a Book can be written by several Authors

In systems analysis, a **many-to-many** relationship is a type of cardinality that refers to the relationship between two entities (see also entity–relationship model) A and B in which A may contain a parent row[*clarify*] for which there are many children[*clarify*] in B and vice versa. For instance, think of A as Authors, and B as Books. An Author can write several Books, and a Book can be written by several Authors. Because most database management systems only support one-to-many relationships, it is necessary to implement such relationships physically via a third junction table (also called *cross-reference table*), say, AB with two one-to-many relationships A -> AB and B -> AB. In this case the logical primary key for AB is formed from the two foreign keys (i.e. copies of the primary keys of A and B).

In web application frameworks such as CakePHP and Ruby on Rails, a **many-to-many** relationship between database tables in a model is sometimes referred to as a HasAndBelongsToMany (HABTM) relationship.[1]

Enhanced Entity-Relationship Model

The **enhanced entity–relationship (EER)** model (or **extended entity-relationship** model) in computer science is a high-level or conceptual data model incorporating extensions to the original entity–relationship (ER) model, used in the design of databases.

It was developed to reflect more precisely the properties and constraints that are found in more complex databases, such as in engineering design and manufacturing (CAD/CAM), telecommunications, complex software systems and geographic information systems (GIS).

The EER model

The EER model includes all of the concepts introduced by the ER model. Additionally it includes the concepts of a subclass and superclass (Is-a), along with the concepts of specialization and generalization. Furthermore, it introduces the concept of a union type or category, which is used to represent a collection of objects that is the union of objects of different entity types.

Subclass and superclass

Entity type Y is a subtype (subclass) of an entity type X if and only if every Y is necessarily an X. A subclass entity inherits all attributes and relationships of its superclass entity. A subclass entity may have its own specific attributes and relationships (together with all the attributes and relationships it inherits from the superclass. One of the most common superclass examples is a vehicle with subclasses of Car and Truck. There are a number of common attributes between a car and a truck, which would be part of the Superclass, while the attributes specific to a car or a truck (such as max payload, truck type...) would make up two subclasses.

Software tools for the EER model

The MySQL Workbench offers creating, editing and exporting EER Models. Exporting to PNG and PDF allows easy sharing for presentations.

Weak entity

In a relational database, a **weak entity** is an entity that cannot be uniquely identified by its attributes alone; therefore, it must use a foreign key in conjunction with its attributes to create a primary key. The foreign key is typically a primary key of an entity it is related to.

In entity relationship diagrams a weak entity set is indicated by a bold (or double-lined) rectangle (the entity) connected by a bold (or double-lined) type arrow to a bold (or double-lined) diamond (the relationship). This type of relationship is called an *identifying relationship* and in IDEF1X notation it is represented by an oval entity rather than a square entity for base tables. An identifying relationship is one where the primary key is populated to the child weak entity as a primary key in that entity.

In general (though not necessarily) a weak entity does not have any items in its primary key other than its inherited primary key and a sequence number. There are two types of weak entities: associative entities and subtype entities. The latter represents a crucial type of normalization, where the super-type entity inherits its attributes to subtype entities based on the value of the discriminator.

In IDEF1X, a government standard for capturing requirements, possible sub-type relationships are:

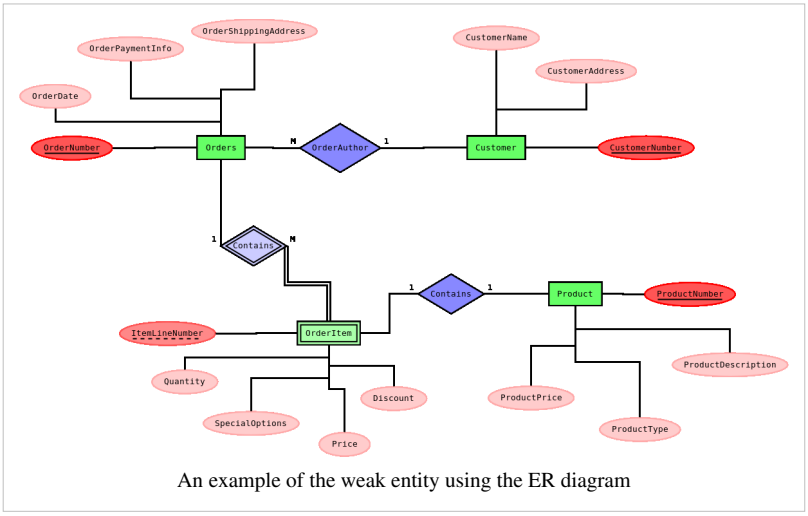
- *Complete subtype relationship*, when all categories are known.
- *Incomplete subtype relationship*, when all categories may not be known.

A classic example of a weak entity without a sub-type relationship would be the "header/detail' records in many real world situations such as claims, orders and invoices, where the header captures information common across all forms and the detail captures information specific to individual items.

The standard example of a **complete subtype relationship** is the *party* entity. Given the discriminator PARTY TYPE (which could be individual, partnership, C Corporation, Sub Chapter S Association, Association, Governmental Unit, Quasi-governmental agency) the two subtype entities are PERSON, which contains individual-specific information such as first and last name and date of birth, and ORGANIZATION, which would contain such attributes as the legal name, and organizational hierarchies such as cost centers.

When sub-type relationships are rendered in a database, the super-type becomes what is referred to as a base table. The sub-types are considered derived tables, which correspond to weak entities. Referential integrity is enforced via cascading updates and deletes.

Example



An example of the weak entity using the ER diagram

Consider a database that records customer orders, where an order is for one or more of the items that the enterprise sells. The database would contain a table identifying customers by a customer number (primary key); another identifying the products that can be sold by a product number (primary key); and it would contain a pair of tables describing orders.

One of the tables could be called Orders and it would have an order number (primary key) to identify this order uniquely, and would contain a customer number (foreign key) to identify who the products are being sold to, plus other information such as the date and time when the order was placed, how it will be paid for, where it is to be shipped to, and so on.

The other table could be called OrderItem; it would be identified by a compound key consisting of both the order number (foreign key) and an item line number; with other non-primary key attributes such as the product number (foreign key) that was ordered, the quantity, the price, any discount, any special options, and so on. There may be zero, one or many OrderItem entries corresponding to an Order entry, but no OrderItem entry can exist unless the corresponding Order entry exists. (The zero OrderItem case normally only applies transiently, when the order is first entered and before the first ordered item has been recorded.)

The OrderItem table stores *weak entities* precisely because an OrderItem has no meaning independent of the Order. Some might argue that an OrderItem does have some meaning on its own; it records that at some time not identified by the record, somebody not identified by the record ordered a certain quantity of a certain product. This information might be of some use on its own, but it is of limited use. For example, as soon as you want to find seasonal or geographical trends in the sales of the item, you need information from the related Order record.

An order would not exist without a product and a person to create the order, so it could be argued that an order would be described as a weak entity and that products ordered would be a multivalue attribute of the order.

Associative Entities

An **associative entity** is an element of the entity–relationship model. The database relational model does not offer direct support to many-to-many relationships, even though such relationships happen frequently in normal usage. The solution to this problem is the creation of another table to hold the necessary information for this relationship. This new table is called an **associative entity**.

An associative entity

To create a relationship, a "child" entity must inherit the primary key of a "parent" entity. However, in a many-to-many relationship, neither entity is the "parent" or the "child"; the relationship is "unresolved". In order to work, these databases require an additional construct to "resolve" the relationship (which is why associative entities are also referred to as "resolving entities").

An associative entity can be thought of as both an entity and a relationship since it encapsulates properties from both. It is a relationship since it is serving to join two or more entities together, but it is also an entity since it may have its own properties. The associative entity must have the primary keys of both adjoining tables as identifiers, but may also contain its own unique identifier and other information about the relationship.

The following guidelines may be used when considering the use of an associative entity:

- All relationships for the associative entity should be many.
- The associative entity could have meaning independent of the other entities.
- The associative entity should not have an additional surrogate key (identity column). The primary key should be a composite of the primary keys from the referenced entities. If the association is temporal, the transaction time may also be part of this composite key. If other entities will be referencing the associative entity and the composite of the referenced primary keys creates a large byte width for the associative entity's primary key, an exception may be made for this rule and an identity column may be added and used as the primary key. In these cases, an alternate key constraint should be implemented on the entity which would be the composite of the referenced primary keys.
- The associative entity may participate in relationships other than the entities of the associated relationship.

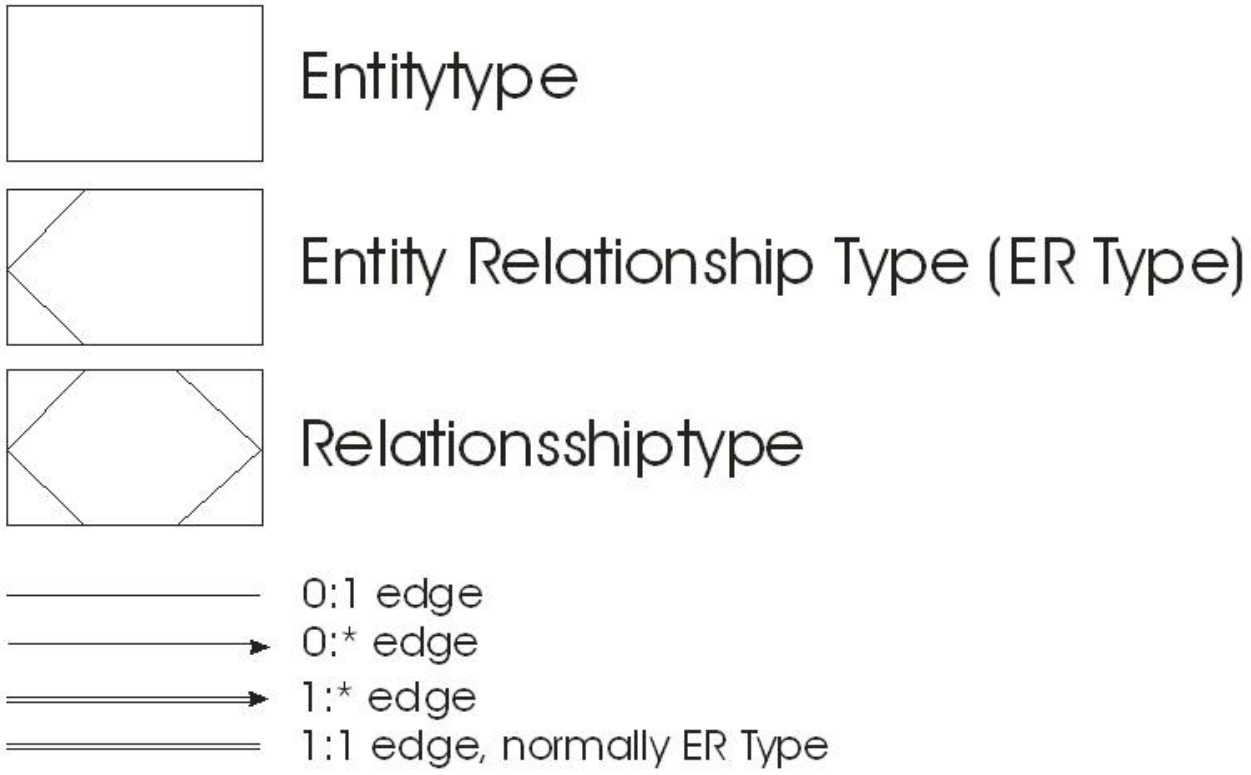
Structured-Entity-Relationship-Model

The **SERM** (Structured Entity Relationship Model) is an amplification of the ERM which is commonly used for data modeling. It was first proposed from Prof. Dr. Sinz in 1989. The SERM is commonly used in the SAP-world for the data modeling.

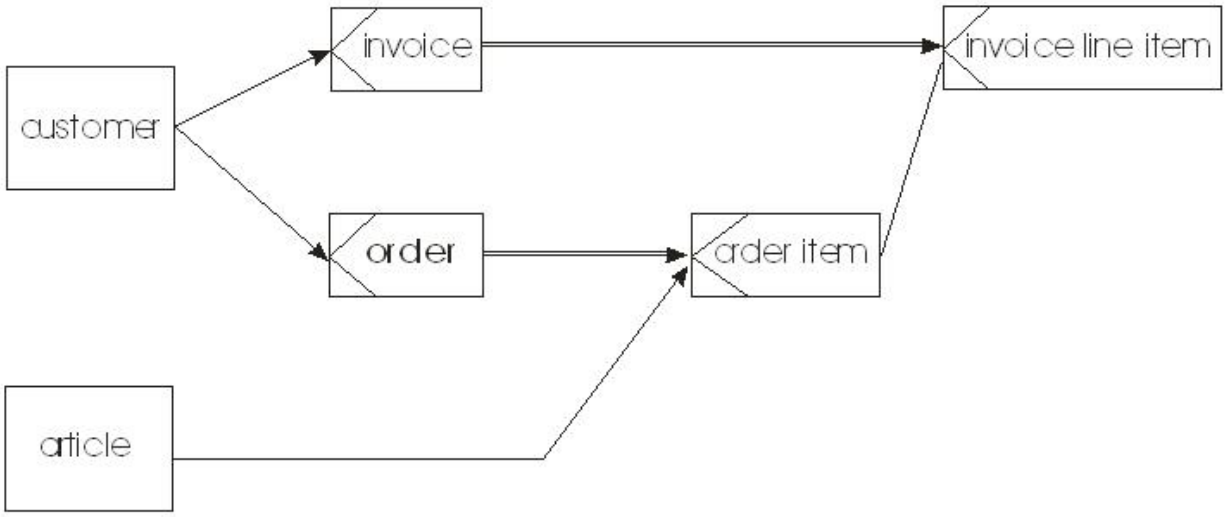
Aims

1. structuring of large schemes
2. visualization of existence dependency
3. avoidance of inconsistencies
4. avoidance of unnecessary relationshiptypes

SERM-Symbols



SERM-Example



- Customer and article are independent entities
- Every order is referred to one customer. Orders without customers are illegal (order is an ER Type). Customers without any orders are legal because they are independent Entities.
- To every order there is belonging at least one order item.
- Every order item is related to exactly one order.
- Every invoice is referred to one customer, as well. Invoices without customers are illegal. Customers without any invoice are legal.
- To every invoice there is belonging at least one invoice line item.
- Every invoice line item is related to exactly order item. An order item could be calculated or not.
- SERM is already in the third normal form

Barker's Notation

Barker's notation refers to the ERD notation developed by Richard Barker, Ian Palmer, Harry Ellis et al. whilst working at the British consulting firm CACI around 1981. The notation was adopted by Barker when he joined Oracle and is effectively defined in his book *Entity Relationship Modelling* as part of the CASE Method series of books. This notation was and still is used by the Oracle CASE modelling tools. It is a variation of the "crows foot" style of data modelling that was favoured by many over the original Chen style of ERD modelling because of its readability and efficient use of drawing space.

The notation has features that represent the properties of relationships including cardinality and optionality (the crows foot and dashing of lines), exclusion (the exclusion arc), recursion (looping structures) and use of abstraction (nested boxes).

Institutions	Carnegie Mellon University Harvard University University of California Massachusetts Institute of Technology Louisiana State University
Alma mater	National Taiwan University Harvard University
Known for	Development of entity-relationship modeling
Notable awards	Stevens Software Innovation Award (2001) ACM/AAAI Allen Newell Award (2002) IEEE Harry H. Goode Memorial Award (2003) DAMA International Achievement Award (2000) Pan Wen-Yuen Research Excellence Award (2004) Software Eng. Society & SDPS Society Transformative Award (2011) Fellow of ACM, IEEE, AAAS, & ER

Peter Pin-Shan Chen (Chinese: 陳 品 山) is an American computer scientist. He is a Distinguished Career Scientist and faculty member at Carnegie Mellon University, who is known for the development of Entity-Relationship Model in 1976.

Biography

Born in Taichung, Taiwan, Peter Chen received a B.S. in electrical engineering in 1968 at the National Taiwan University, and a Ph.D. in computer science/applied mathematics at the Harvard University in 1973. In 1970, he worked one summer at IBM. After graduated from Harvard, he worked one year at Honeywell and one summer at Digital Equipment Corporation.

From 1974 to 1978 Chen was an Assistant Professor at the MIT Sloan School of Management. From 1978 to 1983 he was Associate Professor at the University of California, Los Angeles (UCLA Management School). From 1983 to 2011 Chen held the position of M. J. Foster Distinguished Chair Professor of Computer Science at Louisiana State University and, for several years, Adjunct Professor in its Business School and Medical School (Shreveport).[1] During this time period, he was a Visiting Professor once at Harvard in '89-'90 and three times at Massachusetts Institute of Technology (EECS Dept. in '86-'87, Sloan School in '90-'91, and Division of Engineering Systems in 06-'07). Since 2008, he has been Honorary Chair Professor in the Institute of Service Science at National Tsing Hua University. Currently, Chen is a Distinguished Career Scientist and faculty member at Carnegie Mellon University.

Awards and honors

Chen's original paper[2] is one of the most influential papers in the computer software field based on a survey of more than 1,000 computer science professors documented in a book on "Great Papers in Computer Science".[3][4] Chen's work is also cited in a book *Software Challenges* published by Time-Life Books in 1993 in the series on "Understanding Computers." Chen is recognized as one of the pioneers in a book on "Software Pioneers".[5]

Chen has received many awards in the fields of Information Technology.[6] He received the Data Resource Management Technology Award from the Data Administration Management Association in New York City in 1990. He was elected as a Fellow of the Association for Computing Machinery (ACM), American Association for the Advancement of Science (AAAS), IEEE, and ER.[7] He won the Achievement Award in Information Management in 2000 from DAMA International. He was an inductee into the Data Management Hall of Fame in 2000. He received the Stevens Award in Software Method Innovation in 2001. In 2003, Chen received the IEEE Harry H. Goode Memorial Award at the IEEE-CS Board of Governors meeting in San Diego. He was presented with the ACM/AAAI Allen Newell Award at the ACM Banquet in San Diego in June 2003 and International Joint Conference on Artificial Intelligence (IJCAI) in Acapulco in August 2003. Chen is also the recipient of the Pan Wen-Yuan Outstanding Research Award in 2004.[8] In June 2011 in Jeju Island, Korea, Chen received the Transformative Achievement Medal from Software Engineering Society and the Society for Design and Process Science.

Conceptual modeling field and annual conceptual modeling (ER) conference

His innovative work initiated a new field of research and practice called Conceptual Modeling. Since 1979, an annual international professional meeting, the International Conference on Conceptual Modeling has been held in different countries.

Peter P. Chen Award

To recognize Chen's pioneering leadership role, "Peter P. Chen Award" was established in 2008, to be given to one excellent researcher/educator in the conceptual modeling field each year. The recipients of the Peter P. Chen Award are:

- 2008: Bernhard Thalheim, Professor, University of Kiel, Germany
- 2009: David W. Embley, Professor, Brigham Young University (BYU), U.S.A.
- 2010: John Mylopoulos, Professor, University of Toronto, Canada, and University of Trento, Italy
- 2011: Tok Wang Ling, Professor, University of Singapore, Singapore

Work

Entity-relationship Modeling and data/conceptual modeling

The entity-relationship model model serves as the foundation of many systems analysis and design methodologies, computer-aided software engineering (CASE) tools, and repository systems. The ER Model is the basis for IBM's Repository Manager/MVS and DEC's CDD/Plus.

Dr. Peter Chen's original paper[9] is commonly cited as the definitive reference for Entity Relationship Modelling. Chen is one of the pioneers of using the entity relationship concepts in software and information system modeling and design. Before Chen's paper, the basic entity relationship ideas were used mostly informally by practitioners. Chen first published an abstract and presented his ER model in the First Very Large Database Conference in 1975, the same year of a paper with similar concepts written by A. P. G. Brown.[10] Chen's main contributions are: formalized the concepts, developed a theory with a set of data definition and manipulation operations, and specified

the translation rules from the ER model to several major types of databases (including the Relational Database). He also popularized the model and introduced it to the academic literature.

The ER Model was adopted as the meta model ANSI Standard in Information Resource Directory System (IRDS), and the ER approach has been ranked at the top methodology for database design and one of the top methodologies in systems development by several surveys of Fortune 500 companies.

Computer-aided software engineering

Chen's work is a cornerstone of software engineering,[] in particular Computer-Aided Software Engineering (CASE). In the late 80's and early 90's, IBM's Application Development Cycle (AD/Cycle) framework and DB2 repository (RM/MVS) were based on the ER model. Other vendors' repository systems such as Digital's CDD+ were also based on the ER model. Chen has had a significant impact on the CASE industry through his research and his lecturing around the world on structured system development methodologies. The ER model has influenced most of the major CASE tools, including Computer Associates' ERWIN, Oracle Corporation's Designer/2000, and Sybase's PowerDesigner (and even a general drawing tool like Microsoft Visio), as well as the IDEF1X standard. The ER model is also the basis for Microsoft's ADO.NET Entity Framework.

The hypertext concept, which makes the World Wide Web extremely popular, is very similar to the main concept in the ER model. Chen investigated this linkage as an invited expert of several XML working groups of the World Wide Web Consortium (W3C).

The ER model also serves as the foundation of some of the recent work on Object-oriented analysis and design methodologies and Semantic Web. The UML modeling language has its roots in the ER model.

Computer performance modeling

In his early career, he was active in R&D activities in computer system performance. He was the program chair of an ACM SIGMETRICS conference. He developed a computer performance model for a major computer vendor. His innovative research results were adopted in commercial compter performance tuning and capacity planning tools.

Memory/storage hierarchy, storage technology, CD-ROM, firmware, micro-programming

His Ph.D. thesis at Harvard was one of the first studies of cost/performance optimization models of memory/storage hierarchies. He was also one of the early micro-programmers developing the firmware for a file control unit for an IBM mainframe computer. His article on "CD-ROM" in IEEE Proceedings journal in the 80s was one of the first articles explaining how CD-ROM worked when CD-ROMs became popular. He was a co-author of the "storage technology" article in a major computer encyclopedia.

Cyber security and terrorist detection

In recent years, he led a multidisciplinary research team in developing new efficient and effective techniques in identifying terrorists and malicious cyber transactions. At CMU, he is active in the R&D activities of CERT Coordination Center and Software Engineering Institute (SEI).

Publications

Peter P. Chen published several books, papers and articles. Books, a selection:

- 2007. *Active Conceptual Modeling of Learning: Next Generation Learning-Base System Development*. With Leah Y. Wong (Eds.). Springer.
- 1999. *Advances in Conceptual Modeling: ER'99 Workshops on Evolution and Change in Data Management, Reverse Engineering in Information Systems, and the World ... (Lecture Notes in Computer Science)*. With David W. Embley, Jacques Kouloumdjian, Stephen W. Liddle and John F. Roddick (Eds.) Springer Verlag.

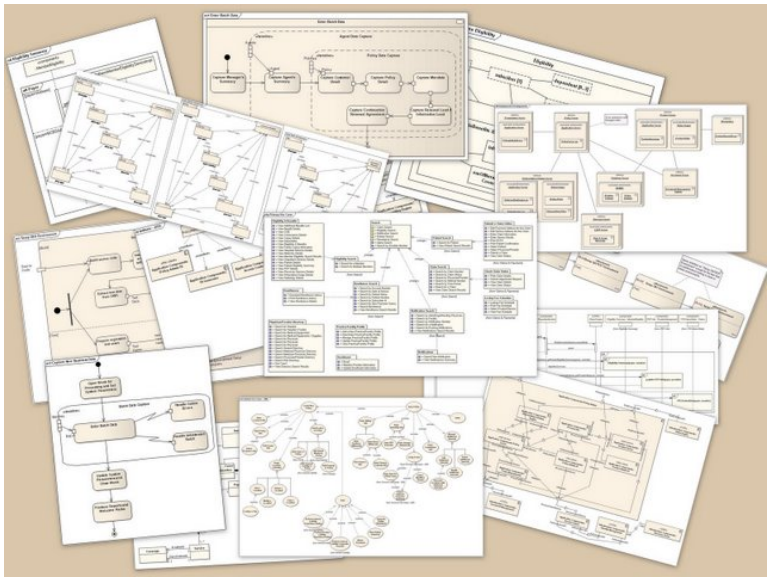
Other Data Modeling Techniques

Unified Modeling Language

The **Unified Modeling Language** (**UML**) is a general-purpose modeling language in the field of software engineering. It provides a set of graphic notation techniques to create visual models of object-oriented software-intensive systems. It was developed by Grady Booch, Ivar Jacobson and James Rumbaugh at Rational Software in the 1990s.[1] It was adopted by the Object Management Group (OMG) in 1997, and has been managed by this organization ever since. In 2000 the Unified Modeling Language was accepted by the International Organization for Standardization (ISO) as a standard for modeling software-intensive systems.

Overview

Unified Modeling Language (UML) combines techniques from data modeling (entity relationship diagrams), business modeling (work flows), object modeling, and component modeling. It can be used with all processes, throughout the software development life cycle, and across different implementation technologies.[2]



A collage of UML diagrams.

The Unified Modeling Language (UML) offers a standard way to visualize a system's architectural blueprints, including elements such as:

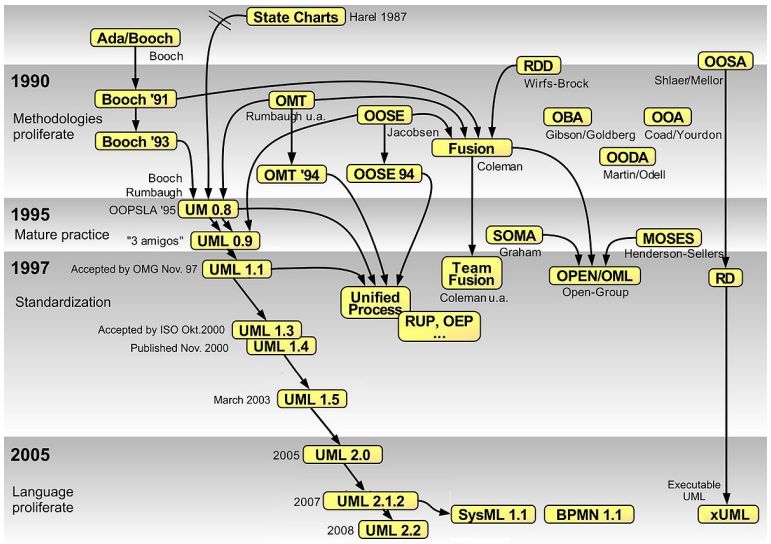
- activities
- actors
- business processes
- database schemas
- (logical) components
- programming language statements
- reusable software components.[3]

UML has synthesized the notations of the Booch method, the Object-modeling technique (OMT) and Object-oriented software engineering (OOSE) by fusing them into a single, common and widely usable modeling language. UML aims to be a standard modeling language which can model concurrent and distributed systems.

UML models may be automatically transformed to other representations (e.g. Java) by means of QVT-like transformation languages. UML is extensible, with two mechanisms for customization: profiles and stereotypes.

History

UML has been evolving since the second half of the 1990s and has its roots in the object-oriented methods developed in the late 1980s and early 1990s. The timeline (see image) shows the highlight of the history of object-oriented modeling methods and notation.



History of object-oriented methods and notation.

Before UML 1.x

After Rational Software Corporation hired James Rumbaugh from General Electric in 1994, the company became the source for two of the most popular object-oriented modeling approaches of the day:[4] Rumbaugh's Object-modeling technique (OMT) and Grady Booch's method known as Object-oriented design (OOD). They were soon assisted in their efforts by Ivar Jacobson, the creator of the object-oriented software engineering (OOSE) method. Jacobson joined Rational in 1995, after his company, Objectory AB,[5] was acquired by Rational. The three methodologists were collectively referred to as the "Three Amigos".

In 1996, Rational concluded that the abundance of modeling languages was slowing the adoption of object technology,[*citation needed*] so repositioning the work on a unified method, they tasked the "Three Amigos" with the development of a non-proprietary Unified Modeling Language. Representatives of competing object technology companies were consulted during OOPSLA '96;[*citation needed*] they chose *boxes* for representing classes rather than the *cloud* symbols that were used in Booch's notation.

Under the technical leadership of the "Three Amigos", an international consortium called the UML Partners was organized in 1996 to complete the *Unified Modeling Language (UML)* specification, and propose it as a response to the OMG RFP. The UML Partners' UML 1.0 specification draft was proposed to the OMG in January 1997. During the same month the UML Partners formed a Semantics Task Force, chaired by Cris Kobryn and administered by Ed Eykholt, to finalize the semantics of the specification and integrate it with other standardization efforts. The result of this work, UML 1.1, was submitted to the OMG in August 1997 and adopted by the OMG in November 1997.

UML 1.x

As a modeling notation, the influence of the OMT notation dominates (e. g., using rectangles for classes and objects). Though the Booch "cloud" notation was dropped, the Booch capability to specify lower-level design detail was embraced. The use case notation from Objectory and the component notation from Booch were integrated with the rest of the notation, but the semantic integration was relatively weak in UML 1.1, and was not really fixed until the UML 2.0 major revision.[*citation needed*]

Concepts from many other OO methods were also loosely integrated with UML with the intent that UML would support all OO methods. Many others also contributed, with their approaches flavouring the many models of the day, including: Tony Wasserman and Peter Pircher with the "Object-Oriented Structured Design (OOSD)" notation (not a method), Ray Buhr's "Systems Design with Ada", Archie Bowen's use case and timing analysis, Paul Ward's data analysis and David Harel's "Statecharts"; as the group tried to ensure broad coverage in the real-time systems domain. As a result, UML is useful in a variety of engineering problems, from single process, single user

applications to concurrent, distributed systems, making UML rich but also large.

The Unified Modeling Language is an international standard:

> ISO/IEC 19501:2005 Information technology – Open Distributed Processing – Unified Modeling Language (UML) Version 1.4.2

UML 2.x

UML has matured significantly since UML 1.1. Several minor revisions (UML 1.3, 1.4, and 1.5) fixed shortcomings and bugs with the first version of UML, followed by the UML 2.0 major revision that was adopted by the OMG in 2005.

Although UML 2.1 was never released as a formal specification, versions 2.1.1 and 2.1.2 appeared in 2007, followed by UML 2.2 in February 2009. UML 2.3 was formally released in May 2010. UML 2.4.1 was formally released in August 2011. UML 2.5 was released in October 2012 as an "In process" version and has yet to become formally released.

There are four parts to the UML 2.x specification:

1. The Superstructure that defines the notation and semantics for diagrams and their model elements
2. The Infrastructure that defines the core metamodel on which the Superstructure is based
3. The Object Constraint Language (OCL) for defining rules for model elements
4. The UML Diagram Interchange that defines how UML 2 diagram layouts are exchanged

The current versions of these standards follow: UML Superstructure version 2.4.1, UML Infrastructure version 2.4.1, OCL version 2.3.1, and UML Diagram Interchange version 1.0.

Although many UML tools support some of the new features of UML 2.x, the OMG provides no test suite to objectively test compliance with its specifications.

Topics

Software development methods

UML is not a development method by itself;[6] however, it was designed to be compatible with the leading object-oriented software development methods of its time (for example OMT, Booch method, Objectory). Since UML has evolved, some of these methods have been recast to take advantage of the new notations (for example OMT), and new methods have been created based on UML, such as IBM Rational Unified Process (RUP). Others include Abstraction Method and Dynamic Systems Development Method.

Modeling

It is important to distinguish between the UML model and the set of diagrams of a system. A diagram is a partial graphic representation of a system's model. The model also contains documentation that drives the model elements and diagrams (such as written use cases).

UML diagrams represent two different views of a system model:[7]

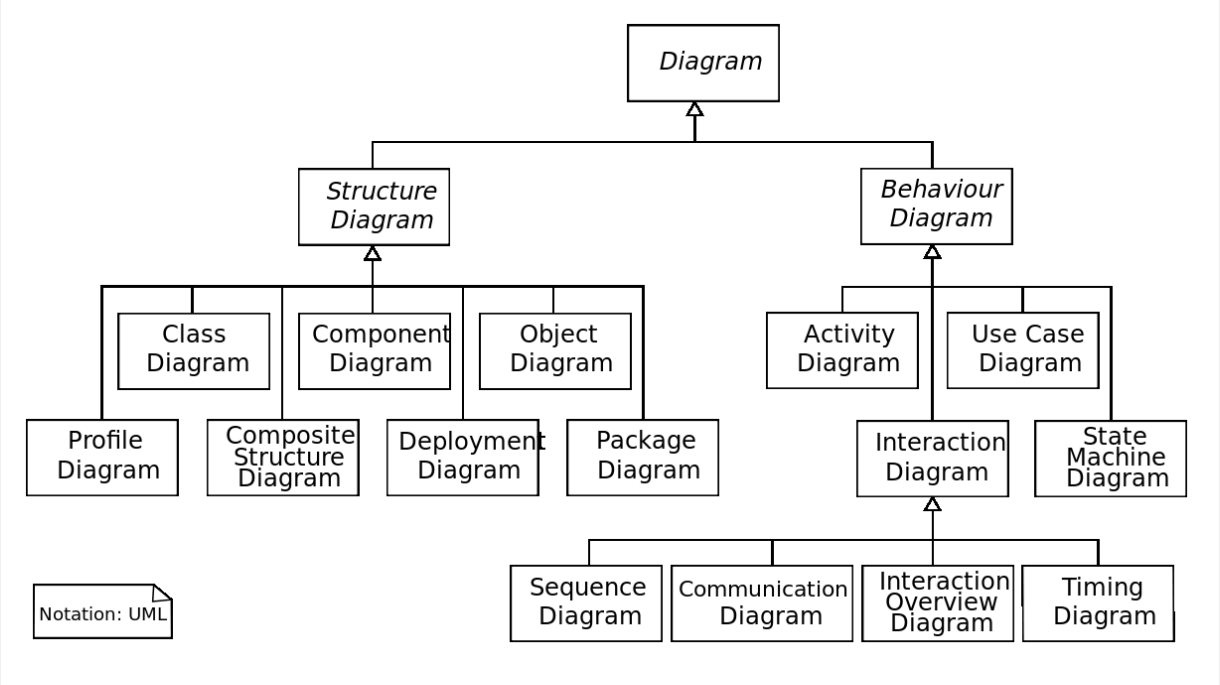
- Static (or *structural*) view: emphasizes the static structure of the system using objects, attributes, operations and relationships. The structural view includes class diagrams and composite structure diagrams.
- Dynamic (or *behavioral*) view: emphasizes the dynamic behavior of the system by showing collaborations among objects and changes to the internal states of objects. This view includes sequence diagrams, activity diagrams and state machine diagrams.

UML models can be exchanged among UML tools by using the XML Metadata Interchange (XMI) interchange format.

Diagrams overview

UML diagrams
Structural UML diagrams
• Class diagram • Component diagram • Composite structure diagram • Deployment diagram • Object diagram • Package diagram • Profile diagram
Behavioral UML diagrams
• Activity diagram • Communication diagram • Interaction overview diagram • Sequence diagram • State diagram • Timing diagram • Use case diagram
• v • t • e [8]

UML 2.2 has 14 types of diagrams divided into two categories.[9] Seven diagram types represent *structural* information, and the other seven represent general types of *behavior*, including four that represent different aspects of *interactions*. These diagrams can be categorized hierarchically as shown in the following class diagram:



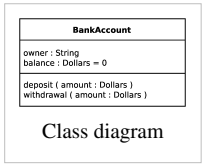
UML does not restrict UML element types to a certain diagram type. In general, every UML element may appear on almost all types of diagrams; this flexibility has been partially restricted in UML 2.0. UML profiles may define additional diagram types or extend existing diagrams with additional notations.

In keeping with the tradition of engineering drawings,[*citation needed*] a comment or note explaining usage, constraint, or intent is allowed in a UML diagram.

Structure diagrams

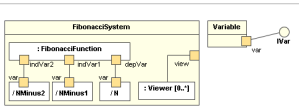
Structure diagrams emphasize the things that must be present in the system being modeled. Since structure diagrams represent the structure, they are used extensively in documenting the software architecture of software systems.

- Class diagram: describes the structure of a system by showing the system's classes, their attributes, and the relationships among the classes.
- Component diagram: describes how a software system is split up into components and shows the dependencies among these components.
- Composite structure diagram: describes the internal structure of a class and the collaborations that this structure makes possible.
- Deployment diagram: describes the hardware used in system implementations and the execution environments and artifacts deployed on the hardware.
- Object diagram: shows a complete or partial view of the structure of an example modeled system at a specific time.
- Package diagram: describes how a system is split up into logical groupings by showing the dependencies among these groupings.
- Profile diagram: operates at the metamodel level to show stereotypes as classes with the <<stereotype>> stereotype, and profiles as packages with the <<profile>> stereotype. The extension relation (solid line with closed, filled arrowhead) indicates what metamodel element a given stereotype is extending.



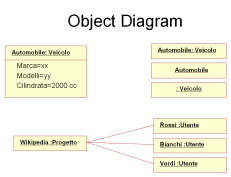
Class diagram

Component diagram

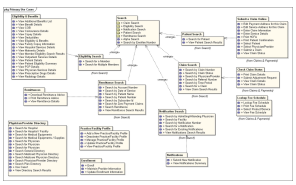


Composite structure diagram

Deployment diagram



Object diagram

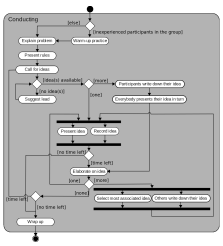


Package diagram

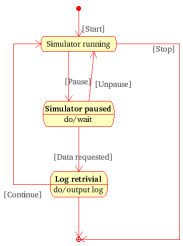
Behavior diagrams

Behavior diagrams emphasize what must happen in the system being modeled. Since behavior diagrams illustrate the behavior of a system, they are used extensively to describe the functionality of software systems.

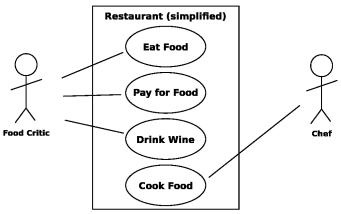
- Activity diagram: describes the business and operational step-by-step workflows of components in a system. An activity diagram shows the overall flow of control.
- UML state machine diagram: describes the states and state transitions of the system.
- Use Case Diagram: describes the functionality provided by a system in terms of actors, their goals represented as use cases, and any dependencies among those use cases.



UML Activity Diagram



State Machine diagram

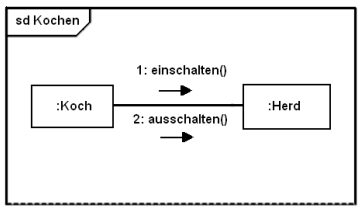


Use Case Diagram

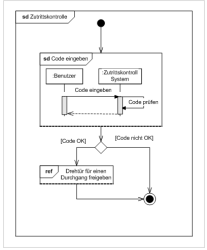
Interaction diagrams

Interaction diagrams, a subset of behavior diagrams, emphasize the flow of control and data among the things in the system being modeled:

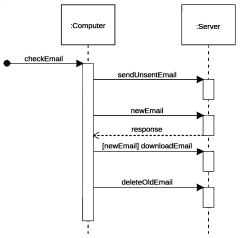
- Communication diagram: shows the interactions between objects or parts in terms of sequenced messages. They represent a combination of information taken from Class, Sequence, and Use Case Diagrams describing both the static structure and dynamic behavior of a system.
- Interaction overview diagram: provides an overview in which the nodes represent communication diagrams.
- Sequence diagram: shows how objects communicate with each other in terms of a sequence of messages. Also indicates the lifespans of objects relative to those messages.
- Timing diagrams: a specific type of interaction diagram where the focus is on timing constraints.



Communication diagram



Interaction overview diagram



Sequence diagram

The Protocol State Machine is a sub-variant of the State Machine. It may be used to model network communication protocols.

Meta modeling

The Object Management Group (OMG) has developed a metamodeling architecture to define the Unified Modeling Language (UML), called the Meta-Object Facility (MOF).[10] The Meta-Object Facility is designed as a four-layered architecture, as shown in the image at right. It provides a meta-meta model at the top layer, called the M3 layer. This M3-model is the language used by Meta-Object Facility to build metamodels, called M2-models.

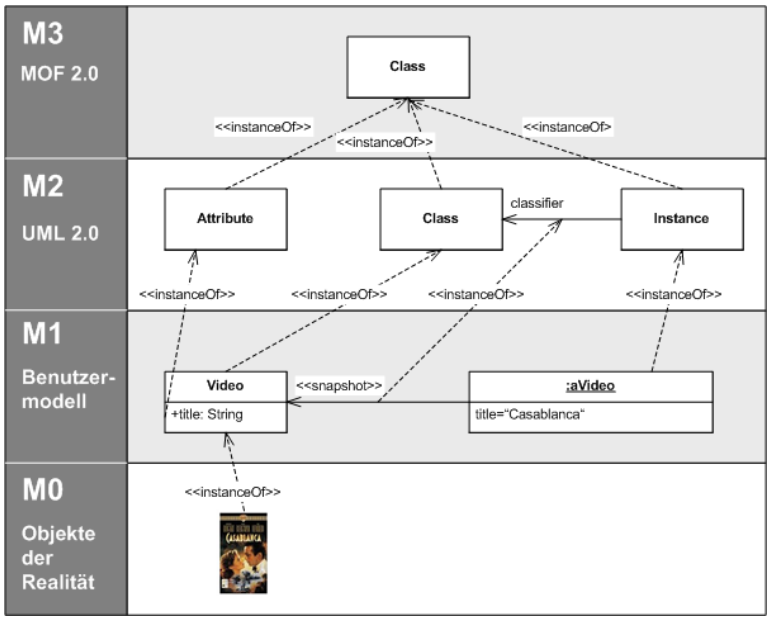


Illustration of the Meta-Object Facility.

The most prominent example of a Layer 2 Meta-Object Facility model is the UML metamodel, the model that describes the UML itself. These M2-models describe elements of the M1-layer, and thus M1-models. These would be, for example, models written in UML. The last layer is the M0-layer or data layer. It is used to describe runtime instance of the system.

Beyond the M3-model, the Meta-Object Facility describes the means to create and manipulate models and metamodels by defining Common Object Request Broker Architecture (CORBA) interfaces that describe those operations. Because of the similarities between the Meta-Object Facility M0-model and UML structure models, Meta-Object Facility metamodels are usually modeled as UML class diagrams. A supporting standard of the Meta-Object Facility is XMI, which defines an XML-based exchange format for models on the M3-, M2-, or M1-Layer.

Criticisms

Although UML is a widely recognized and used modeling standard, it is frequently[*citation needed*] criticized for the following:

Standards bloat

> Bertrand Meyer, in a satirical essay framed as a student's request for a grade change, apparently criticized UML as of 1997 for being unrelated to object-oriented software development; a disclaimer was added later pointing out that his company nevertheless supports UML. Ivar Jacobson, a co-architect of UML, said that objections to UML 2.0's size were valid enough to consider the application of intelligent agents to the problem.[11] It contains many diagrams and constructs that are redundant or infrequently used.

Problems in learning and adopting

> The problems cited in this section make learning and adopting UML problematic, especially when required of engineers lacking the prerequisite skills.[12] In practice, people often draw diagrams with the symbols provided by their CASE tool, but without the meanings those symbols are intended to provide. Simple user narratives e.g. "what I do at work ..." have shown to be much simpler to record and more immediately useful.[*citation needed*]

Linguistic incoherence

The standards have been cited as being ambiguous and inconsistent.[13] The UML 2.0 standard still suffers many issues.

Capabilities of UML and implementation language mismatch

Typical of other notational systems, UML is able to represent some systems more concisely or efficiently than others. Thus a developer gravitates toward solutions that reside at the intersection of the capabilities of UML and the implementation language. This problem is particularly pronounced if the implementation language does not adhere to orthodox object-oriented doctrine, since the intersection set between UML and implementation language may be that much smaller or equal in size.[*citation needed*]

Dysfunctional interchange format

While the XMI (XML Metadata Interchange) standard is designed to facilitate the interchange of UML models, it has been largely ineffective in the practical interchange of UML 2.x models. This interoperability ineffectiveness is attributable to several reasons. Firstly, XMI 2.x is large and complex in its own right, since it purports to address a technical problem more ambitious than exchanging UML 2.x models. In particular, it attempts to provide a mechanism for facilitating the exchange of any arbitrary modeling language defined by the OMG's Meta-Object Facility (MOF). Secondly, the UML 2.x Diagram Interchange specification lacks sufficient detail to facilitate reliable interchange of UML 2.x notations between modeling tools. Since UML is a visual modeling language, this shortcoming is substantial for modelers who don't want to redraw their diagrams. The Diagram Definition OMG project is another alternative.

Cardinality notation

As with database Chen, Bachman, and ISO ER diagrams, class models are specified to use "look-across" cardinalities, even though several authors (Merise,[14] Elmasri & Navathe [15] amongst others [16]) prefer same-side or "look-here" for roles and both minimum and maximum cardinalities. Recent researchers (Feinerer, Dullea et. alia) have shown that the "look-across" technique used by UML and ER diagrams is less effective and less coherent when applied to n-ary relationships of order >2.

In Feinerer it says "Problems arise if we operate under the look-across semantics as used for UML associations. Hartmann investigates this situation and shows how and why different transformations fail." *(Although the "reduction" mentioned is spurious as the two diagrams 3.4 and 3.5 are in fact the same)* and also "As we will see on the next few pages, the look-across interpretation introduces several difficulties which prevent the extension of simple mechanisms from binary to n-ary associations."

Exclusive

The term "unified" applies only to the unification of the many prior existing and competing object-oriented languages. Important well known and popular techniques, almost universally used in industry, such as data flow diagrams and structure charts were not included in the specification.[*citation needed*]

Modeling experts have written criticisms of UML, including Brian Henderson-Sellers and Cesar Gonzalez-Perez in "Uses and Abuses of the Stereotype Mechanism in UML 1.x and 2.0".[17]

Complexity

UML has been criticized for being extremely complex compared to other tools.

The Third Manifesto

The Third Manifesto (1995) is Christopher J. Date's and Hugh Darwen's proposal for future database management systems, a response to two earlier Manifestos with the same purpose. The theme of the manifestos is how to avoid the 'object-relational impedance mismatch' between object-oriented programming languages and relational database management systems. The Third Manifesto proposes to maintain the relational model for databases and to support objects as user-defined types.

A major theme of the manifesto is to explain how the inadequacies of existing relational database management systems are not shortcomings of the relational database model *per se*, but rather, of implementation decisions in those systems, and of the SQL query language that most of these systems use.

The manifesto describes an alternative to SQL, named D. D is a specification of desirable characteristics of a database language, rather than a specific syntax or grammar. As such, it describes a family of languages rather than any particular language. However, as an example, a particular member of the hypothetical D "family" called Tutorial D is described in detail, including significant portions of its grammar.

Several partial implementations of D exist, including:

- Alphora Dataphor, an open source product which implements D atop SQL databases.
- Rel, an Open Source implementation of Tutorial D in Java.
- Muldis Rosetta (Muldis D), an Open Source implementation in Perl

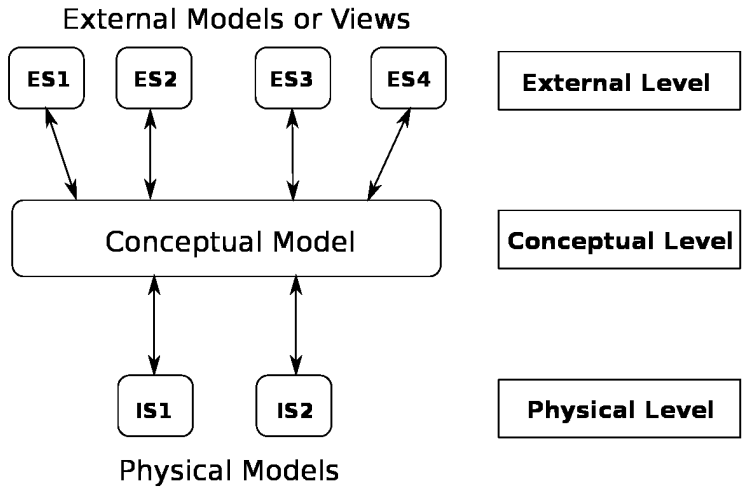
Three schema approach

The **three-schema approach**, or the *Three Schema Concept*, in software engineering is an approach to building information systems and systems information management from the 1970s. It proposes to use three different views in systems development, in which conceptual modelling is considered to be the key to achieving data integration.[2]



The notion of a three-schema model was first introduced in 1975 by the ANSI/X3/SPARC three level architecture, which determined three levels to model data.[1]

Overview

The three-schema approach offers three types of schemas with schema techniques based on formal language descriptions:[3]

- External schema for user views
- Conceptual schema integrates external schemata
- Internal schema that defines physical storage structures

At the center, the conceptual schema defines the ontology of the concepts as the users think of them and talk about them. The physical schema according to Sowa (2004) "describes the internal formats of the data stored in the database, and the external schema defines the view of the data presented to the application programs".[4] The framework attempted to permit multiple data models to be used for external schemata.[5]

Over the years, the skill and interest in building information systems has grown tremendously. However, for the most part, the traditional approach to building systems has only focused on defining data from two distinct views, the "user view" and the "computer view". From the user view, which will be referred to as the “external schema,” the definition of data is in the context of reports and screens designed to aid individuals in doing their specific jobs. The required structure of data from a usage view changes with the business environment and the individual preferences of the user. From the computer view, which will be referred to as the “internal schema,” data is defined in terms of file structures for storage and retrieval. The required structure of data for computer storage depends upon the specific computer technology employed and the need for efficient processing of data.[6]

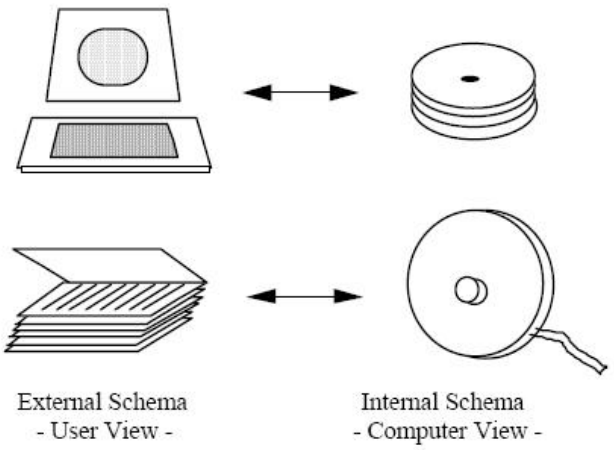


Figure 1: Traditional View of Data

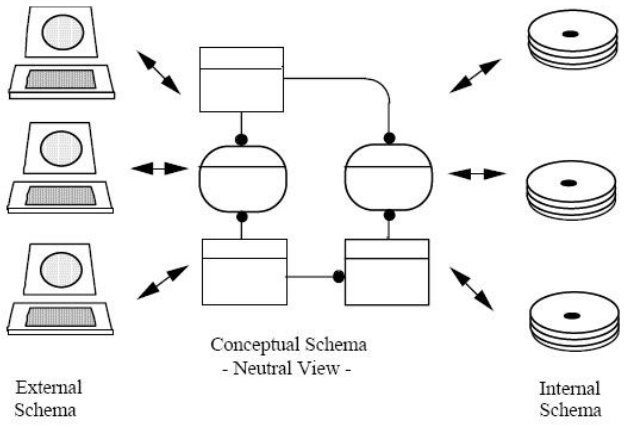

Figure 2: Three schema approach

These two traditional views of data have been defined by analysts over the years on an application by application basis as specific business needs were addressed, see Figure 1. Typically, the internal schema defined for an initial application cannot be readily used for subsequent applications, resulting in the creation of redundant and often inconsistent definition of the same data. Data was defined by the layout of physical records and processed sequentially in early information systems. The need for flexibility, however, led to the introduction of Database Management Systems (DBMSs), which allow for random access of logically connected pieces of data. The logical data structures within a DBMS are typically defined as either hierarchies, networks or relations. Although DBMSs have greatly improved the shareability of data, the use of a DBMS alone does not guarantee a consistent definition of data. Furthermore, most large companies have had to develop multiple databases which are often under the control of different DBMSs and still have the problems of redundancy and inconsistency.

The recognition of this problem led the ANSI/X3/SPARC Study Group on Database Management Systems to conclude that in an ideal data management environment a third view of data is needed. This view, referred to as a “conceptual schema” is a single integrated definition of the data within an enterprise which is unbiased toward any single application of data and is independent of how the data is physically stored or accessed, see Figure 2. The primary objective of this conceptual schema is to provide a consistent definition of the meanings and interrelationship of data which can be used to integrate, share, and manage the integrity of data.

History

The notion of a three-schema model consisting of a conceptual model, an external model, and an internal or physical model was first introduced by the ANSI/X3/SPARC Standards Planning and Requirements Committee directed by Charles Bachman in 1975. The ANSI/X3/SPARC Report characterized DBMSs as having a two schema organization. That is, DBMSs utilize an internal schema, which represents the structure of the data as viewed by the DBMS, and an external schema, which represents various structures of the data as viewed by the end user. The concept of a third schema (conceptual) was introduced in the report. The conceptual schema represents the basic underlying structure of data as viewed by the enterprise as a whole.

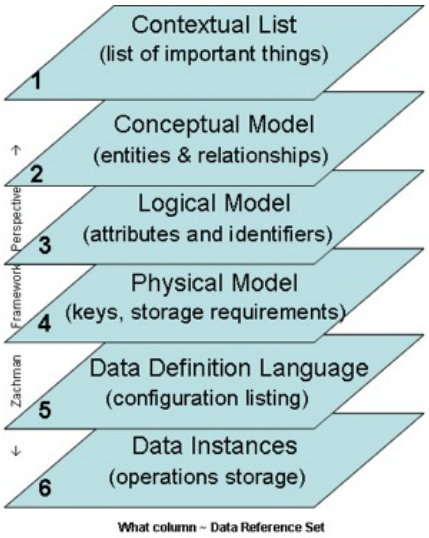

Image of the six layers in the Zachman Framework.

The ANSI/SPARC report was intended as a basis for interoperable computer systems. All database vendors adopted the three-schema terminology, but they implemented it in incompatible ways. Over the next twenty years, various groups attempted to define standards for the conceptual schema and its mappings to databases and programming languages. Unfortunately, none of the vendors had a strong incentive to make their formats compatible with their competitors'. A few reports were produced, but no standards.

As the practice of Data Administration has evolved and more graphical techniques have evolved, the term "schema" has given way to the term "model". The conceptual model represents the view of data that is negotiated between end users and database administrators covering those entities about which it is important to keep data, the meaning of the data, and the relationships of the data to each other.

One further development is the IDEF1X information modeling methodology, which is based on the three-schema concept. Another is the Zachman Framework, proposed by John Zachman in 1987 and developed ever since in the field of Enterprise Architecture. In this framework, the three-schema model has evolved into a layer of six perspectives. In other Enterprise Architecture frameworks some kind of view model is incorporated.

White pages schema

A **white pages schema** is a data model, specifically a logical schema, for organizing the data contained in entries in a directory service, database, or application, such as an address book. In a white pages directory, each entry typically represents an individual person that makes use of network resources, such as by receiving email or having an account to log into a system. In some environments, the schema may also include the representation of organizational divisions, roles, groups, and devices. The term is derived from the white pages, the listing of individuals in a telephone directory, typically sorted by the individual's home location (e.g. city) and then by their name.

While many telephone service providers have for decades published a list of their subscribers in a telephone directory, and similarly corporations published a list of their employees in an internal directory, it was not until the rise of electronic mail systems that a requirement for standards for the electronic exchange of subscriber information between different systems appeared.

A white pages schema typically defines, for each real-world object being represented:

- what attributes of that object are to be represented in the entry for that object
- what relationships of that object to other objects are to be represented
- how is the entry to be named in a DIT
- how an entry is to be located by a client searching for it
- how similar entries are to be distinguished
- how are entries to be ordered when displayed in a list

One of the earliest attempts to standardize a white pages schema for electronic mail use was in X.520 and X.521, part of the X.500 specifications, that was derived from the addressing requirements of X.400 and defined a Directory Information Tree that mirrored the international telephone system, with entries representing residential and organizational subscribers. This evolved into the Lightweight Directory Access Protocol standard schema in RFC 2256. One of the most widely deployed white pages schemas used in LDAP for representing individuals in an organizational context is **inetOrgPerson**, defined in RFC 2798, although versions of Active Directory require a different object class, **User**. Many large organizations have also defined their own white pages schemas for their employees or customers, as part of their Identity management architecture. Converting between data bases and directories using different schemas is often the function of a Metadirectory, and data interchange standards such as Common Indexing Protocol.

Some early directory deployments suffered due to poor design choices in their white pages schema, such as:

- attributes used for naming purposes were non-unique in large environments (such as a person's common name)
- attributes used for naming purposes were likely to change (such as surnames)
- attributes were included which could lead to Identity theft, such as a Social security number
- users were required during provisioning to choose attributes which are unique but still memorable to them

Numerous other proposed schemas exist, both as standalone definitions suitable for use with general purpose directories, or as embedded into network protocols.

Examples of other generic white pages schemas include vCard, defined in RFC 2426, and FOAF.

Anchor Modeling

Anchor Modeling is an agile database modeling technique suited for information that change over time both in structure and content. It provides a graphical notation used for conceptual modeling similar to that of entity—relationship modeling, with extensions for working with temporal data. The modeling technique is based around four modeling constructs: the anchor, attribute, tie and knot, each capturing different aspects of the domain being modeled.[1] The resulting models can be translated to physical database designs using formalized rules. When such a translation is done the tables in the relational database will mostly be in the sixth normal form.

Philosophy and history

Anchor Modeling was created in order to take advantage of the benefits from a high degree of normalization while avoiding its drawbacks. Advantages such as being able to non-destructively evolve the model, avoid null values, and keep the information free from redundancies are gained. Performance issues due to extra joins are largely avoided thanks to a feature in modern database engines called 'table elimination'. In order to handle changes in the information content Anchor Modeling emulates aspects of a temporal database in the resulting relational database schema.

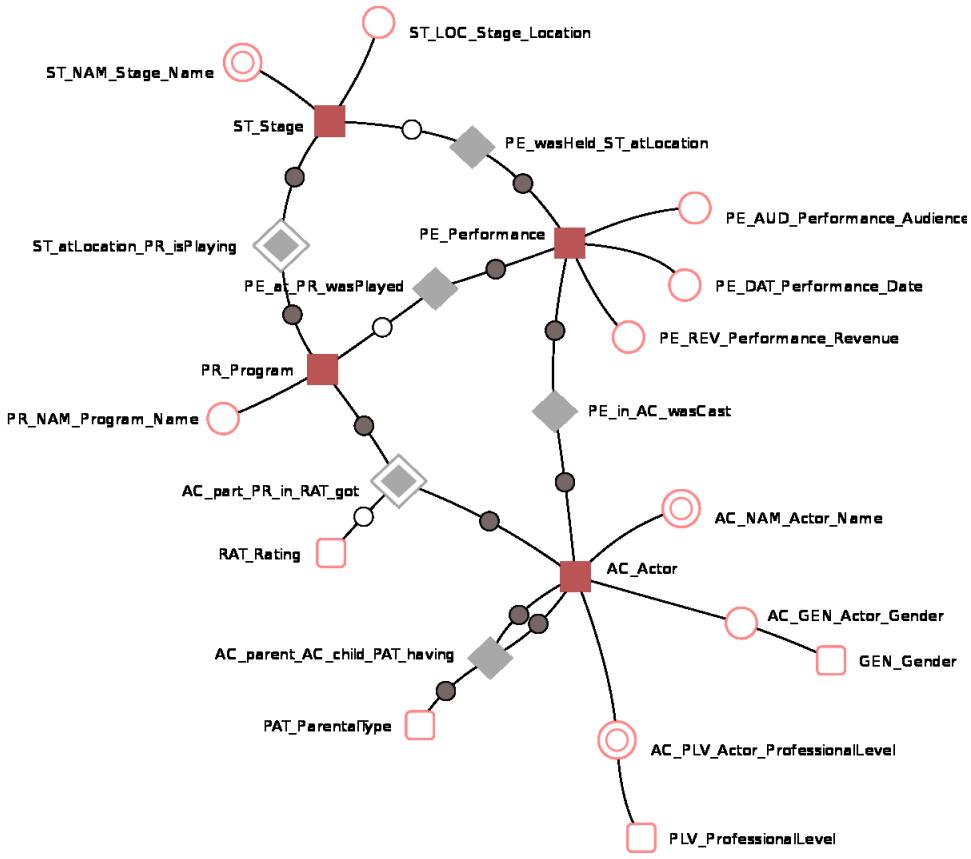
The earliest installations using Anchor Modeling were made in Sweden with the first dating back to 2004, when a data warehouse for an insurance company was built using the technique. In 2007 the technique was being used in a few data warehouses and one OLTP system, and it was presented internationally by Lars Rönnbäck at the TDWI (The Data Warehousing Institute) conference in Amsterdam.[2] This stirred enough interest for the technique to warrant a more formal description. Since then research concerning Anchor Modeling is being done in a collaboration between the creators Olle Regardt and Lars Rönnbäck and a team at the Department of Computer and Systems Sciences, Stockholm University. The first paper,[3] in which Anchor Modeling is formalized, was presented at the 28th International Conference on Conceptual Modeling[4] and won the best paper award.

The research can be followed at www.anchormodeling.com [5], where material on Anchor Modeling is made public and free to use under a Creative Commons license. An online modeling tool is also available, which is free to use and Open Source.

Basic notions

Anchor Modeling has four basic modeling concepts, anchors, attributes, ties, and knots. Anchors are used to model entities and events, attributes are used to model properties of anchors, ties model the relationships between anchors, and knots are used to model shared properties, such as states. Attributes and ties can be historized when changes in the information they model need to be kept.

An example model showing the different graphical symbols for all the concepts can be seen below. The symbols resemble those used in Entity-Relationship modeling, with a couple of extensions. A double outline on an attribute or tie indicates that a history of changes is kept and the knot symbol (an outlined square with rounded edges) is also available.



Temporal aspects

Anchor Modeling handles two types of informational evolution, structural changes and content changes. Changes to the structure of information is represented through extensions. The high degree of normalization makes it possible to non-destructively add the necessary modeling concepts needed to capture a change, in such a way that every previous schema always remains as a subset of the current schema. Since the existing schema is not touched, this gives the benefit of being able to evolve the database in a highly iterative manner and without causing any downtime.

Changes in the content of information is done by emulating similar features of a temporal database in a relational database. In Anchor Modeling, pieces of information can be tied to points in time or to intervals of time (both open and closed). The time points when events occur are modeled using attributes, e g the birth dates of persons or the time of a purchase. The intervals of time in which a value is valid are captured through the historization of attributes and ties, e g the changes of hair color of a person or the period of time during which a person was married. In a relational database this is achieved by adding a single column, with a data type granular enough to capture the speed of the changes, to the table corresponding to the historized attribute or tie. This adds a slight complexity as more than one row in the table have to be examined in order to know if an interval is closed or not.

Points or intervals of time not directly related to the domain being modeled, such as the points of time information entered the database, are handled through the use of metadata in Anchor Modeling, rather than any of the above mentioned constructs. If information about such changes to the database needs to be kept Bitemporal Anchor Modeling can be used, where in addition to updates, also delete statements become non-destructive.

Relational representation

In Anchor Modeling there is a one-to-one mapping between the symbols used in the conceptual model and tables in the relational database. Every anchor, attribute, tie, and knot have a corresponding table in the database with an unambiguously defined structure. A conceptual model can thereby be translated to a relational database schema using simple automated rules, and vice versa. This is different from many other modeling techniques in which there are complex and sometimes subjective translation steps between the conceptual, logical, and physical levels.

Anchor tables contain a single column in which identities are stored. An identity is assumed to be the only property of an entity that is always present and immutable. As identities are rarely available from the domain being modeled, they are instead technically generated, e g from an incrementing number sequence.

An example of an anchor for the identities of the nephews of Donald Duck is a set of 1-tuples:
{⟨#42⟩, ⟨#43⟩, ⟨#44⟩}

Knots can be thought of as the combination of an anchor and a single attribute. Knot tables contain two columns, one for an identity and one for a value. Due to storing identities and values together, knots cannot be historized. Their usefulness comes from being able to reduce storage requirements and improve performance, since tables referencing knots can store a short value rather than a long string.

An example of a knot for genders is a set of 2-tuples:
{⟨#1, 'Male'⟩, ⟨#2, 'Female'⟩}

Static attribute tables contain two columns, one for the identity of the entity to which the value belongs and one for the actual property value. Historized attribute tables have an extra column for storing the starting point of a time interval. In a knotted attribute table, the value column is an identity that references a knot table.

An example of a static attribute for their names is a set of 2-tuples:
{⟨#42, 'Huey'⟩, ⟨#43, 'Dewey'⟩, ⟨#44, 'Louie'⟩}

An example of a knotted static attribute for their genders is a set of 2-tuples:
{⟨#42, #1⟩, ⟨#43, #1⟩, ⟨#44, #1⟩}

An example of a historized attribute for the (changing) colors of their outfits is a set of 3-tuples:
{⟨#44, 'Orange', 1938-04-15⟩, ⟨#44, 'Green', 1939-04-28⟩, ⟨#44, 'Blue', 1940-12-13⟩}

Static tie tables relate two or more anchors to each other, and contain two or more columns for storing the identities. Historized tie tables have an extra column for storing the starting point of a time interval. Knotted tie tables have an additional column for each referenced knot.

An example of a static tie for the sibling relationship is a set of 2-tuples:
{⟨#42, #43⟩, ⟨#42, #44⟩, ⟨#43, #42⟩, ⟨#43, #44⟩, ⟨#44, #42⟩, ⟨#44, #43⟩}

The resulting tables will all be in sixth normal form except for ties in which not all columns are part of the primary key.

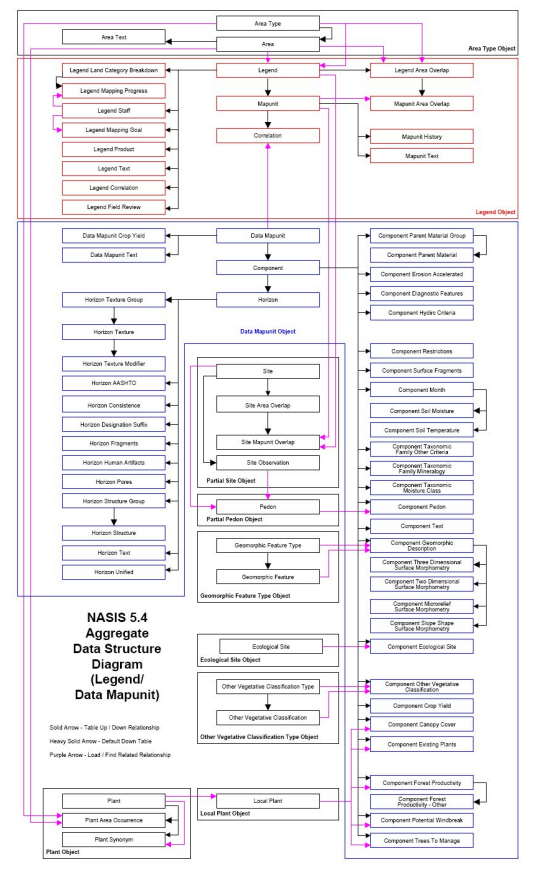
Bachman diagram

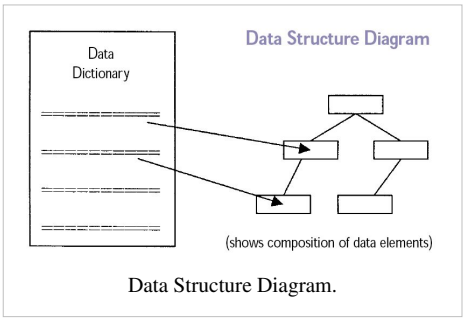
Data Structure Diagram (DSD) is a diagram of the conceptual data model which documents the entities and their relationships, as well as the constraints that connect to them.

The basic graphic notation elements of DSDs are boxes which represent entities.The arrow symbol represents relationships. Data structure diagrams are most useful for documenting complex data entities.



Example of a Data Structure Diagram.

Overview



Data Structure Diagram.

Data Structure Diagram is a diagram type that is used to depict the structure of data elements in the data dictionary. The data structure diagram is a graphical alternative to the composition specifications within such data dictionary entries.[1]

The data structure diagrams is a predecessor of the entity-relationship model (E-R model). In DSDs, attributes are specified inside the entity boxes rather than outside of them, while relationships are drawn as boxes composed of attributes which specify the constraints that bind entities together. DSDs differ from the E-R model in that the E-R model focuses on the relationships between different entities, whereas DSDs focus on the relationships of the elements within an entity.

There are several styles for representing data structure diagrams, with the notable difference in the manner of defining cardinality. The choices are between arrow heads, inverted arrow heads (crow's feet), or numerical representation of the cardinality.

Bachman diagram

A Bachman diagram is a certain type of data structure diagram,[2] and is used to design the data with a network or relational "logical" model, separating the data model from the way the data is stored in the system. The model is named after database pioneer Charles Bachman, and mostly used in computer software design.

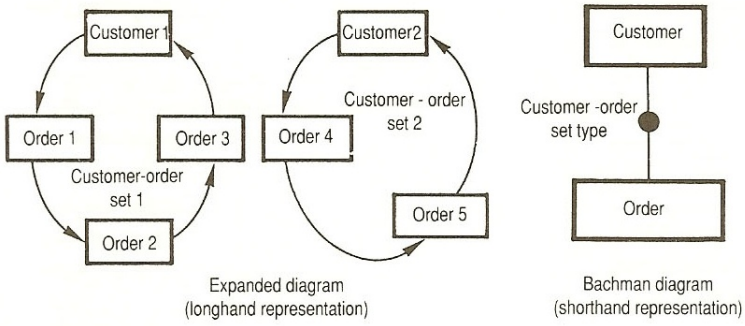


Illustration of set type using a Bachman diagram.

In a relational model, a relation is the cohesion of attributes that are fully and not transitive functional dependent[*clarify*] of every key in that relation. The coupling between the relations is based on accordant attributes. For every relation, a rectangle has to be drawn and every coupling is illustrated by a line that connects the relations. On the edge of each line, arrows indicate the cardinality. We have 1-to-n, 1-to-1 and n-to-n. The latter has to be avoided and must be replaced by two 1-to-n couplings.

Bitemporal Modeling

Bitemporal Modeling is an information modeling technique designed to handle historical data along two different timelines. This makes it possible to rewind the information to "as it actually was" in combination with "as it was recorded" at some point in time. In order to able do so, information cannot be discarded even if it is erroneous. Within, for example, financial reporting it is often desirable to be able to recreate an old report both as it actually looked at the time of creation and as it should have looked given corrections made to the data after its creation.

Implementations of Bitemporal Modeling are mostly done using relational databases. As such, Bitemporal Modeling is considered different from Dimensional Modeling and complementary to database normalization. The upcoming SQL standard SQL:2011 will provide language constructs for working with bitemporal data. As no standard is yet in place, current solutions are vendor specific.

Philosophy

Bitemporal modeling uses bitemporal structures as the basic components. This results in the databases which have a consistent type of temporality for all data.

Benefits of Bitemporal Modeling

By focusing on completness and accuracy of data Bitemporal Modeling facilitates the creation of complete audit trails of data. Specifically this allows for queries which provide:

1. The most accurate data possible as we know it now
2. Data as we knew it at any point in time
3. When and why the most accurate data we had changed

Bitemporal data

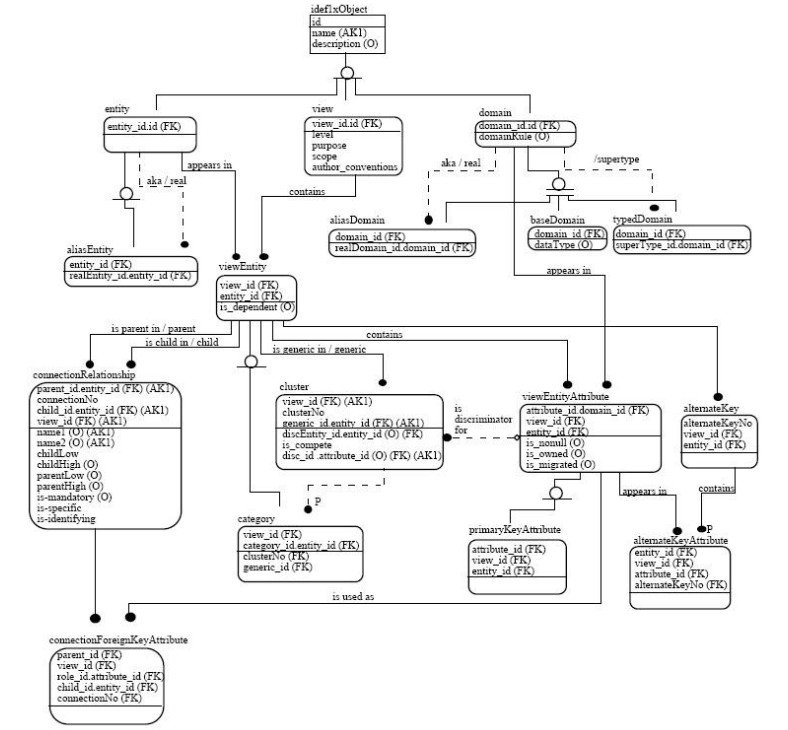
Bitemporal data is a concept used in a temporal database. It denotes both the valid time and transaction time of the data.

In a database table bitemporal data is often represented by four extra table-columns StartVT and EndVT, StartTT and EndTT. Normally each time interval is closed at its lower bound, and open at its upper bound.

IDEF1X

Integration DEFinition for Information Modeling (IDEF1X) is a data modeling language for the development of semantic data models. IDEF1X is used to produce a graphical information model which represents the structure and semantics of information within an environment or system.[1]

IDEF1X permits the construction of semantic data models which may serve to support the management of data as a resource, the integration of information systems, and the building of computer databases. This standard is part of the IDEF family of modeling languages in the field of software engineering.



Example of an IDEF1X Diagram.

Overview

A data modeling technique is used to model data in a standard, consistent and predictable manner in order to manage it as a resource. It can be used in projects requiring a standard means of defining and analyzing the data resources within an organization. Such projects include the incorporation of a data modeling technique into a methodology, managing data as a resource, integrating information systems, or designing computer databases. The primary objectives of the IDEF1X standard are to provide:

- Means for completely understanding and analyzing an organization's data resources
- Common means of representing and communicating the complexity of data
- A technique for presenting an overall view of the data required to run an enterprise
- Means for defining an application-independent view of data which can be validated by users and transformed into a physical database design
- A technique for deriving an integrated data definition from existing data resources.

A principal objective of IDEF1X is to support integration. The approach to integration focuses on the capture, management, and use of a single semantic definition of the data resource referred to as a “Conceptual schema.” The “conceptual schema” provides a single integrated definition of the data within an enterprise which is not biased toward any single application of data and is independent of how the data is physically stored or accessed. The

primary objective of this conceptual schema is to provide a consistent definition of the meanings of and interrelationships between data that can be used to integrate, share, and manage the integrity of data. A conceptual schema must have three important characteristics:

- Consistent with the infrastructure of the business and true across all application areas
- Extendible, such that new data can be defined without altering previously defined data
- Transformable to both the required user views and to a variety of data storage and access structures.

History

The need for semantic data models was first recognized by the U.S. Air Force in the mid-1970s as a result of the Integrated Computer Aided Manufacturing (ICAM) Program. The objective of this program was to increase manufacturing productivity through the systematic application of computer technology. The ICAM Program identified a need for better analysis and communication techniques for people involved in improving manufacturing productivity. As a result, the ICAM Program developed a series of techniques known as the IDEF (ICAM Definition) Methods which included the following:

- IDEF0 used to produce a “function model” which is a structured representation of the activities or processes within the environment or system
- IDEF1 used to produce an “information model” which represents the structure and semantics of information within the environment or system
- IDEF2 used to produce a “dynamics model”.

The initial approach to IDEF information modeling (IDEF1) was published by the ICAM program in 1981, based on current research and industry needs. The theoretical roots for this approach stemmed from the early work of Edgar F. Codd on relational theory and Peter Chen on the entity-relationship model. The initial IDEF1 technique was based on the work of Dr R. R. Brown and Mr T. L. Ramey of Hughes Aircraft and Mr D. S. Coleman of D. Appleton Company (DACOM), with critical review and influence by Charles Bachman, Peter Chen, Dr M. A. Melkanoff, and Dr G.M. Nijssen.

In 1983, the U.S. Air Force initiated the Integrated Information Support System (I2S2) project under the ICAM program. The objective of this project was to provide the enabling technology to logically and physically integrate a network of heterogeneous computer hardware and software. As a result of this project, and industry experience, the need for an enhanced technique for information modeling was recognized.

From the point of view of the contract administrators of the Air Force IDEF program, IDEF1X was a result of the ICAM IISS-6201 project and was further extended by the IISS-6202 project. To satisfy the data modeling enhancement requirements that were identified in the IISS-6202 project, a sub-contractor, DACOM, obtained a license to the Logical Database Design Technique (LDDT) and its supporting software (ADAM). From the point of view of the technical content of the modeling technique, IDEF1X is a renaming of LDDT.

Logical Database Design Technique

The Logical Database Design Technique (LDDT) had been developed in 1982 by Robert G. Brown of The Database Design Group entirely outside the IDEF program and with no knowledge of IDEF1. Nevertheless, the central goal of IDEF1 and LDDT was the same: to produce a database-neutral model of the persistent information needed by an enterprise by modeling the real-world entities involved. LDDT combined elements of the relational data model, the E-R model, and data generalization in a way specifically intended to support data modeling and the transformation of the data models into database designs.

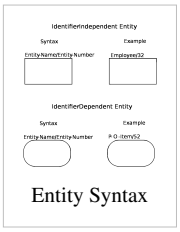
LDDT included an environmental (namespace) hierarchy, multiple levels of model, the modeling of generalization/specialization, and the explicit representation of relationships by primary and foreign keys, supported by a well defined role naming facility. The primary keys and unambiguously role-named foreign keys expressed

sometimes subtle uniqueness and referential integrity constraints that needed to be known and honored by whatever type of database was ultimately designed. Whether the database design used the integrity constraint based keys of the LDDT model as database access keys or indexes was an entirely separate decision. The precision and completeness of the LDDT models was an important factor in enabling the relatively smooth transformation of the models into database designs. Early LDDT models were transformed into database designs for IBM's hierarchical database, IMS. Later models were transformed into database designs for Cullinet's network database, IDMS, and many varieties of relational database.

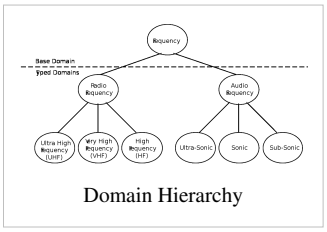
The LDDT software, ADAM, supported view (model) entry, view merging, selective (subset) viewing, namespace inheritance, normalization, a quality assurance analysis of views, entity relationship graph and report generation, transformation to a relational database expressed as SQL data declaration statements, and referential integrity checking SQL. Logical models were serialized with a structural modeling language.

The graphic syntax of LDDT differed from that of IDEF1 and, more importantly, LDDT contained many interrelated modeling concepts not present in IDEF1. Therefore, instead of extending IDEF1, Mary E. Loomis of DACOM wrote a concise summary of the syntax and semantics of a substantial subset of LDDT, using terminology compatible with IDEF1 wherever possible. DACOM labeled the result IDEF1X and supplied it to the ICAM program, which published it in 1985. (IEEE 1998, p. iii) (Bruce 1992, p. xii) DACOM also converted the ADAM software to C and sold it under the name Leverage.

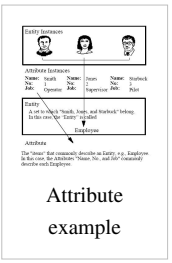
IDEF1X Building blocks



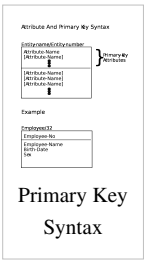
Entity Syntax



Domain Hierarchy



Attribute example



Primary Key Syntax

Entities

The representation of a class of real or abstract things (people, objects, places, events, ideas, combination of things, etc.) that are recognized as instances of the same class because they share the same characteristics and can participate in the same relationships.

Domains

A named set of data values (fixed, or possibly infinite in number) all of the same data type, upon which the actual value for an attribute instance is drawn. Every attribute must be defined on exactly one underlying domain. Multiple attributes may be based on the same underlying domain.

Attributes

A property or characteristic that is common to some or all of the instances of an entity. An attribute represents the use of a domain in the context of an entity.

Keys

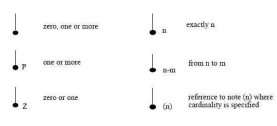
An attribute, or combination of attributes, of an entity whose values uniquely identify each entity instance. Each such set constitutes a candidate key.

Primary Keys

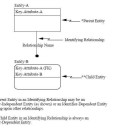
The candidate key selected as the unique identifier of an entity.

Foreign Keys

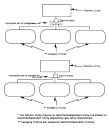
An attribute, or combination of attributes of a child or category entity instance whose values match those in the primary key of a related parent or generic entity instance. A foreign key can be viewed as the result of the "migration" of the primary key of the parent or generic entity through a specific connection or categorization relationship. An attribute or combination of attributes in the foreign key can be assigned a role name reflecting its role in the child or category entity.



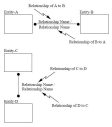
Relationship Cardinality Syntax



Identifying Relationship Syntax



Categorization Relationship Syntax



Non-Specific Relationship Syntax

Relationships

An association between the instances of two entities or between instances of the same entity.

Connection Relationships

A relationship having no semantics in addition to association. See Constraint, Cardinality.

Categorization Relationships

A relationship in which instances of both entities represent the same real or abstract thing. One entity (generic entity) represents the complete set of things, the other (category entity) represents a sub-type or sub-classification of those things. The category entity may have one or more characteristics, or a relationship with instances of another entity, not shared by all generic entity instances. Each instance of the category entity is simultaneously an instance of the generic entity.

Non-Specific Relationships

A relationship in which an instance of either entity can be related to any number of instances of the other.

View Levels

Three levels of view are defined in IDEF1X: Entity Relationship (ER), Key Based (KB), and Fully Attributed (FA). They differ in level of abstraction. The ER level is the most abstract. It models the most fundamental elements of the subject area - the entities and their relationships. It is usually broader in scope than the other levels. The KB level adds keys and the FA level adds all the attributes.

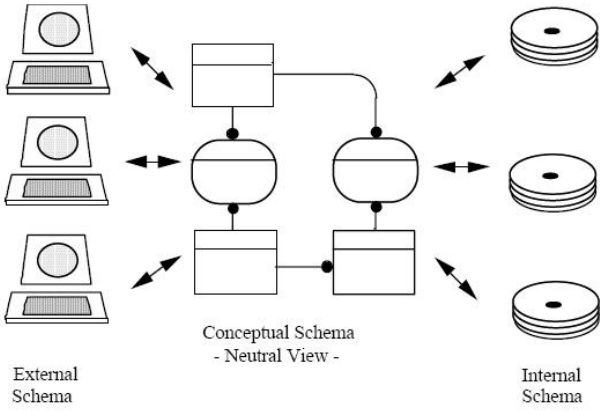
IDEF1X Topics

The Three Schema Approach

The three-schema approach in software engineering is an approach to building information systems and systems information management, that promotes the conceptual model as the key to achieving data integration.[3]

A schema is a model, usually depicted by a diagram and sometimes accompanied by a language description. The three schemas used in this approach are:[4]

- External schema for user views
- Conceptual schema integrates external schemata
- Internal schema that defines physical storage structures.



The three schema approach .[2]

At the center, the conceptual schema defines the ontology of the concepts as the users think of them and talk about them. The physical schema describes the internal formats of the data stored in the database, and the external schema defines the view of the data presented to the application programs.[5] The framework attempted to permit multiple data models to be used for external schemata.[6]

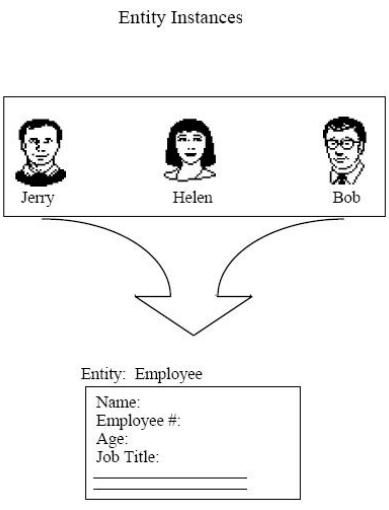
Modeling Guidelines

The modeling process can be divided into five stages of model developing.

Phase Zero – Project Initiation

The objectives of the Project Initiation phase include:

- Project definition – a general statement of what has to be done, why, and how it will get done
- Source material – a plan for the acquisition of source material, including indexing and filing
- Author conventions – a fundamental declaration of the conventions (optional methods) by which the author chooses to make and manage the model.



Synthesizing an Entity in Phase One – Entity Definition

Phase One – Entity Definition

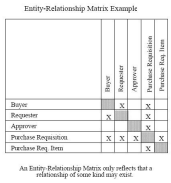
The objective of the Entity Definition phase is to identify and define the entities that fall within the problem domain being modeled.

Phase Two – Relationship Definition

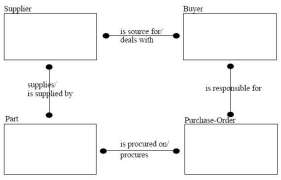
The objective of the Relationship Definition phase is to identify and define the basic relationships between entities. At this stage of modeling, some relationships may be non-specific and will require additional refinement in subsequent phases. The primary outputs from Phase Two are:

- Relationship matrix

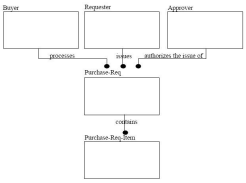
- Relationship definitions
- Entity-level diagrams.



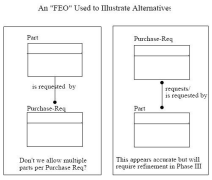
Entity Relationship Matrix



Entity Level Diagram



Entity Level Diagram Example



Reference Diagram

Phase Three - Key Definitions

The objectives of the Key Definitions phase are to:

- Refine the non-specific relationships from Phase Two
- Define key attributes for each entity
- Migrate primary keys to establish foreign keys
- Validate relationships and keys.

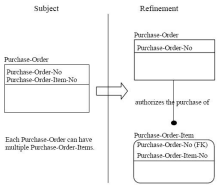
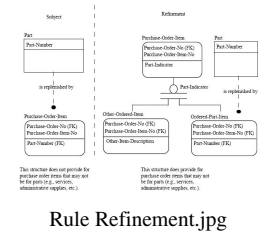
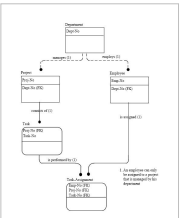
Attribute Examples



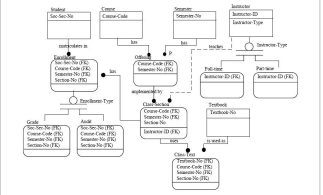
No-Repeat Rule Refinement



Rule Refinement.jpg



Path Assertions

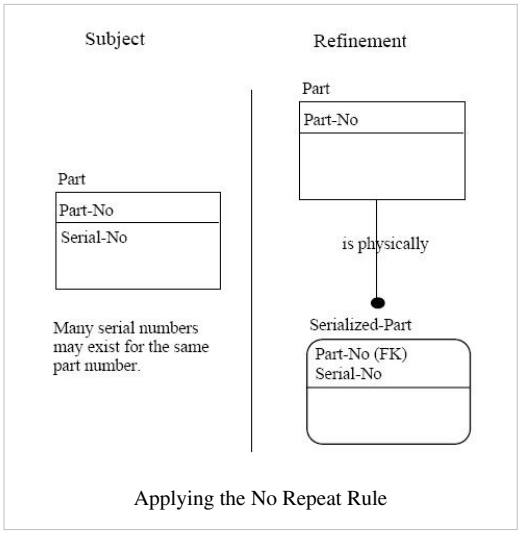


Example of Phase Three Function View Diagram

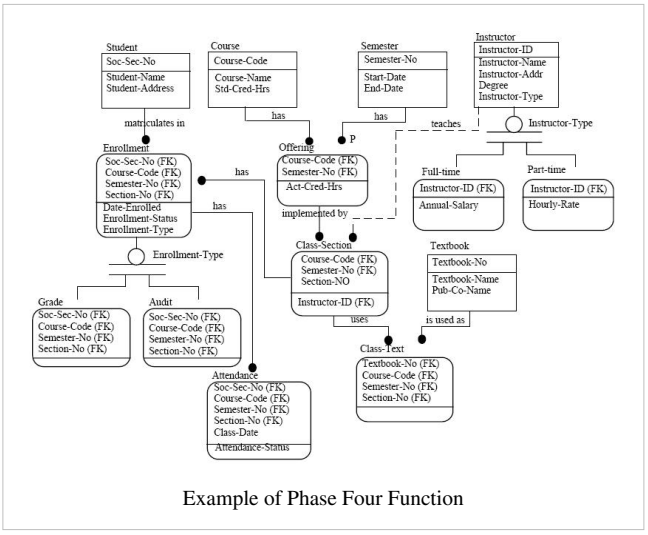
Phase Four - Attribute Definition

The objectives of the Attribute Definition phase are to:

- Develop an attribute pool
- Establish attribute ownership
- Define nonkey attributes
- Validate and refine the data structure.



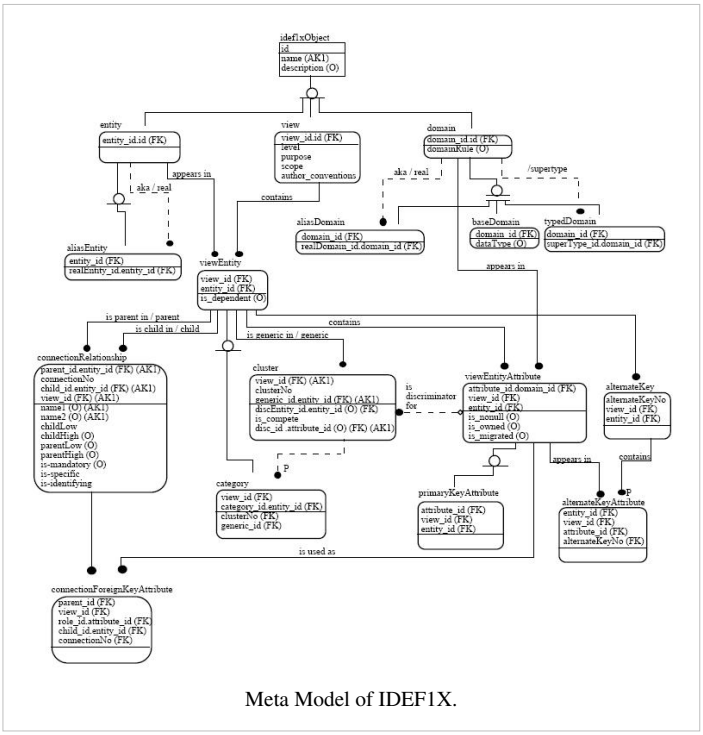
Applying the No Repeat Rule



Example of Phase Four Function

IDEF1X Meta Model

A meta model is a model of the constructs of a modeling system. Like any model, it is used to represent and reason about the subject of the model - in this case IDEF1X. The meta model is used to reason about IDEF1X, i.e., what the constructs of IDEF1X are and how they relate to one another. The model shown is an IDEF1X model of IDEF1X. Such meta models can be used for various purposes, such as repository design, tool design, or in order to specify the set of valid IDEF1X models. Depending on the purpose, somewhat different models result. There is no “one right model.” For example, a model for a tool that supports building models incrementally must allow incomplete or even inconsistent models. The meta model for formalization, however, emphasizes alignment with the concepts of the formalization and hence incomplete or inconsistent models are not allowed.



Meta Model of IDEF1X.

Meta models have two important limitations. First, they specify syntax but not semantics. Second, a meta model must be supplemented with constraints in natural or formal language. The formal theory of IDEF1X provides both the semantics and a means to precisely express the necessary constraints.

A meta model for IDEF1X is given in the adjacent figure. The name of the view is *mm*. The domain hierarchy and constraints are also given. The constraints are expressed as sentences in the formal theory of the meta model. The meta model informally defines the set of valid IDEF1X models in the usual way, as the sample instance tables that correspond to a valid IDEF1X model. The meta model also formally defines the set of valid IDEF1X models in the following way. The meta model, as an IDEF1X model, has a corresponding formal theory. The semantics of the theory are defined in the standard way. That is, an interpretation of a theory consists of a domain of individuals and a set of assignments:

- To each constant in the theory, an individual in the domain is assigned
- To each n-ary function symbol in the theory, an n-ary function over the domain is assigned
- To each n-ary predicate symbol in the theory, an n-ary relation over the domain is assigned.

In the intended interpretation, the domain of individuals consists of views, such as production; entities, such as part and vendor; domains, such as qty_on_hand; connection relationships; category clusters; and so on. If every axiom in the theory is true in the interpretation, then the interpretation is called a model for the theory. Every model for the IDEF1X theory corresponding to the IDEF1X meta model and its constraints is a valid IDEF1X model.

Universal Data Element Framework

The **Universal Data Element Framework** (**UDEF**) provides the foundation for building an enterprise-wide controlled vocabulary. It is a standard way of indexing enterprise information that can produce big cost savings. UDEF simplifies information management through consistent classification and assignment of a global standard identifier to the data names and then relating them to similar data element concepts defined by other organizations. Though this approach is a small part of the overall picture, it is potentially a crucial enabler of semantic interoperability.

How UDEF works

UDEF provides semantic links, through assigning an intelligent, derived ID as an attribute of the data element, essentially labeling the element as a specific data element concept. When this UDEF ID exists in both source and target formats, it can then be used as an easy analysis point via a match report, and then as the primary pivot point for transformations between source and target.

UDEF takes a list of high-level root object classes and assigns an integer to each class plus alpha characters to each specialization modifier. It then also assigns integers to property word plus integers to each specialization modifier. These object class alpha-integers are concatenated together with the property integers to form a dewey-decimal like code for each data element concept.

For the following examples, go to http:// www. opengroup. org/ udefinfo/ htm/ en_defs. htm and expand the applicable UDEF object and property trees

Assuming an application used by a hospital needs to map the data element concepts to the UDEF, the last name and first name (within UDEF you will find Family Name and Given Name under the UDEF property Name) of several people that are likely to appear on a medical record that could include the following example data element concepts –

Patient Person Family Name – find the word “Patient” under the UDEF object “Person” and find the word “Family” under the UDEF property “Name”

Patient Person Given Name – find the word “Patient” under the UDEF object “Person” and find the word “Given” under the UDEF property “Name”

Doctor Person Family Name – find the word “Doctor” under the UDEF object “Person” and find the word “Family” under the UDEF property “Name”

Doctor Person Given Name – find the word “Doctor” under the UDEF object “Person” and find the word “Given” under the UDEF property “Name”

The associated UDEF IDs for the above are derived by walking up each tree respectively and using an underscore to separate the object from the property. For the examples above, the following data element concepts are available within the current UDEF – see http:// www. opengroup. org/ udefinfo/ htm/ en_ob5. htm and http:// www. opengroup.org/udefinfo/htm/en_pr10.htm

“Patient Person Family Name” the UDEF ID is “au.5_11.10”

“Patient Person Given Name” the UDEF ID is “au.5_12.10”

“Doctor Person Family Name” the UDEF ID is “aq.5_11.10”

“Doctor Person Given Name” the UDEF ID is “aq.5_12.10”

Six basic steps to map enterprise data to the UDEF

There are six basic steps to follow when mapping data element concepts to the UDEF.

1. Identify the applicable UDEF property word that characterizes the dominant attribute (property) of the data element concept. For example: Name, Identifier, Date, etc.

2. Identify the dominant UDEF object word that the dominant property (selected in step 1) is describing. For example, Person_Name, Product_Identifier, Document_Date, etc.

3. By reviewing the UDEF tree for the selected property identified in step 1, identify applicable qualifiers that are necessary to describe the property word term unambiguously. For example, Family Name.

4. By reviewing the UDEF tree for the selected object identified in step 2, identify applicable qualifiers that are necessary to describe the object word term unambiguously. For example, Customer Person.

5. Concatenate the object term and the property term to create a UDEF naming convention compliant name where it is recognized that the name may seem artificially long. For example, Customer Person_Family Name.

6. Derive a structured ID based on the UDEF taxonomy that carries the UDEF inherited indexing scheme. For example <CustomerPersonFamilyName UDEFID=”as.5_11.10”>.

The Open Group UDEF Project objectives

The UDEF Project aims to establish the Universal Data Element Framework (UDEF) as the universally-used classification system for data element concepts. It focuses on developing and maintaining the UDEF as an open standard, advocating and promoting it, putting in place a technical infrastructure to support it, implementing a Registry for it, and setting up education programs to train information professionals in its use.

Organizations that implement UDEF will likely realize the greatest benefit by defining their controlled vocabulary based on the UDEF. To help an organization manage its UDEF based controlled vocabulary, it should seriously consider a metadata registry that is based on ISO/IEC 11179-5.

History of UDEF

Ron Schuldt, Sr. Enterprise Data Architect, Lockheed Martin, originated the UDEF concept based on ISO/IEC 11179 Metadata standards in the early 1990s. Currently, he is a Senior Partner with UDEF-IT, LLC.

Ownership of UDEF intellectual property

The Open Group assumed from AFEI the right to grant public use licensing of the UDEF.

The Supplier Management Council Electronic Enterprise Working Group of the Aerospace Industry Association (AIA) supports the UDEF as the naming convention solution to XML interoperability between standards that include all functions throughout a product's life-cycle and is working through a well defined process to obtain approval of this position from AIA and its member companies.

Criticism

Classification in UDEF is not sometimes hampered by ad hoc decisions that might produce problems. Example:

- b.be.5 is "United-Kingdom Citizen Person" and
- c.be.5 is "European Union Citizen Person"

As the United Kingdom is part of the European Union, the classification is not unique. Response: The UDEF is flexible and is designed to match the semantics and behaviour of existing systems. Therefore, if one system has a table for United Kingdom Citizens and a different system has a table for European Union Citizens, the UDEF can handle both situations.

Some of the concepts in UDEF are not as universal as it is claimed. They show a lot of bias to Anglo-American tradition and way of thinking and are not easily transferable to other languages. Example: The following part of the hierarchy shows the concept of an officer.

- j.5 Officer.Person
- a.j.5 Contracting.Officer.Person
- a.a.j.5 Procuring.Contracting.Officer.Person
- a.a.a.j.5 Government.Procuring.Contracting.Officer.Person
- b.a.j.5 Administrative.Contracting.Officer.Person
- b.j.5 Police.Officer.Person
- c.j.5 Military.Officer.Person

In many cultures, the part of the tree below "a.j.5 Contracting Officer Person" would not be placed under j.5 (see officer) as b.j.5 (see Law enforcement officer) or c.j.5 (see Officer (armed forces)).

Terminology model

A terminology model is a refinement of a concept system.[1] Within a terminology model the concepts (object types) of a specific problem or subject area are defined by subject matter experts in terms of concept (object type) definitions and definitions of subordinated concepts or characteristics (properties). Besides object types, the terminology model allows defining hierarchical classifications, definitions for object type and property behavior and definition of casual relations.

The terminology model is a means for subject matter experts to express their knowledge about the subject in subject specific terms. Since the terminology model is structured rather similar to an object-oriented database schema, is can be transformed without loss of information into an object-oriented database schema. Thus, the terminology model is a method for problem analysis on the one side and a mean of defining database schema on the other side.

Several terminology models have been developed and published in the field of statistics:

- Terminology model for classifications[2]
- Terminology model for statistical variables[3]
- Reference model for statistical metadata[4]

Georelational data model

A **georelational data model** is a geographic data model that represents geographic features as an interrelated set of spatial and attribute data. The georelational model is the fundamental data model used in coverages.[1]

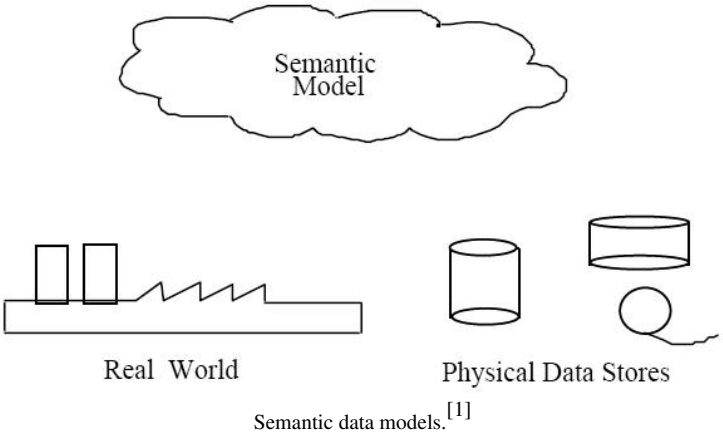
Semantic data model

A **semantic data model** in software engineering has various meanings:

1. It is a conceptual data model in which semantic information is included. This means that the model describes the meaning of its instances. Such a semantic data model is an abstraction that defines how the stored symbols (the instance data) relate to the real world.
2. It is a conceptual data model that includes the capability to express information that enables parties to the information exchange to interpret meaning (semantics) from the instances, without the need to know the meta-model. Such semantic models are fact oriented (as opposed to object oriented). Facts are typically expressed by binary relations between data elements, whereas higher order relations are expressed as collections of binary relations. Typically binary relations have the form of triples: Object-RelationType-Object. For example: the Eiffel Tower <is located in> Paris.



Semantic data models.[1]

Typically the instance data of semantic data models explicitly include the kinds of relationships between the various data elements, such as <is located in>. To interpret the meaning of the facts from the instances it is required that the meaning of the kinds of relations (relation types) is known. Therefore, semantic data models typically standardise such relation types. This means that the second kind of semantic data models enable that the instances express facts that include their own meaning. The second kind of semantic data models are usually meant to create semantic databases. The ability to include meaning in semantic databases facilitates building distributed databases that enable applications to interpret the meaning from the content. This implies that semantic databases can be integrated when they use the same (standard) relation types. This also implies that in general they have a wider applicability than relational or object oriented databases.

Overview

The logical data structure of a database management system (DBMS), whether hierarchical, network, or relational, cannot totally satisfy the requirements for a conceptual definition of data, because it is limited in scope and biased toward the implementation strategy employed by the DBMS. Therefore, the need to define data from a conceptual view has led to the development of semantic data modeling techniques. That is, techniques to define the meaning of data within the context of its interrelationships with other data. As illustrated in the figure. The real world, in terms

of resources, ideas, events, etc., are symbolically defined within physical data stores. A semantic data model is an abstraction which defines how the stored symbols relate to the real world. Thus, the model must be a true representation of the real world.

According to Klas and Schrefl (1995), the "overall goal of semantic data models is to capture more meaning of data by integrating relational concepts with more powerful abstraction concepts known from the Artificial Intelligence field. The idea is to provide high level modeling primitives as integral part of a data model in order to facilitate the representation of real world situations".[2]

History

The need for semantic data models was first recognized by the U.S. Air Force in the mid-1970s as a result of the Integrated Computer-Aided Manufacturing (ICAM) Program. The objective of this program was to increase manufacturing productivity through the systematic application of computer technology. The ICAM Program identified a need for better analysis and communication techniques for people involved in improving manufacturing productivity. As a result, the ICAM Program developed a series of techniques known as the IDEF (ICAM Definition) Methods which included the following:

- IDEF0 used to produce a “function model” which is a structured representation of the activities or processes within the environment or system.
- IDEF1 used to produce an “information model” which represents the structure and semantics of information within the environment or system.
  - IDEF1X is a semantic data modeling technique. It is used to produce a graphical information model which represents the structure and semantics of information within an environment or system. Use of this standard permits the construction of semantic data models which may serve to support the management of data as a resource, the integration of information systems, and the building of computer databases.
- IDEF2 used to produce a “dynamics model” which represents the time varying behavioral characteristics of the environment or system.

During the 1990s the application of semantic modelling techniques resulted in the semantic data models of the second kind. An example of such is the semantic data model that is standardised as ISO 15926-2 (2002), which is further developed into the semantic modelling language Gellish (2005). The definition of the Gellish language is documented in the form of a semantic data model. Gellish itself is a semantic modelling language, that can be used to create other semantic models. Those semantic models can be stored in Gellish Databases, being semantic databases.

Applications

A semantic data model can be used to serve many purposes. Some key objectives include:

- Planning of Data Resources: A preliminary data model can be used to provide an overall view of the data required to run an enterprise. The model can then be analyzed to identify and scope projects to build shared data resources.
- Building of Shareable Databases: A fully developed model can be used to define an application independent view of data which can be validated by users and then transformed into a physical database design for any of the various DBMS technologies. In addition to generating databases which are consistent and shareable, development costs can be drastically reduced through data modeling.
- Evaluation of Vendor Software: Since a data model actually represents the infrastructure of an organization, vendor software can be evaluated against a company’s data model in order to identify possible inconsistencies between the infrastructure implied by the software and the way the company actually does business.
- Integration of Existing Databases: By defining the contents of existing databases with semantic data models, an integrated data definition can be derived. With the proper technology, the resulting conceptual schema can be

used to control transaction processing in a distributed database environment. The U.S. Air Force Integrated Information Support System (I2S2) is an experimental development and demonstration of this type of technology applied to a heterogeneous DBMS environment.

Relational Model/Tasmania

Relational Model/Tasmania (RM/T) was published by E.F. Codd in 1979 and is the name given to a number of extensions to his original relational model (RM) published in 1970. The overall goal of the RM/T was to define some fundamental semantic units, at "atomic" and "molecular" levels, for data modelling. Codd writes: "*the result is a model with a richer variety of objects than the original relational model, additional insert-update-delete rules and some additional operators that make the algebra more powerful*".

RM History

Between 1968 and 1988 Codd published over 30 papers on the relational model (RM) - the most famous of which is his 1970 paper. Up to 1978 the papers describe RM Version 1 (RM/V1). In early 1979 Codd first presented some new ideas, called RM/T ('T' for Tasmania), at an invited talk for the *Australian Computer Science Conference* in Hobart, Tasmania. Later that year the ACM journal published a paper on RM/T, in which Codd acknowledges the influence of Schmid & Swensen (1975) and Wiederhold (1977).

A later version of RM/T (we shall call it here "RM/D") was described in Date (1983) in which Date and Codd improved and refined RM/T, adding an entity type called *designative*. Although Codd writes nothing about this new type, Date offers a rationale in Date (1983, page 262). Date revised this 1983 article in Date (1995), which additionally compares the RM/T model with the E/R model.

Following a disappointing uptake of RM/T by the database industry, Codd decided to introduce the RM/T model more gradually. He planned to release a sequence of RM versions: RM/V2, RM/V3 etc. each time progressively including some of the ideas of the original RM/T into the new version. Perhaps this explains why there is no obvious mapping of concepts between RM/T and RM/V2. For example, there is no reference to *associative* or *designative* entity types in Codd's 1990 book that defines RM/V2. On the other hand, the book extends and builds on the existing body of query language issues, many of which were addressed by Codd in several papers throughout the 1980s.

Summary of RM/T

First we shall introduce some of the new concepts of RM/T:

Surrogates A surrogate is a unique value assigned to each entity. If two relations use the same surrogate value then they represent the same entity in the modelled universe. The surrogate *value* can be any unique string or number but cannot be assigned or changed by the database user. For example, a SQL SEQUENCE is often used to generate *numerical* surrogate values.

Entities and Nonentities An *entity* is some *thing* in the modelled universe and is typically identified by a surrogate. A *nonentity* is some *thing* that is not an entity and does not have its own identifying surrogate. An *independent* entity has its own surrogate. A *dependent* entity has a surrogate but it belongs to another entity, i.e. the surrogate is a foreign key.

Atomic Semantics The RM/T addresses *atomic* semantics by describing how the original RM *relation* can be used to describe entities with attributes. An entity is represented as an *Entity-relation* or *E-relation* and its attributes (or immediate properties) are stored in separate *Property-relations* or *P-relations*. Each *E-relation* shares its surrogate with the associated *P-relation*s.

E-relations mark the *existence* of an entity. An *E-relation* is a relation (table) storing only the *surrogates* for a particular entity type. A surrogate value entered into the *E-relation* table implies the corresponding existence of an entity of that type in the *modelled world*. For example, the *E-relation* "Employee" is a table containing the surrogates of all entities of type *Employee*.

P-relations store the *attribute values* of an entity. A *P-relation* is a relation (table) storing the surrogate and one or more attributes of an entity. The surrogate value of a *P-relation* is that of the corresponding *E-relation*; it plays the role (K-role) of the primary key for that *P-relation*. For example, the *P-relation* "Employee_Number" is a table with two columns: one containing the surrogate value of the "Employee" *E-relation*, the other containing the employee *number*.

Note that by performing an OUTER NATURAL JOIN on the RM/T "Employee" *E-relation* and "Employee_Person" *P-relation* we can construct the RM/V1 "Employee" relation. This illustrates why the *E-relation* and *P-relation* concepts of RM/T are more *atomic* than the *relation* concept of RM/V1.

Molecular Semantics The RM/T addresses *molecular* semantics by taking the original RM and categorising the relations into several entity types, increasing the information captured by the semantic data model. However Codd does not define a notation for diagramming his new semantics. Each entity may play several roles at once and thus belong to one or more of the following entity types:

- *Characteristic* - subordinate entities that describe kernel entities.
- *Associative* - superordinate entities that interrelate kernel entities.
- *Kernel* - entities that are neither characteristic or associative.

Codd goes on to introduce subtyping of entities, giving yet another qualifier for entities:

- *Inner* - entities that are not subtypes of another entity.

Hence Codd speaks of *inner kernel* and *inner associative* entities.

The following definition is based on the RM/D model in Date (1983); it does *not* appear in Codd (1979):

- *Designative* - entities that contain a designation. A designative entity is at the *many* end of a *one-to-many* relationship between two independent entities. For example, a writer may write many books, hence a one-to-many relationship between writer and book entities; the book is the *designative* entity because it contains a designation (or *designative reference*) to the writer - namely the primary key of the writer entity. Note that an *associative* entity contains at least two designations. For example, we can regard a booking as either an entity that *associates* a person with a flight, or as an entity that *designates* a person and *designates* a flight. Hence a designative entity must contain at least *one* designation whereas an associative entity must contain at least *two* designations.

Associations These are what we might otherwise call *relationships* between entities or non-entities. The value *E-null* is used when deleteting entities from the RM/T model; all associations that have surrogates referring to a non-existing entity are assigned the value *E-null*, meaning the entity is unknown.

Associative Entity and Nonentity Association An *associative entity* is an entity that represents an association between two independent entities; the *associative entity* is an entity in itself because it has a surrogate. A *nonentity association* is similar to an *associative entity* however it has *no* surrogate. This lack of a surrogate stops the *nonentity association* from having, for example, any descriptive *characteristic entities*.

Directed Graph Relations Several *directed graph* relations are defined to capture further semantic features of the RM/T model. These graphs are named as follows:

- PG-relation (Property Graph) stores *property* relationships
- CG-relation (Characteristic Graph) stores *characteristic* relationships
- AG-relation (Association Graph) stores *association* relationships
- UGI-relation (Unconditional Generalisation by Inclusion) stores *generalisation by inclusion* relationships
- AGI-relation (Alternative Generalisation by Inclusion) stores *generalisation by alternative* relationships
- US-relation (Unconditional Successor) stores *unconditional successor* relationships
- AS-relation (Alternative Successor) stores *alternative successor* relationships
- KG-relation (Cover Membership) stores *cover membership* relationships
- UP-relation (Unconditional Precedence) stores *unconditional succession of event* relationships
- AP-relation (Alternative Precedence) stores *alternative succession of eve*nt relationships

RM/T Catalog The Catalog is a meta-model storing the descriptions of the relations themselves. The RM/T Catalog comprises the following relations:

- CATR (R-surrogate, *relname*, RelType) describes relations
- CATRA (RA-surrogate, R-surrogate, A-surrogate) relates relations and attributes
- CATA (A-surrogate, *attname*, UserKey) describes attributes
- CATAD (AD-surrogate, A-surrogate, D-surrogate) relates attributes and domains
- CATD (D-surrogate, *domname*, VType, Ordering) describes domains
- CATC (C-surrogate, *pername*) describes categories
- CATRC (RC-surrogate, R-surrogate, C-surrogate) relates relations and categories

where

- *relname* is the textual name of a relation. e.g. "Address"
- *attname* is the textual name of an attribute. e.g. "Street"
- *domname* is the textual name of a domain. e.g. "Salary"
- *pername* is the category label (from the PER-domain)
- RN-domain is the domain of all relnames in the database
- PER-domain is the domain of all category labels
- E-domain is the domain of all surrogates in the database
- E-attribute is any attribute that plays the role of a surrogate (from the E-domain)
- E-null is the "entity unknown" surrogate (from the E-domain)
- R-surrogate is the relation surrogate (from the E-domain)
- A-surrogate is the attribute surrogate (from the E-domain)
- D-surrogate is the domain surrogate (from the E-domain)
- C-surrogate is the category label surrogate (from the E-domain)
- RA-surrogate is the relation-attribute surrogate (from the E-domain)
- AD-surrogate is the attribute-domain surrogate (from the E-domain)
- RC-surrogate is the relation-category-label surrogate (from the E-domain)
- RelType is the type of object represented by the relation
- UserKey shows whether the attribute participates in a user-defined key
- VType is the syntactic type of the value
- Ordering shows whether the operator > is applicable between values of the domain

Operators Numerous operators are defined on names, sets and graphs. See Codd's 1979 paper for details.

RM/T Today

There is little mention of RM/T today and no articles have appeared recently. Peckam and Maryanski (1988) wrote about RM/T in their study of semantic data models. Codd published his book in 1990 but wrote nothing more about RM/T. RM/V1 and RM/V2 have a chapter each in *Date and Darwen* (1992) and the Date (1983) article was updated in (1995) and now contains a long overdue comparison of the E/R model and RM/T. Date's most recent reflections can be found on the Web at Date (1999), *The Database Relational Model* (2001) and *Date on RM/T* (2003).

RM/T contributed to the body of knowledge called semantic data modeling and semantic object modeling and continues to influence new data modellers. See the paper by Hammer and McLeod (1981), the book by Knoenke (2001) and implementation by Grabczewski et alia (2004).

Relational Schema

Relational model

The **relational model** for database management is a database model based on first-order predicate logic, first formulated and proposed in 1969 by Edgar F. Codd.[1] In the relational model of a database, all data is represented in terms of tuples, grouped into relations. A database organized in terms of the relational model is a relational database.

The purpose of the relational model is to provide a declarative method for specifying data and queries: users directly state what information the database contains and what information they want from it, and let the database management system software take care of describing data structures for storing the data and retrieval procedures for answering queries.

Most relational databases use the SQL data definition and query language; these systems implement what can be regarded as an engineering approximation to the relational model. A *table* in an SQL database schema corresponds to a predicate variable; the contents of a table to a relation; key constraints, other constraints, and SQL queries correspond to predicates. However, SQL databases, including DB2, deviate from the relational model in many details, and Codd fiercely argued against deviations that compromise the original principles.[3]

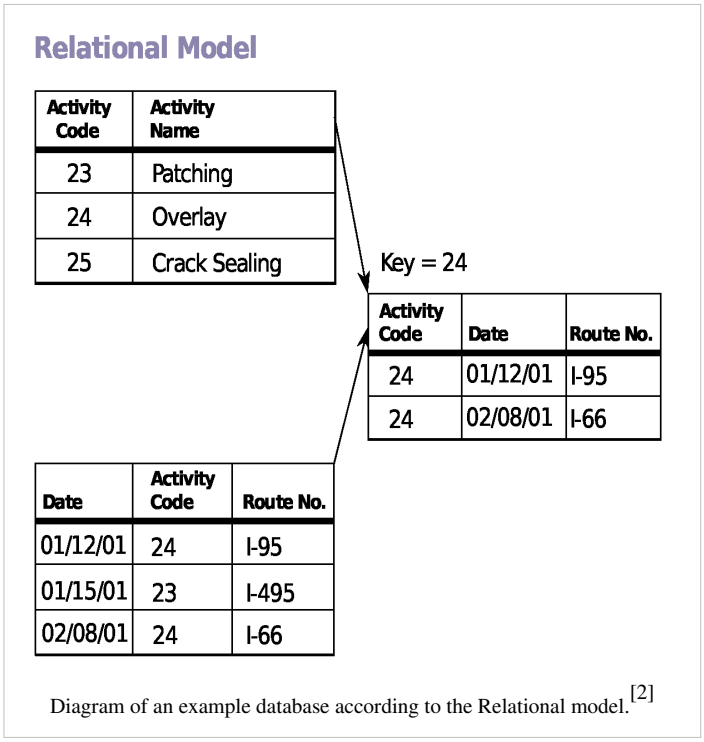

Diagram of an example database according to the Relational model.[2]

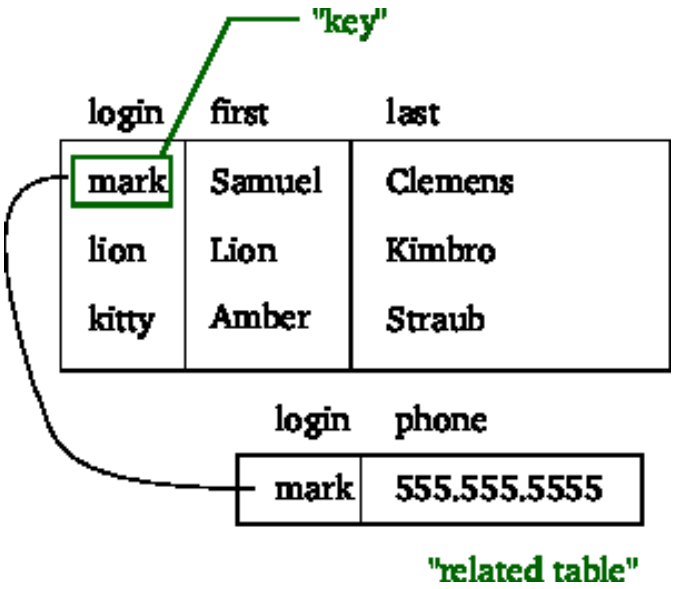


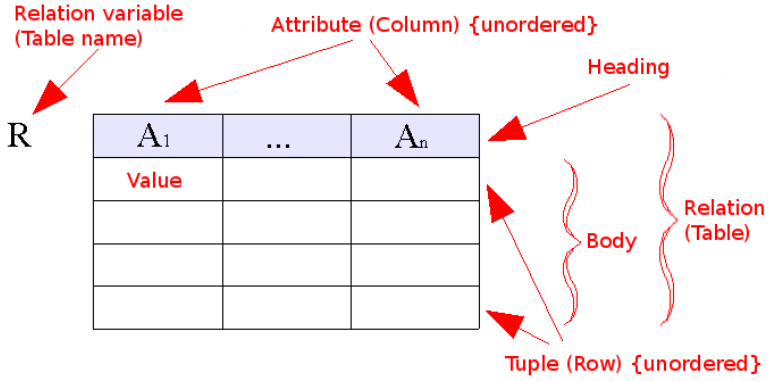
In the relational model, related records are linked together with a "key".

Overview

The relational model's central idea is to describe a database as a collection of predicates over a finite set of predicate variables, describing constraints on the possible values and combinations of values. The content of the database at any given time is a finite (logical) model of the database, i.e. a set of relations, one per predicate variable, such that all predicates are satisfied. A request for information from the database (a database query) is also a predicate.

Alternatives to the relational model

Other models are the hierarchical model and network model. Some systems using these older architectures are still in use today in data centers with high data volume needs, or where existing systems are so complex and abstract it would be cost-prohibitive to migrate to systems employing the relational model; also of note are newer object-oriented databases.



Relational model concepts.

Implementation

There have been several attempts to produce a true implementation of the relational database model as originally defined by Codd and explained by Date, Darwen and others, but none have been popular successes so far. Rel is one of the more recent attempts to do this.

The relational model was the first database model to be described in formal mathematical terms. Hierarchical and network databases existed before relational databases, but their specifications were relatively informal. After the relational model was defined, there were many attempts to compare and contrast the different models, and this led to the emergence of more rigorous descriptions of the earlier models; though the procedural nature of the data manipulation interfaces for hierarchical and network databases limited the scope for formalization.[*citation needed*]

History

The relational model was invented by E.F. (Ted) Codd as a general model of data, and subsequently maintained and developed by Chris Date and Hugh Darwen among others. In The Third Manifesto (first published in 1995) Date and Darwen show how the relational model can accommodate certain desired object-oriented features.

Controversies

Codd himself, some years after publication of his 1970 model, proposed a three-valued logic (True, False, Missing or NULL) version of it to deal with missing information, and in his *The Relational Model for Database Management Version 2* (1990) he went a step further with a four-valued logic (True, False, Missing but Applicable, Missing but Inapplicable) version. But these have never been implemented, presumably because of attending complexity. SQL's NULL construct was intended to be part of a three-valued logic system, but fell short of that due to logical errors in the standard and in its implementations.[*citation needed*]

Relational model topics

The model

The fundamental assumption of the relational model is that all data is represented as mathematical *n*-ary **relations**, an *n*-ary relation being a subset of the Cartesian product of *n* domains. In the mathematical model, reasoning about such data is done in two-valued predicate logic, meaning there are two possible evaluations for each proposition: either *true* or *false* (and in particular no third value such as *unknown*, or *not applicable*, either of which are often associated with the concept of NULL). Data are operated upon by means of a relational calculus or relational

algebra, these being equivalent in expressive power.

The relational model of data permits the database designer to create a consistent, logical representation of information. Consistency is achieved by including declared ***constraints*** in the database design, which is usually referred to as the logical schema. The theory includes a process of database normalization whereby a design with certain desirable properties can be selected from a set of logically equivalent alternatives. The access plans and other implementation and operation details are handled by the DBMS engine, and are not reflected in the logical model. This contrasts with common practice for SQL DBMSs in which performance tuning often requires changes to the logical model.

The basic relational building block is the domain or data type, usually abbreviated nowadays to ***type***. A *tuple* is an ordered set of ***attribute values***. An attribute is an ordered pair of ***attribute name*** and ***type name***. An attribute value is a specific valid value for the type of the attribute. This can be either a scalar value or a more complex type.

A relation consists of a ***heading*** and a ***body***. A heading is a set of attributes. A body (of an *n*-ary relation) is a set of *n*-tuples. The heading of the relation is also the heading of each of its tuples.

A relation is defined as a set of *n*-tuples. In both mathematics and the relational database model, a set is an *unordered* collection of unique, non-duplicated items, although some DBMSs impose an order to their data. In mathematics, a tuple has an order, and allows for duplication. E.F. Codd originally defined tuples using this mathematical definition. Later, it was one of E.F. Codd's great insights that using attribute names instead of an ordering would be so much more convenient (in general) in a computer language based on relations [*citation needed*]. This insight is still being used today. Though the concept has changed, the name "tuple" has not. An immediate and important consequence of this distinguishing feature is that in the relational model the Cartesian product becomes commutative.

A table is an accepted visual representation of a relation; a tuple is similar to the concept of a *row*.

A *relvar* is a named variable of some specific relation type, to which at all times some relation of that type is assigned, though the relation may contain zero tuples.

The basic principle of the relational model is the Information Principle: all information is represented by data values in relations. In accordance with this Principle, a relational database is a set of relvars and the result of every query is presented as a relation.

The consistency of a relational database is enforced, not by rules built into the applications that use it, but rather by *constraints*, declared as part of the logical schema and enforced by the DBMS for all applications. In general, constraints are expressed using relational comparison operators, of which just one, "is subset of" ($\subseteq$), is theoretically sufficient[*citation needed*]. In practice, several useful shorthands are expected to be available, of which the most important are candidate key (really, superkey) and foreign key constraints.

Interpretation

To fully appreciate the relational model of data it is essential to understand the intended *interpretation* of a relation.

The body of a relation is sometimes called its extension. This is because it is to be interpreted as a representation of the extension of some predicate, this being the set of true propositions that can be formed by replacing each free variable in that predicate by a name (a term that designates something).

There is a one-to-one correspondence between the free variables of the predicate and the attribute names of the relation heading. Each tuple of the relation body provides attribute values to instantiate the predicate by substituting each of its free variables. The result is a proposition that is deemed, on account of the appearance of the tuple in the relation body, to be true. Contrariwise, every tuple whose heading conforms to that of the relation, but which does not appear in the body is deemed to be false. This assumption is known as the closed world assumption: it is often violated in practical databases, where the absence of a tuple might mean that the truth of the corresponding proposition is unknown. For example, the absence of the tuple ('John', 'Spanish') from a table of language skills

cannot necessarily be taken as evidence that John does not speak Spanish.

For a formal exposition of these ideas, see the section Set-theoretic Formulation, below.

Application to databases

A **data type** as used in a typical relational database might be the set of integers, the set of character strings, the set of dates, or the two boolean values *true* and *false*, and so on. The corresponding **type names** for these types might be the strings "int", "char", "date", "boolean", etc. It is important to understand, though, that relational theory does not dictate what types are to be supported; indeed, nowadays provisions are expected to be available for *user-defined* types in addition to the *built-in* ones provided by the system.

Attribute is the term used in the theory for what is commonly referred to as a **column**. Similarly, **table** is commonly used in place of the theoretical term **relation** (though in SQL the term is by no means synonymous with relation). A table data structure is specified as a list of column definitions, each of which specifies a unique column name and the type of the values that are permitted for that column. An **attribute *value*** is the entry in a specific column and row, such as "John Doe" or "35".

A **tuple** is basically the same thing as a **row**, except in an SQL DBMS, where the column values in a row are ordered. (Tuples are not ordered; instead, each attribute value is identified solely by the **attribute name** and never by its ordinal position within the tuple.) An attribute name might be "name" or "age".

A **relation** is a **table** structure definition (a set of column definitions) along with the data appearing in that structure. The structure definition is the **heading** and the data appearing in it is the **body**, a set of rows. A database **relvar** (relation variable) is commonly known as a **base table**. The heading of its assigned value at any time is as specified in the table declaration and its body is that most recently assigned to it by invoking some **update operator** (typically, INSERT, UPDATE, or DELETE). The heading and body of the table resulting from evaluation of some query are determined by the definitions of the operators used in the expression of that query. (Note that in SQL the heading is not always a set of column definitions as described above, because it is possible for a column to have no name and also for two or more columns to have the same name. Also, the body is not always a set of rows because in SQL it is possible for the same row to appear more than once in the same body.)

SQL and the relational model

SQL, initially pushed as the standard language for relational databases, deviates from the relational model in several places. The current ISO SQL standard doesn't mention the relational model or use relational terms or concepts. However, it is possible to create a database conforming to the relational model using SQL if one does not use certain SQL features.

The following deviations from the relational model have been notedWikipedia:Avoid weasel words in SQL. Note that few database servers implement the entire SQL standard and in particular do not allow some of these deviations. Whereas NULL is ubiquitous, for example, allowing duplicate column names within a table or anonymous columns is uncommon.

Duplicate rows

: The same row can appear more than once in an SQL table. The same tuple cannot appear more than once in a relation.

Anonymous columns

: A column in an SQL table can be unnamed and thus unable to be referenced in expressions. The relational model requires every attribute to be named and referenceable.

Duplicate column names

: Two or more columns of the same SQL table can have the same name and therefore cannot be referenced, on account of the obvious ambiguity. The relational model requires every attribute to be referenceable.

Column order significance

The order of columns in an SQL table is defined and significant, one consequence being that SQL's implementations of Cartesian product and union are both noncommutative. The relational model requires there to be no significance to any ordering of the attributes of a relation.

Views without CHECK OPTION

Updates to a view defined without CHECK OPTION can be accepted but the resulting update to the database does not necessarily have the expressed effect on its target. For example, an invocation of INSERT can be accepted but the inserted rows might not all appear in the view, or an invocation of UPDATE can result in rows disappearing from the view. The relational model requires updates to a view to have the same effect as if the view were a base relvar.

Columnless tables unrecognized

SQL requires every table to have at least one column, but there are two relations of degree zero (of cardinality one and zero) and they are needed to represent extensions of predicates that contain no free variables.

NULL

This special mark can appear instead of a value wherever a value can appear in SQL, in particular in place of a column value in some row. The deviation from the relational model arises from the fact that the implementation of this *ad hoc* concept in SQL involves the use of three-valued logic, under which the comparison of NULL with itself does not yield *true* but instead yields the third truth value, *unknown*; similarly the comparison NULL with something other than itself does not yield *false* but instead yields *unknown*. It is because of this behaviour in comparisons that NULL is described as a mark rather than a value. The relational model depends on the law of excluded middle under which anything that is not true is false and anything that is not false is true; it also requires every tuple in a relation body to have a value for every attribute of that relation. This particular deviation is disputed by some if only because E.F. Codd himself eventually advocated the use of special marks and a 4-valued logic, but this was based on his observation that there are two distinct reasons why one might want to use a special mark in place of a value, which led opponents of the use of such logics to discover more distinct reasons and at least as many as 19 have been noted, which would require a 21-valued logic. [*citation needed*] SQL itself uses NULL for several purposes other than to represent "value unknown". For example, the sum of the empty set is NULL, meaning zero, the average of the empty set is NULL, meaning undefined, and NULL appearing in the result of a LEFT JOIN can mean "no value because there is no matching row in the right-hand operand".

Relational operations

Users (or programs) request data from a relational database by sending it a query that is written in a special language, usually a dialect of SQL. Although SQL was originally intended for end-users, it is much more common for SQL queries to be embedded into software that provides an easier user interface. Many Web sites, such as Wikipedia, perform SQL queries when generating pages.

In response to a query, the database returns a result set, which is just a list of rows containing the answers. The simplest query is just to return all the rows from a table, but more often, the rows are filtered in some way to return just the answer wanted.

Often, data from multiple tables are combined into one, by doing a join. Conceptually, this is done by taking all possible combinations of rows (the Cartesian product), and then filtering out everything except the answer. In practice, relational database management systems rewrite ("optimize") queries to perform faster, using a variety of techniques.

There are a number of relational operations in addition to join. These include project (the process of eliminating some of the columns), restrict (the process of eliminating some of the rows), union (a way of combining two tables

with similar structures), difference (that lists the rows in one table that are not found in the other), intersect (that lists the rows found in both tables), and product (mentioned above, which combines each row of one table with each row of the other). Depending on which other sources you consult, there are a number of other operators – many of which can be defined in terms of those listed above. These include semi-join, outer operators such as outer join and outer union, and various forms of division. Then there are operators to rename columns, and summarizing or aggregating operators, and if you permit relation values as attributes (RVA – relation-valued attribute), then operators such as group and ungroup. The SELECT statement in SQL serves to handle all of these except for the group and ungroup operators.

The flexibility of relational databases allows programmers to write queries that were not anticipated by the database designers. As a result, relational databases can be used by multiple applications in ways the original designers did not foresee, which is especially important for databases that might be used for a long time (perhaps several decades). This has made the idea and implementation of relational databases very popular with businesses.

Database normalization

Relations are classified based upon the types of anomalies to which they're vulnerable. A database that's in the first normal form is vulnerable to all types of anomalies, while a database that's in the domain/key normal form has no modification anomalies. Normal forms are hierarchical in nature. That is, the lowest level is the first normal form, and the database cannot meet the requirements for higher level normal forms without first having met all the requirements of the lesser normal forms.[4]

Examples

Database

An idealized, very simple example of a description of some relvars (relation variables) and their attributes:

- Customer (**Customer ID**, Tax ID, Name, Address, City, State, Zip, Phone, Email)
- Order (**Order No**, Customer ID, Invoice No, Date Placed, Date Promised, Terms, Status)
- Order Line (**Order No**, **Order Line No**, Product Code, Qty)
- Invoice (**Invoice No**, Customer ID, Order No, Date, Status)
- Invoice Line (**Invoice No**, **Invoice Line No**, Product Code, Qty Shipped)
- Product (**Product Code**, Product Description)

In this design we have six relvars: Customer, Order, Order Line, Invoice, Invoice Line and Product. The bold, underlined attributes are *candidate keys*. The non-bold, underlined attributes are *foreign keys*.

Usually one candidate key is arbitrarily chosen to be called the primary key and used in preference over the other candidate keys, which are then called alternate keys.

A *candidate key* is a unique identifier enforcing that no tuple will be duplicated; this would make the relation into something else, namely a bag, by violating the basic definition of a set. Both foreign keys and superkeys (that includes candidate keys) can be composite, that is, can be composed of several attributes. Below is a tabular depiction of a relation of our example Customer relvar; a relation can be thought of as a value that can be attributed to a relvar.

Customer relation

Customer ID	Tax ID	Name	Address	[More fields…]
1234567890	555-5512222	Munmun	323 Broadway	…
2223344556	555-5523232	Wile E.	1200 Main Street	…
3334445563	555-5533323	Ekta	871 1st Street	…
4232342432	555-5325523	E. F. Codd	123 It Way	…

If we attempted to *insert* a new customer with the ID *1234567890*, this would violate the design of the relvar since **Customer ID** is a *primary key* and we already have a customer *1234567890*. The DBMS must reject a transaction such as this that would render the database inconsistent by a violation of an integrity constraint.

Foreign keys are integrity constraints enforcing that the value of the attribute set is drawn from a *candidate key* in another relation. For example in the Order relation the attribute **Customer ID** is a foreign key. A *join* is the operation that draws on information from several relations at once. By joining relvars from the example above we could *query* the database for all of the Customers, Orders, and Invoices. If we only wanted the tuples for a specific customer, we would specify this using a restriction condition.

If we wanted to retrieve all of the Orders for Customer *1234567890*, we could query the database to return every row in the Order table with **Customer ID** *1234567890* and join the Order table to the Order Line table based on **Order No**.

There is a flaw in our database design above. The Invoice relvar contains an Order No attribute. So, each tuple in the Invoice relvar will have one Order No, which implies that there is precisely one Order for each Invoice. But in reality an invoice can be created against many orders, or indeed for no particular order. Additionally the Order relvar contains an Invoice No attribute, implying that each Order has a corresponding Invoice. But again this is not always true in the real world. An order is sometimes paid through several invoices, and sometimes paid without an invoice. In other words there can be many Invoices per Order and many Orders per Invoice. This is a **many-to-many** relationship between Order and Invoice (also called a *non-specific relationship*). To represent this relationship in the database a new relvar should be introduced whose role is to specify the correspondence between Orders and Invoices:

OrderInvoice(**Order No**,**Invoice No**)

Now, the Order relvar has a *one-to-many relationship* to the OrderInvoice table, as does the Invoice relvar. If we want to retrieve every Invoice for a particular Order, we can query for all orders where **Order No** in the Order relation equals the **Order No** in OrderInvoice, and where **Invoice No** in OrderInvoice equals the **Invoice No** in Invoice.

Set-theoretic formulation

Basic notions in the relational model are *relation names* and *attribute names*. We will represent these as strings such as "Person" and "name" and we will usually use the variables $r, s, t, \ldots$ and a, b, c to range over them. Another basic notion is the set of *atomic values* that contains values such as numbers and strings.

Our first definition concerns the notion of *tuple*, which formalizes the notion of row or record in a table:

Tuple

: A tuple is a partial function from attribute names to atomic values.

Header

: A header is a finite set of attribute names.

Projection

The projection of a tuple t on a finite set of attributes A is $t[A] = \{(a, v) : (a, v) \in t, a \in A\}$.

The next definition defines *relation* that formalizes the contents of a table as it is defined in the relational model.

Relation

A relation is a tuple (H, B) with H, the header, and B, the body, a set of tuples that all have the domain H.

Such a relation closely corresponds to what is usually called the extension of a predicate in first-order logic except that here we identify the places in the predicate with attribute names. Usually in the relational model a database schema is said to consist of a set of relation names, the headers that are associated with these names and the constraints that should hold for every instance of the database schema.

Relation universe

A relation universe U over a header H is a non-empty set of relations with header H.

Relation schema

A relation schema (H, C) consists of a header H and a predicate $C(R)$ that is defined for all relations R with header H. A relation satisfies a relation schema (H, C) if it has header H and satisfies C.

Key constraints and functional dependencies

One of the simplest and most important types of relation constraints is the *key constraint*. It tells us that in every instance of a certain relational schema the tuples can be identified by their values for certain attributes.

Superkey

A superkey is written as a finite set of attribute names.

A superkey K holds in a relation (H, B) if:

- $K \subseteq H$ and
- there exist no two distinct tuples $t_1, t_2 \in B$ such that $t_1[K] = t_2[K]$.

A superkey holds in a relation universe U if it holds in all relations in U.

Theorem: A superkey K holds in a relation universe U over H if and only if $K \subseteq H$ and $K \to H$ holds in U.

Candidate key

A superkey K holds as a candidate key for a relation universe U if it holds as a superkey for U and there is no proper subset of K that also holds as a superkey for U.

Functional dependency

A functional dependency (FD for short) is written as $X \to Y$ for X, Y finite sets of attribute names.

A functional dependency $X \to Y$ holds in a relation (H, B) if:

- $X, Y \subseteq H$ and
- $\forall$ tuples $t_1, t_2 \in B$, $t_1[X] = t_2[X] \Rightarrow t_1[Y] = t_2[Y]$

A functional dependency $X \to Y$ holds in a relation universe U if it holds in all relations in U.

Trivial functional dependency

A functional dependency is trivial under a header H if it holds in all relation universes over H.

Theorem: An FD $X \to Y$ is trivial under a header H if and only if $Y \subseteq X \subseteq H$.

Closure

Armstrong's axioms: The closure of a set of FDs S under a header H, written as S^+, is the smallest superset of S such that:

- $Y \subseteq X \subseteq H \Rightarrow X \to Y \in S^+$ (reflexivity)

- $X \to Y \in S^+ \wedge Y \to Z \in S^+ \Rightarrow X \to Z \in S^+$ (transitivity) and
- $X \to Y \in S^+ \wedge Z \subseteq H \Rightarrow (X \cup Z) \to (Y \cup Z) \in S^+$ (augmentation)

  Theorem: Armstrong's axioms are sound and complete; given a header H and a set S of FDs that only contain subsets of H, $X \to Y \in S^+$ if and only if $X \to Y$ holds in all relation universes over H in which all FDs in S hold.

Completion

The completion of a finite set of attributes X under a finite set of FDs S, written as X^+, is the smallest superset of X such that:

- $Y \to Z \in S \wedge Y \subseteq X^+ \Rightarrow Z \subseteq X^+$

  The completion of an attribute set can be used to compute if a certain dependency is in the closure of a set of FDs.

  Theorem: Given a set S of FDs, $X \to Y \in S^+$ if and only if $Y \subseteq X^+$.

Irreducible cover

An irreducible cover of a set S of FDs is a set T of FDs such that:

- $S^+ = T^+$
- there exists no $U \subset T$ such that $S^+ = U^+$
- $X \to Y \in T \Rightarrow Y$ is a singleton set and
- $X \to Y \in T \wedge Z \subset X \Rightarrow Z \to Y \notin S^+$.

Algorithm to derive candidate keys from functional dependencies

```
INPUT: a set S of FDs that contain only subsets of a header H
OUTPUT: the set C of superkeys that hold as candidate keys in
        all relation universes over H in which all FDs in S hold
begin
  C := ∅;          // found candidate keys
  Q := { H };      // superkeys that contain candidate keys
  while Q <> ∅ do
    let K be some element from Q;
    Q := Q − { K };
    minimal := true;
    for each X->Y in S do
      K' := (K − Y) ∪ X;   // derive new superkey
      if K' ⊂ K then
        minimal := false;
        Q := Q ∪ { K' };
      end if
    end for
    if minimal and there is not a subset of K in C then
      remove all supersets of K from C;
      C := C ∪ { K };
    end if
  end while
end
```

Relational database

A **relational database** is a database that has a collection of tables of data items, all of which is formally described and organized according to the relational model. Data in a single table represents a relation, from which the name of the database type comes. In typical solutions, tables may have additionally defined relationships with each other.

In the relational model, each table schema must identify a column or group of columns, called the *primary key*, to uniquely identify each row. A relationship can then be established between each row in the table and a row in another table by creating a *foreign key*, a column or group of columns in one table that points to the primary key of another table. The relational model offers various levels of refinement of table organization and reorganization called database normalization. (See Normalization below.) The database management system (DBMS) of a relational database is called an RDBMS, and is the software of a relational database.

In relational databases, each data item has a row of attributes, so the database displays a fundamentally tabular organization. The table goes down a row of items (the records) and across many columns of attributes or fields. The same data (along with new and different attributes) can be organized into different tables.

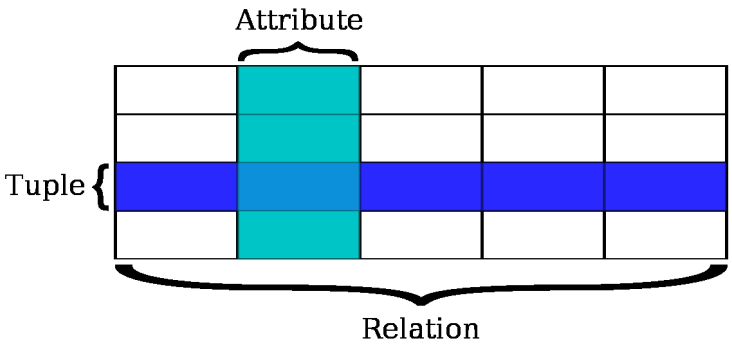
The term relational does not just refer to relationships between tables: firstly, it refers to the table itself[*citation needed*], or rather, the relationship between columns within a table; and secondly, it refers to links between tables.

Important columns in any relational database's tables will be a column whose entry (customer ID, serial number) can uniquely identify any particular item or record (the primary key), and any column(s) that link to other tables (the foreign key(s)). The size and complexity of relational databases typically requires stored procedures to support the relationships and provide access (interfaces) to external programs which, for example, "query" the relational database to retrieve and present selected data.

Relational databases are both created and queried by DataBase Management Systems (DBMSs). Relational databases displaced hierarchical databases because the ability to add new relations made it possible to add new information that was valuable but "broke" a database's original hierarchical conception. The trend continues as a networked planet and social media create the world of "big data" which is larger and less structured than the datasets and tasks that relational databases handle well (it is instructive to compare Hadoop).

Terminology

The relational database was first defined in June 1970 by Edgar Codd, of IBM's San Jose Research Laboratory. Codd's view of what qualifies as an RDBMS is summarized in Codd's 12 rules. A relational database has become the predominant choice in storing data. Other models besides the *relational model* include the hierarchical database model and the network model.



Relational database terminology.

The table below summarizes some of the most important relational database terms and their SQL equivalents.

SQL term	Relational database term	Description
Row	***Tuple*** or ***record***	A data set representing a single item
Column	***Attribute*** or ***field***	A labeled element of a tuple, e.g. "Address" or "Date of birth"
Table	***Relation*** or ***Base relvar***	A set of tuples sharing the same attributes; a set of columns and rows
View or ***result set***	***Derived relvar***	Any set of tuples; a data report from the RDBMS in response to a query

Relations or Tables

A *relation* is defined as a set of tuples that have the same attributes. A tuple usually represents an object and information about that object. Objects are typically physical objects or concepts. A relation is usually described as a table, which is organized into rows and columns. All the data referenced by an attribute are in the same domain and conform to the same constraints.

The relational model specifies that the tuples of a relation have no specific order and that the tuples, in turn, impose no order on the attributes. Applications access data by specifying queries, which use operations such as *select* to identify tuples, *project* to identify attributes, and *join* to combine relations. Relations can be modified using the *insert*, *delete*, and *update* operators. New tuples can supply explicit values or be derived from a query. Similarly, queries identify tuples for updating or deleting.

Tuples by definition are unique. If the tuple contains a candidate or primary key then obviously it is unique; however, a primary key need not be defined for a row or record to be a tuple. The definition of a tuple requires that it be unique, but does not require a primary key to be defined. Because a tuple is unique, its attributes by definition constitute a superkey.

Base and derived relations

In a relational database, all data are stored and accessed via relations. Relations that store data are called "base relations", and in implementations are called "tables". Other relations do not store data, but are computed by applying relational operations to other relations. These relations are sometimes called "derived relations". In implementations these are called "views" or "queries". Derived relations are convenient in that they act as a single relation, even though they may grab information from several relations. Also, derived relations can be used as an abstraction layer.

Domain

A domain describes the set of possible values for a given attribute, and can be considered a constraint on the value of the attribute. Mathematically, attaching a domain to an attribute means that any value for the attribute must be an element of the specified set. The character data value 'ABC', for instance, is not in the integer domain, but the integer value 123 is in the integer domain.

Constraints

Constraints make it possible to further restrict the domain of an attribute. For instance, a constraint can restrict a given integer attribute to values between 1 and 10. Constraints provide one method of implementing business rules in the database. SQL implements constraint functionality in the form of check constraints. Constraints restrict the data that can be stored in relations. These are usually defined using expressions that result in a boolean value, indicating whether or not the data satisfies the constraint. Constraints can apply to single attributes, to a tuple (restricting combinations of attributes) or to an entire relation. Since every attribute has an associated domain, there are constraints (**domain constraints**). The two principal rules for the relational model are known as **entity integrity**

and **referential integrity**.

Primary key

A primary key uniquely specifies a tuple within a table. In order for an attribute to be a good primary key it must not repeat. While natural attributes (attributes used to describe the data being entered) are sometimes good primary keys, surrogate keys are often used instead. A surrogate key is an artificial attribute assigned to an object which uniquely identifies it (for instance, in a table of information about students at a school they might all be assigned a student ID in order to differentiate them). The surrogate key has no intrinsic (inherent) meaning, but rather is useful through its ability to uniquely identify a tuple. Another common occurrence, especially in regards to N:M cardinality is the composite key. A composite key is a key made up of two or more attributes within a table that (together) uniquely identify a record. (For example, in a database relating students, teachers, and classes. Classes *could* be uniquely identified by a composite key of their room number and time slot, since no other class could have exactly the same combination of attributes. In fact, use of a composite key such as this can be a form of data verification, albeit a weak one.)

Foreign key

A foreign key is a field in a relational table that matches the primary key column of another table. The foreign key can be used to cross-reference tables. Foreign keys need not have unique values in the referencing relation. Foreign keys effectively use the values of attributes in the referenced relation to restrict the domain of one or more attributes in the referencing relation. A foreign key could be described formally as: "For all tuples in the referencing relation projected over the referencing attributes, there must exist a tuple in the referenced relation projected over those same attributes such that the values in each of the referencing attributes match the corresponding values in the referenced attributes."

Stored procedures

A stored procedure is executable code that is associated with, and generally stored in, the database. Stored procedures usually collect and customize common operations, like inserting a tuple into a relation, gathering statistical information about usage patterns, or encapsulating complex business logic and calculations. Frequently they are used as an application programming interface (API) for security or simplicity. Implementations of stored procedures on SQL RDBMSs often allow developers to take advantage of procedural extensions (often vendor-specific) to the standard declarative SQL syntax. Stored procedures are not part of the relational database model, but all commercial implementations include them.

Index

An index is one way of providing quicker access to data. Indices can be created on any combination of attributes on a relation. Queries that filter using those attributes can find matching tuples randomly using the index, without having to check each tuple in turn. This is analogous to using the index of a book to go directly to the page on which the information you are looking for is found, so that you do not have to read the entire book to find what you are looking for. Relational databases typically supply multiple indexing techniques, each of which is optimal for some combination of data distribution, relation size, and typical access pattern. Indices are usually implemented via B+ trees, R-trees, and bitmaps. Indices are usually not considered part of the database, as they are considered an implementation detail, though indices are usually maintained by the same group that maintains the other parts of the database. It should be noted that use of efficient indexes on both primary and foreign keys can dramatically improve query performance. This is because B-tree indexes result in query times proportional to log(n) where n is the number of rows in a table and hash indexes result in constant time queries (no size dependency so long as the relevant part of the index fits into memory).

Relational operations

Queries made against the relational database, and the derived relvars in the database are expressed in a relational calculus or a relational algebra. In his original relational algebra, Codd introduced eight relational operators in two groups of four operators each. The first four operators were based on the traditional mathematical set operations:

- The union operator combines the tuples of two relations and removes all duplicate tuples from the result. The relational union operator is equivalent to the SQL UNION operator.
- The intersection operator produces the set of tuples that two relations share in common. Intersection is implemented in SQL in the form of the INTERSECT operator.
- The difference operator acts on two relations and produces the set of tuples from the first relation that do not exist in the second relation. Difference is implemented in SQL in the form of the EXCEPT or MINUS operator.
- The cartesian product of two relations is a join that is not restricted by any criteria, resulting in every tuple of the first relation being matched with every tuple of the second relation. The cartesian product is implemented in SQL as the CROSS JOIN operator.

The remaining operators proposed by Codd involve special operations specific to relational databases:

- The selection, or restriction, operation retrieves tuples from a relation, limiting the results to only those that meet a specific criterion, i.e. a subset in terms of set theory. The SQL equivalent of selection is the SELECT query statement with a WHERE clause.
- The projection operation extracts only the specified attributes from a tuple or set of tuples.
- The join operation defined for relational databases is often referred to as a natural join. In this type of join, two relations are connected by their common attributes. SQL's approximation of a natural join is the INNER JOIN operator. In SQL, an INNER JOIN prevents a cartesian product from occurring when there are two tables in a query. For each table added to a SQL Query, one additional INNER JOIN is added to prevent a cartesian product. Thus, for N tables in a SQL query, there must be N-1 INNER JOINS to prevent a cartesian product.
- The relational division operation is a slightly more complex operation, which involves essentially using the tuples of one relation (the dividend) to partition a second relation (the divisor). The relational division operator is effectively the opposite of the cartesian product operator (hence the name).

Other operators have been introduced or proposed since Codd's introduction of the original eight including relational comparison operators and extensions that offer support for nesting and hierarchical data, among others.

Normalization

Normalization was first proposed by Codd as an integral part of the relational model. It encompasses a set of procedures designed to eliminate nonsimple domains (non-atomic values) and the redundancy (duplication) of data, which in turn prevents data manipulation anomalies and loss of data integrity. The most common forms of normalization applied to databases are called the normal forms.

Relational database management system

A **relational database management system** (**RDBMS**) is a database management system (DBMS) that is based on the relational model as introduced by E. F. Codd, of IBM's San Jose Research Laboratory. Many popular databases currently in use are based on the relational database model.

RDBMSs have become a predominant choice for the storage of information in new databases used for financial records, manufacturing and logistical information, personnel data, and much more since the 1980s. Relational databases have often replaced legacy hierarchical databases and network databases because they are easier to understand and use. However, relational databases have been challenged by object databases, which were introduced in an attempt to address the object-relational impedance mismatch in relational database, and XML databases.[*citation needed*]

Market share

According to research company Gartner, the five leading commercial relational database vendors by revenue in 2011 were Oracle (48.8%), IBM (20.2%), Microsoft (17.0%), SAP including Sybase (4.6%), and Teradata (3.7%).

The three leading open source implementations are MySQL, PostgreSQL, and SQLite. MariaDB is a prominent fork of MySQL prompted by Oracle's acquisition of MySQL AB.

According to Gartner, in 2008, the percentage of database sites using any given technology were (a given site may deploy multiple technologies):

- Oracle Database - 70%
- Microsoft SQL Server - 68%
- MySQL (Oracle Corporation) - 50%
- IBM DB2 - 39%
- IBM Informix - 18%
- SAP Sybase Adaptive Server Enterprise - 15%
- SAP Sybase IQ - 14%
- Teradata - 11%

According to DB-Engines, the most popular systems are Oracle, MySQL, Microsoft SQL Server, PostgreSQL and IBM DB2.

History

In 1974, IBM began developing System R, a research project to develop a prototype RDBMS. Its first commercial product was SQL/DS, released in 1981. However, the first commercially available RDBMS was Oracle, released in 1979 by Relational Software, now Oracle Corporation. Other examples of an RDBMS include DB2, SAP Sybase ASE, and Informix.

Historical usage of the term

The term "relational database" was invented by E. F. Codd at IBM in 1970, Codd introduced the term in his seminal paper "A Relational Model of Data for Large Shared Data Banks".[1] In this paper and later papers, he defined what he meant by "relational". One well-known definition of what constitutes a relational database system is composed of Codd's 12 rules. However, many of the early implementations of the relational model did not conform to all of Codd's rules, so the term gradually came to describe a broader class of database systems, which at a minimum:

- Present the data to the user as relations (a presentation in tabular form, i.e. as a *collection* of tables with each table consisting of a set of rows and columns);

- Provide relational operators to manipulate the data in tabular form.

The first systems that were relatively faithful implementations of the relational model were from the University of Michigan; Micro DBMS (1969), the Massachusetts Institute of Technology;[2] (1971), and from IBM UK Scientific Centre at Peterlee; IS1 (1970–72) and its followon PRTV (1973–79). The first system sold as an RDBMS was Multics Relational Data Store, first sold in 1978. Others have been Berkeley Ingres QUEL and IBM BS12. The most popular definition of an RDBMS is a product that presents a view of data as a collection of rows and columns, even if it is not based strictly upon relational theory. By this definition, RDBMS products typically implement some but not all of Codd's 12 rules.

A second school of thought argues that if a database does not implement all of Codd's rules (or the current understanding on the relational model, as expressed by Christopher J Date, Hugh Darwen and others), it is not relational. This view, shared by many theorists and other strict adherents to Codd's principles, would disqualify most DBMSs as not relational. For clarification, they often refer to some RDBMSs as *Truly-Relational Database Management Systems* (TRDBMS), naming others *Pseudo-Relational Database Management Systems* (PRDBMS).

As of 2009, most commercial relational DBMSes employ SQL as their query language.[*citation needed*] Alternative query languages have been proposed and implemented, notably the pre-1996 implementation of Berkeley Ingres QUEL.

Life cycle of a relational database

The **life cycle of a relational database** is the cycle of development and changes that a relational database goes through during the course of its life. The cycle typically consists of several stages. There is a possibility that the database designer/developer can go back to any of the previous stages. This represents an admission that a full understanding of a problem, and its solution is likely to evolve as the various stages of design and implementation proceed. The typical eleven stages involved in the life cycle of a relational database are as follows:

Process

1. The designer must try to obtain as complete as possible an understanding of the real world problem that is going to be helped by the introduction of a database. This understanding of the nature of the problem and the constraints and outline feasible solutions is often performed using some systems analysis methodology.
2. The entity relationship diagram is drawn, and this diagram in its modified form serves as an essential part of the logical schema. Attributes of the entity types so produced are then added. Primary and foreign keys are specified.
3. Normalization is used to check the entity-relationship model. Some splitting and even recombination of entity types may result from normalization and the entity relationship model will have to be updated accordingly. The entity relationship model and the table definitions resulting from normalization should be consistent.
4. Set of Table(s) definition for the required schema is finalized.
5. The database tables are created. Primary, Foreign keys, database constraints and database integrity rules are specified at this stage.
6. At this stage, the file organization is performed. File organization is the way the database relations are to be stored on the storage medium. The file organization is decided on the basis of maximum speed of access, the type of access required and storage space considerations. There are two factors to consider; firstly how the records are to be physically mapped onto the storage medium, and secondly which indexes are to be used and if so, which

fields (attributes, columns) are to be indexed. Indexes are designed to increase the speed of access to required records. Views can also be defined at this stage. Views are used to limit access to parts of database only, when used in conjunction with access privileges. Views also make programming simpler.

7. The designer will be able to design the required queries at this stage. The designer should have a good idea of the main types of query and reports the database will have to accommodate.
8. At this stage, application screens are designed. The application screens are used to capture the input information that will be kept in the database. Screen design is partially determined by the data items that must be input and output by particular applications and partially in human-computer interface terms. When designing screens, special consideration is given to the suggestions given by the application end users. There are published standards which can be exactly followed for screens design or organization can develop their own screen design standards as per their requirements.
9. Report design is another area where input from users is paramount. They will specify what they want to see on the reports and the format of the reports and in the case of regular reports, when they should be produced. Nowadays most of the application design tools provide easy to use friendly tools for quick reports development. e.g. report builder in Oracle, Crystal Reports, R&R Report Writer etc.
10. Testing is performed at this stage. Application screens, various functions offered by the application screens, data validations through screens and reports are tested and it serves as the ultimate test of the correctness of the database schema and the viability of the system as a whole. It is recommended to create a test database separate of the production database. The test database will be useful for testing any schema changes and new and modified application before applying the changes to the production (live) database. Careful testing of the system before handover will minimize the expense of later modifications to the schema and major applications.
11. The final stage is Handover. This is the stage where the users receive the finished database and applications and begin data entry. In practice, it is likely that the core of the system will be handed over to users and later extensions to the system will be implemented.

Logical data model

In computing and more specifically systems engineering, a **logical data model** (**LDM**) is a type of data model showing a detailed representation of some or all of an organization's data, independent of any particular data management technology, and described in business language. It is typically represented as a diagram, organized in terms of entities and relationships, with underlying definitions.

Overview

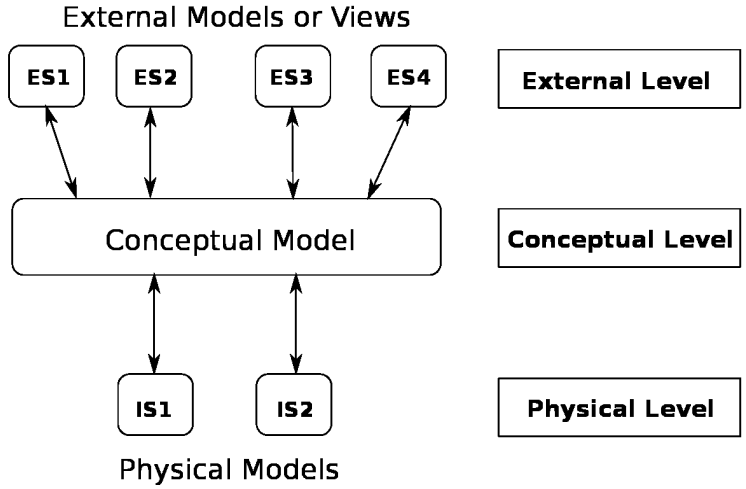
Logical data models represent the abstract structure of a domain of information. They are often diagrammatic in nature and are most typically used in business processes that seek to capture things of importance to an organization and how they relate to one another. Once validated and approved, the logical data model can become the basis of a physical data model and inform the design of a database.

Logical data models should be based on the structures identified in a preceding conceptual data model, since this describes the semantics of the information context, which the logical model should also reflect. Even so, since the logical data model anticipates implementation on a specific computing system, the content of the logical data model is adjusted to achieve certain efficiencies.

The term 'Logical Data Model' is sometimes used as a synonym of 'domain model' or as an alternative to the domain model. While the two concepts are closely related, and have overlapping goals, a domain model is more focused on capturing the concepts in the problem domain rather than the structure of the data associated with that domain.

History

When ANSI first laid out the idea of a *logical schema* in 1975,[2] the choices were *hierarchical* and *network*. The relational model – where data is described in terms of tables and columns – had just been recognized as a data organization theory but no software existed to support that approach. Since that time, an object-oriented approach to data modelling – where data is described in terms of classes, attributes, and associations – has also been introduced.



The ANSI/SPARC three level architecture, which "shows that a data model can be an external model (or view), a conceptual model, or a physical model. This is not the only way to look at data models, but it is a useful way, particularly when comparing models".[1]

Logical data model topics

Reasons for building a logical data model

- Helps common understanding of business data elements and requirements
- Provides foundation for designing a database
- Facilitates avoidance of data redundancy and thus prevent data & business transaction inconsistency
- Facilitates data re-use and sharing
- Decreases development and maintenance time and cost

- Confirms a logical process model and helps impact analysis.

Conceptual, logical and physical data model

A logical data model is sometimes incorrectly called a physical data model, which is not what the ANSI people had in mind. The physical design of a database involves deep use of particular database management technology. For example, a table/column design could be implemented on a collection of computers, located in different parts of the world. That is the domain of the physical model.

Conceptual, Logical and physical data models are very different in their objectives, goals and content. Key differences noted below.

Conceptual Data Model (CDM)	Logical Data Model (LDM)	Physical Data Model (PDM)
Includes high-level data constructs	Includes entities (tables), attributes (columns/fields) and relationships (keys)	Includes tables, columns, keys, data types, validation rules, database triggers, stored procedures, domains, and access constraints
Non-technical names, so that executives and managers at all levels can understand the data basis of Architectural Description	Uses business names for entities & attributes	Uses more defined and less generic specific names for tables and columns, such as abbreviated column names, limited by the database management system (DBMS) and any company defined standards
Uses general high-level data constructs from which Architectural Descriptions are created in non-technical terms	Is independent of technology (platform, DBMS)	Includes primary keys and indices for fast data access.
May not be normalized	Is normalized to fourth normal form (4NF)	May be de-normalized to meet performance requirements based on the nature of the database. If the nature of the database is Online Transaction Processing (OLTP) or Operational Data Store (ODS) it is usually not de-normalized. De-normalization is common in Datawarehouses.
Represented in the DIV-1 Viewpoint (DoDAF V2.0)	Represented in the DIV-2 Viewpoint (DoDAF V2.0), and OV-7 View (DoDAF V1.5)	Represented in the DIV-3 Viewpoint (DoDAF V2.0), and SV-11 View (DoDAF V1.5)

- Building a Logical Data Model (http://replay.web.archive.org/20080509063521/http://www.dbmsmag.com/9506d16.html) By George Tillmann, DBMS, June 1995.

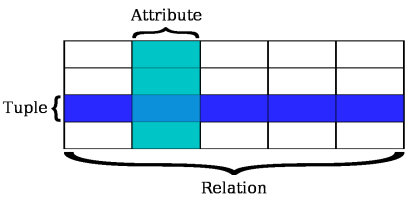
Logical schema

A **logical schema** is a data model of a specific problem domain expressed in terms of a particular data management technology.

Without being specific to a particular database management product, it is in terms of either relational tables and columns, object-oriented classes, or XML tags. This is as opposed to a conceptual data model, which describes the semantics of an organization without reference to technology, or a physical data model, which describes the particular physical mechanisms used to capture data in a storage medium.

The next step in creating a database, after the logical schema is produced, is to create the physical schema.

Relation (database)



Relation, tuple, and attribute represented as table, row, and column.

In relational database theory, a **relation**, as originally defined by E.F. Codd, is a set of tuples $(d_1, d_2, ..., d_n)$, where each element d_j is a member of D_j, a data domain. Codd's original definition notwithstanding, and contrary to the usual definition in mathematics, there is no ordering to the elements of the tuples of a relation. Instead, each element is termed an **attribute value**. An **attribute** is a name paired with a domain (nowadays more commonly referred to as **type** or **data type**). An **attribute value** is an attribute name paired with an element of that attribute's domain, and a tuple is a *set* of attribute values in which no two distinct elements have the same name. Thus, in some accounts, a tuple is described as a function, mapping names to values.

A set of attributes in which no two distinct elements have the same name is called a **heading**. A set of tuples having the same heading is called a **body**. A relation is thus a heading paired with a body, the heading of the relation being also the heading of each tuple in its body. The number of attributes constituting a heading is called the **degree**, which term also applies to tuples and relations. The term *n*-tuple refers to a tuple of degree *n* (n>=0).

E. F. Codd used the term relation in its mathematical sense of a finitary relation, a set of tuples on some set of *n* sets $S_1, S_2, ... ,S_n$. Thus, an *n*-ary relation is interpreted, under the Closed World Assumption, as the extension of some *n*-adic predicate: all and only those *n*-tuples whose values, substituted for corresponding free variables in the predicate, yield propositions that hold true, appear in the relation.

The term relation schema refers to a heading paired with a set of constraints defined in terms of that heading. A relation can thus be seen as an instantiation of a relation schema if it has the heading of that schema and it satisfies the applicable constraints.

Sometimes a relation schema is taken to include a name. A relational database definition (database schema, sometimes referred to as a relation*al* schema) can thus be thought of as a collection of named relation schemas.

In implementations, the domain of each attribute is effectively a data type and a named relation schema is effectively a relation variable or relvar for short (see **Relation Variables** below).

In SQL, a database language for relational databases, relations are represented by tables, where each row of a table represents a single tuple, and where the values of each attribute form a column.

Examples

Below is an example of a relation having three named attributes: 'ID' from the domain of integers, and 'Name' and 'Address' from the domain of strings:

ID (Integer)	Name (String)	Address (String)
102	Yonezawa Akinori	Naha, Okinawa
202	Murata Makoto	Sendai, Miyagi
104	Sakamura Ken	Kumamoto, Kumamoto
152	Matsumoto Yukihiro	Okinawa, Okinawa

A predicate for this relation, using the attribute names to denote free variables, might be "Employee number *ID* is known as *Name* and lives at *Address*". Examination of the relation tells us that there are just four tuples for which the predicate holds true. So, for example, employee 102 is known only by that name, Yonezawa Akinori, and does not live anywhere else but in Naha, Okinawa. Also, apart from the four employees shown,there is no other employee who has both a name and an address.

Under the definition of **body**, the tuples of a body do not appear in any particular order - one cannot say "The tuple of 'Murata Makoto' is above the tuple of 'Matsumoto Yukihiro'", nor can one say "The tuple of 'Yonezawa Akinori' is the first tuple." A similar comment applies to the rows of an SQL table.

Under the definition of **heading** the elements of a element do not appear in any particular order either, nor, therefore do the elements of a tuple. A similar comment does *not* apply here to SQL, which does define an ordering to the columns of a table.

Relation Variables

A relational database consists of named relation variables (relvars) for the purposes of updating the database in response to changes in the real world. An update to a single relvar causes the body of the relation assigned to that variable to be replaced by a different set of tuples. Such variables are classified into two classes: **base relation variables** and **derived relation variables**, the latter also known as **virtual relvars** but usually referred to by the short term **view**.

A **base relation variable** is a relation variable which is not derived from any other relation variables. In SQL the term **base table** equates approximately to base relation variable.

A view can be defined by an expression using the operators of the relational algebra or the relational calculus. Such an expression operates on one or more relations and when evaluated yields another relation. The result is sometimes referred to as a "derived" relation when the operands are relations assigned to database variables. A view is defined by giving a name to such an expression, such that the name can subsequently be used as a variable name. (Note that the expression must then mention at least one base relation variable.)

By using a Data Definition Language (DDL), it is able to define base relation variables. In SQL, `CREATE TABLE` syntax is used to define base tables. The following is an example.

```
CREATE TABLE List_of_people (
 ID INTEGER,
 Name CHAR(40),
 Address CHAR(200),
 PRIMARY KEY (ID)
)
```

The Data Definition Language (DDL) is also used to define derived relation variables. In SQL, `CREATE VIEW` syntax is used to define a derived relation variable. The following is an example.

```
CREATE VIEW List_of_Okinawa_people AS (
 SELECT ID, Name, Address
  FROM List_of_people
  WHERE Address LIKE '%, Okinawa'
)
```

Table (database)

In relational databases and flat file databases, a **table** is an organized set of data elements (values) using a model of vertical columns (which are identified by their name) and horizontal rows, the cell being the unit where a row and column intersect. A table has a specified number of columns, but can have any number of rows. Each row is identified by the values appearing in a particular column subset which has been identified as a unique key index.

Table is another term for relation; although there is the difference in that a table is usually a multiset (bag) of rows whereas a relation is a set and does not allow duplicates. Besides the actual data rows, tables generally have associated with them some metadata, such as constraints on the table or on the values within particular columns.Wikipedia:Disputed statement|

The data in a table does not have to be physically stored in the database. Views are also relational tables, but their data are calculated at query time. Another example are nicknames[*clarify*], which represent a pointer to a table in another database.

Comparisons

In non-relational systems, hierarchical databases, the distant counterpart of a table is a structured file, representing the rows of a table in each record of the file and each column in a record.This structure implies that a record can have repeating information, Generally in the child data segments.Data are stored in sequence of records which are equivalent to table term of a relational database.with each record having equivalent rows.

Unlike a spreadsheet, the datatype of field is ordinarily defined by the schema describing the table. Some SQL systems, such as SQLite, are less strict about field datatype definitions.

Tables versus relations

In terms of the relational model of databases, a table can be considered a convenient representation of a relation, but the two are not strictly equivalent. For instance, an SQL table can potentially contain duplicate rows, whereas a true relation cannot contain duplicate tuples. Similarly, representation as a table implies a particular ordering to the rows and columns, whereas a relation is explicitly unordered. However, the database system does not guarantee any ordering of the rows unless an `ORDER BY` clause is specified in the `SELECT` statement that queries the table.

An equally valid representations of a relation is as an n-dimensional chart, where n is the number of attributes (a table's columns). For example, a relation with two attributes and three values can be represented as a table with two columns and three rows, or as a two-dimensional graph with three points. The table and graph representations are only equivalent if the ordering of rows is not significant, and the table has no duplicate rows.

Table types

Two types of tables exist:

- A relational table, which is the basic structure to hold user data in a relational database.
- An object table, which is a table that uses an object type to define a column. It is defined to hold instances of objects of a defined type.

In SQL, the `CREATE TABLE` statement creates these tables.

Tuple

In mathematics, computer science, linguistics,[1] and philosophy[2] a **tuple** is an ordered list of elements. In set theory, an **(ordered) n-tuple** is a sequence (or ordered list) of n elements, where n is a non-negative integer. There is only one 0-tuple, an empty sequence. An n-tuple is defined inductively using the construction of an ordered pair. Tuples are usually written by listing the elements within parentheses " $(\ )$ " and separated by commas; for example, $(2, 7, 4, 1, 7)$ denotes a 5-tuple. Sometimes other delimiters are used, such as square brackets " $[\ ]$ " or angle brackets " $\langle\ \rangle$ ". Braces " $\{\}$ " are almost never used for tuples, as they are the standard notation for sets. Tuples are often used to describe other mathematical objects, such as vectors. In computer science, tuples are directly implemented as product types in most functional programming languages. More commonly, they are implemented as record types, where the components are labeled instead of being identified by position alone. This approach is also used in relational algebra. Tuples are also used in relation to programming the semantic web with Resource Description Framework or RDF.

Etymology

The term originated as an abstraction of the sequence: single, double, triple, quadruple, quintuple, sextuple, septuple, octuple, ..., *n*-tuple, ..., where the prefixes are taken from the Latin names of the numerals. The unique 0-tuple is called the null tuple. A 1-tuple is called a singleton, a 2-tuple is called an ordered pair and a 3-tuple is a triple or triplet. *n* can be any nonnegative integer. For example, a complex number can be represented as a 2-tuple, a quaternion can be represented as a 4-tuple, an octonion can be represented as an 8-tuple and a sedenion can be represented as a 16-tuple.

Although these uses treat *-tuple* as the suffix, the original suffix was *-ple* as in "triple" (three-fold) or "decuple" (ten-fold). This originates from a medieval Latin suffix *-plus* (meaning "more") related to Greek -πλοῦς, which replaced the classical and late antique *-plex* (meaning "folded"), as in "duplex".[3]

Names for tuples of specific lengths

Tuple Length n	Name	Alternate names
0	empty tuple	unit
1	single	Monad
2	double	pair / dual / twin
3	triple	treble
4	quadruple	quad
5	quintuple	pentuple
6	sextuple	hextuple
7	septuple	
8	octuple	
9	nonuple	
10	decuple	
11	undecuple	hendecuple
12	duodecuple	
13	tredecuple	
100	centuple	

Properties

The general rule for the identity of two n-tuples is

$$(a_1, a_2, \ldots, a_n) = (b_1, b_2, \ldots, b_n) \text{ if and only if } a_1 = b_1,\ a_2 = b_2,\ \ \ldots,\ \ a_n = b_n.$$

Thus a tuple has properties that distinguish it from a set.

1. A tuple may contain multiple instances of the same element, so tuple $(1, 2, 2, 3) \neq (1, 2, 3)$; but set $\{1, 2, 2, 3\} = \{1, 2, 3\}$.
2. Tuple elements are ordered: tuple $(1, 2, 3) \neq (3, 2, 1)$, but set $\{1, 2, 3\} = \{3, 2, 1\}$.
3. A tuple has a finite number of elements, while a set or a multiset may have an infinite number of elements.

Definitions

There are several definitions of tuples that give them the properties described in the previous section.

Tuples as functions

An n-tuple can be regarded as a function, *F*, whose domain is the tuple's implicit set of element indices, *X*, and whose codomain, *Y*, is the tuple's set of elements. Formally:

$$(a_1, a_2, \ldots, a_n) \equiv (X, Y, F)$$

where:

$$X = \{1, 2, \ldots, n\}$$
$$Y = \{a_1, a_2, \ldots, a_n\}$$
$$F = \{(1, a_1), (2, a_2), \ldots, (n, a_n)\}$$

Tuples as nested ordered pairs

Another way of formalizing tuples is as nested ordered pairs. This approach assumes that the notion of ordered pair has already been defined; thus a 2-tuple

1. The 0-tuple (i.e. the empty tuple) is represented by the empty set $\emptyset$.
2. An n -tuple, with $n > 0$, can be defined as an ordered pair of its first entry and an $(n-1)$-tuple (which contains the remaining entries when $n > 1$):

$$(a_1, a_2, a_3, \ldots, a_n) = (a_1, (a_2, a_3, \ldots, a_n))$$

This definition can be applied recursively to the $(n-1)$-tuple:

$$(a_1, a_2, a_3, \ldots, a_n) = (a_1, (a_2, (a_3, (\ldots, (a_n, \emptyset)\ldots))))$$

Thus, for example:

$$(1, 2, 3) = (1, (2, (3, \emptyset)))$$
$$(1, 2, 3, 4) = (1, (2, (3, (4, \emptyset))))$$

A variant of this definition starts "peeling off" elements from the other end:

1. The 0-tuple is the empty set $\emptyset$.
2. For $n > 0$:

$$(a_1, a_2, a_3, \ldots, a_n) = ((a_1, a_2, a_3, \ldots, a_{n-1}), a_n)$$

This definition can be applied recursively:

$$(a_1, a_2, a_3, \ldots, a_n) = ((\ldots(((\emptyset, a_1), a_2), a_3), \ldots), a_n)$$

Thus, for example:

$$(1, 2, 3) = (((\emptyset, 1), 2), 3)$$
$$(1, 2, 3, 4) = ((((\emptyset, 1), 2), 3), 4)$$

Tuples as nested sets

Using Kuratowski's representation for an ordered pair, the second definition above can be reformulated in terms of pure set theory:

1. The 0-tuple (i.e. the empty tuple) is represented by the empty set $\emptyset$;
2. Let x be an n -tuple $(a_1, a_2, \ldots, a_n)$, and let $x \to b \equiv (a_1, a_2, \ldots, a_n, b)$. Then, $x \to b \equiv \{\{x\}, \{x, b\}\}$. (The right arrow, $\to$, could be read as "adjoined with".)

In this formulation:

$$\begin{aligned}
() &= \emptyset \\
(1) &= () \to 1 = \{\{()\}, \{(), 1\}\} \\
&= \{\{\emptyset\}, \{\emptyset, 1\}\} \\
(1, 2) &= (1) \to 2 = \{\{(1)\}, \{(1), 2\}\} \\
&= \{\{\{\emptyset\}, \{\emptyset, 1\}\}\}, \\
&\quad \{\{\{\emptyset\}, \{\emptyset, 1\}\}, 2\}\} \\
(1, 2, 3) &= (1, 2) \to 3 = \{\{(1, 2)\}, \{(1, 2), 3\}\} \\
&= \{\{\{\{\{\emptyset\}, \{\emptyset, 1\}\}\}\}, \\
&\quad \{\{\{\emptyset\}, \{\emptyset, 1\}\}, 2\}\}\}, \\
&\quad \{\{\{\{\emptyset\}, \{\emptyset, 1\}\}\}, \\
&\quad \{\{\{\emptyset\}, \{\emptyset, 1\}\}, 2\}\}, 3\}\}
\end{aligned}$$

Relational model

In database theory, the relational model uses a tuple definition similar to tuples as functions, but each tuple element is identified by a distinct name, called an *attribute*, instead of a number; this leads to a more user-friendly and practical notation.[4] A tuple in the relational model is formally defined as a finite function that maps attributes to values. For example:

(player : "Harry", score : 25)

In this notation, attribute–value pairs may appear in any order. The distinction between tuples in the relational model and those in set theory is only superficial; the above example can be interpreted as a 2-tuple if an arbitrary total order is imposed on the attributes (e.g. $player \leq score$) and then the elements are distinguished by this ordering rather than by the attributes themselves. Conversely, a 2-tuple may be interpreted as relational model tuple over the attributes $\{1, 2\}$.

In the relational model, a relation is a (possibly empty) finite set of tuples all having the same finite set of attributes. This set of attributes is more formally called the sort of the relation, or more casually referred to as the set of column names. A tuple is usually implemented as a row in a database table, but see relational algebra for means of deriving tuples not physically represented in a table.

Type theory

In type theory, commonly used in programming languages, a tuple has a product type; this fixes not only the length, but also the underlying types of each component. Formally:

$$(x_1, x_2, \ldots, x_n) : \mathsf{T}_1 \times \mathsf{T}_2 \times \ldots \times \mathsf{T}_n$$

and the projections are term constructors:

$$\pi_1(x) : \mathsf{T}_1,\ \pi_2(x) : \mathsf{T}_2,\ \ \ldots,\ \pi_n(x) : \mathsf{T}_n$$

The tuple with labeled elements used in the relational model has a record type. Both of these types can be defined as simple extensions of the simply typed lambda calculus.

The notion of a tuple in type theory and that in set theory are related in the following way: If we consider the natural model of a type theory, and use the Scott brackets to indicate the semantic interpretation, then the model consists of some sets $S_1, S_2, \ldots, S_n$ (note: the use of italics here that distinguishes sets from types) such that:

$$[\![\mathsf{T}_1]\!] = S_1,\ [\![\mathsf{T}_2]\!] = S_2,\ \ \ldots,\ [\![\mathsf{T}_n]\!] = S_n$$

and the interpretation of the basic terms is:

$$[\![x_1]\!] \in [\![\mathsf{T}_1]\!],\ [\![x_2]\!] \in [\![\mathsf{T}_2]\!],\ \ \ldots,\ [\![x_n]\!] \in [\![\mathsf{T}_n]\!].$$

The n-tuple of type theory has the natural interpretation as an n-tuple of set theory:[5]

$$[\![(x_1, x_2, \ldots, x_n)]\!] = ([\![x_1]\!], [\![x_2]\!], \ldots, [\![x_n]\!])$$

The unit type has as semantic interpretation the 0-tuple.

Row (database)

In the context of a relational database, a **row**—also called a **record** —represents a single, implicitly structured data item in a table. In simple terms, a database table can be thought of as consisting of *rows* and columns or fields. Each row in a table represents a set of related data, and every row in the table has the same structure.

For example, in a table that represents companies, each row would represent a single company. Columns might represent things like company name, company street address, whether the company is publicly held, its VAT number, etc.. In a table that represents *the association* of employees with departments, each row would associate one employee with one department.

In a less formal usage, e.g. for a database which is not formally relational, a record is equivalent to a row as described above, but is not usually referred to as a row.

The implicit structure of a row, and the meaning of the data values in a row, requires that the row be understood as providing a succession of data values, one in each column of the table. The row is then interpreted as a relvar composed of a set of tuples, with each tuple consisting of the two items: the name of the relevant column and the value this row provides for that column.

Each column expects a data value of a particular type. For example, one column might require a unique identifier, another might require text representing a person's name, another might require an integer representing hourly pay in cents.

-	Column 1	Column 2
Row (Record) 1	Row 1, Column (Field)1	Row 1, Column 2
Row 2	Row 2, Column 1	Row 2, Column 2
Row 3	Row 3, Column 1	Row 3, Column 2

Attribute domain

In computing, the **attribute domain** is the set of values allowed in an attribute.

For example:

```
Rooms in hotel (1-300)
Age (1-99)
Married (yes or no)
Nationality (Nepalese, Indian, American, or British)
Colors(Red , Yellow , Green)
```

For the relational model it is a requirement that each part of a tuple be atomic. The consequence is that each value in the tuple must be of some basic type, like a string or an integer. For the elementary type to be atomic it cannot be broken into more pieces. Alas, the domain is an elementary type, and attribute domain the domain a given attribute belongs to an abstraction belonging to or characteristic of an entity.

Candidate key

In the relational model of databases, a **candidate key** of a relation is a minimal superkey for that relation; that is, a set of attributes such that

1. the relation does not have two distinct tuples (i.e. rows or records in common database language) with the same values for these attributes (which means that the set of attributes is a superkey)
2. there is no proper subset of these attributes for which (1) holds (which means that the set is minimal).

The constituent attributes are called **prime attributes**. Conversely, an attribute that does not occur in ANY candidate key is called a **non-prime attribute**.

Since a relation contains no duplicate tuples, the set of all its attributes is a superkey if NULL values are not used. It follows that every relation will have at least one candidate key.

The candidate keys of a relation tell us all the possible ways we can identify its tuples. As such they are an important concept for the design of database schema.

Example

The definition of candidate keys can be illustrated with the following (abstract) example. Consider a relation variable (relvar) *R* with attributes (*A*, *B*, *C*, *D*) that has only the following two legal values *r1* and *r2*:

r1

A	B	C	D
a1	b1	c1	d1
a1	b2	c2	d1
a2	b1	c2	d1

r2

A	B	C	D
a1	b1	c1	d1
a1	b2	c2	d1
a1	b1	c2	d2

Here *r2* differs from *r1* only in the **A** and **D** values of the last tuple.

For *r1* the following sets have the uniqueness property, i.e., there are no two distinct tuples in the instance with the same values for the attributes in the set:

{A,B}, {A,C}, {B,C}, {A,B,C}, {A,B,D}, {A,C,D}, {B,C,D}, {A,B,C,D}

For *r2* the uniqueness property holds for the following sets;

{B,C}, {B,D}, {C,D}, {A,B,C}, {A,B,D}, {A,C,D}, {B,C,D}, {A,B,C,D}

Since superkeys of a relvar are those sets of attributes that have the uniqueness property for *all* legal values of that relvar and because we assume that *r1* and *r2* are all the legal values that *R* can take, we can determine the set of superkeys of *R* by taking the intersection of the two lists:

{B,C}, {A,B,C}, {A,B,D}, {A,C,D}, {B,C,D}, {A,B,C,D}

Finally we need to select those sets for which there is no proper subset in the list, which are in this case:

{B,C}, {A,B,D}, {A,C,D}

These are indeed the candidate keys of relvar *R*.

We have to consider *all* the relations that might be assigned to a relvar to determine whether a certain set of attributes is a candidate key. For example, if we had considered only *r1* then we would have concluded that {A,B} is a candidate key, which is incorrect. However, we *might* be able to conclude from such a relation that a certain set is *not* a candidate key, because that set does not have the uniqueness property (example {A,D} for *r1*). Note that the existence of a proper subset of a set that has the uniqueness property *cannot* in general be used as evidence that the superset is not a candidate key. In particular, note that in the case of an empty relation, every subset of the heading has the uniqueness property, including the empty set.

Determining candidate keys

The set of all candidate keys can be computed e.g. from the set of functional dependencies. To this end we need to define the attribute closure α^+ for an attribute set α. The set α^+ contains all attributes that are functionally implied by α.

It is quite simple to find a single candidate key. We start with a set α of attributes and try to remove successively each attribute. If after removing an attribute the attribute closure stays the same, then this attribute is not necessary and we can remove it permanently. We call the result $\text{minimize}(\alpha)$. If α is the set of all attributes, then $\text{minimize}(\alpha)$ is a candidate key.

Actually we can detect every candidate key with this procedure by simply trying every possible order of removing attributes. However there are much more permutations of attributes ($n!$) than subsets (2^n). That is, many attribute orders will lead to the same candidate key.

There is a fundamental difficulty for efficient algorithms for candidate key computation: Certain sets of functional dependencies lead to exponentially many candidate keys. Consider the $2 \cdot n$ functional dependencies $\{A_i \to B_i : i \in \{1, \ldots, n\}\} \cup \{B_i \to A_i : i \in \{1, \ldots, n\}\}$ which yields 2^n candidate keys: $\{A_1, B_1\} \times \ldots \times \{A_n, B_n\}$. That is, the best we can expect is an algorithm that is efficient with respect to the number of candidate keys.

The following algorithm actually runs in polynomial time in the number of candidate keys and functional dependencies:

```
K[0] := minimize(A);  /* A is the set of all attribute */
n := 1; /* Number of Keys known so far */
i := 0; /* Currently processed key */
while i < n do
  foreach α → β ∈ F do
    S := α ∪ (K[i] − β);
    found := false;
    for j := 0 to n-1 do
      if K[j] ⊆ S then found := true;
    if not found then
      K[n] := minimize(S);
      n := n + 1;
```

The idea behind the algorithm is that given a candidate key K_i and a functional dependency $\alpha \to \beta$, the reverse application of the functional dependency yields the set $\alpha \cup (K_i \setminus \beta)$, which is a key, too. It may however be covered by other already known candidate keys. (The algorithm checks this case using the 'found' variable.) If not, then minimizing the new key yields a new candidate key. The key insight is (pun not intended) that all candidate keys can be created this way.

Unique key

A **unique key** or **primary key** is a key that uniquely defines the characteristics of each row. The **primary key** has to consist of characteristics that cannot collectively be duplicated by any other row. A Primary and Foreign key is needed in order to link tables.

In an entity relationship diagram of a data model, one or more **unique keys** may be declared for each data entity. Each unique key is composed from one or more data attributes of that data entity. The set of unique keys declared for a data entity is often referred to as the candidate keys for that data entity. From the set of candidate keys, a single unique key is selected and declared the primary key for that data entity. In an entity relationship diagram, each entity relationship uses a unique key, most often the primary key, of one data entity and copies the unique key data attributes to another data entity to which it relates. This inheritance of the unique key data attributes is referred to as a foreign key and is used to provide data access paths between data entities. Once the data model is instantiated into a database, each data entity usually becomes a database table, unique keys become unique indexes associated with their assigned database tables, and entity relationships become foreign key constraints. In integrated data models,[1] commonality relationships[2] do not become foreign key constraints since commonality relationships are a peer-to-peer type of relationship.

The primary key may consist of a single attribute or a multiple attributes in combination. For example, a birthday could be shared by many people and so would not be a prime candidate for the Primary Key, but a social security number or Driver's License number would be ideal since it correlates to one single data value. Another unique characteristic of a Primary Key as it pertains to a relational database, is that a Primary Key must also serve as a Foreign Key on a related table[*citation needed*]. For example:

```
Author Table Schema:

AuthorTable(AUTHOR_ID,AuthorName,CountryBorn,YearBorn)

Book Table Schema:

Book(ISBN,Author_ID,Title,Publisher,Price)
```

Here we can see that AUTHOR_ID serves as the Primary Key in AuthorTable but also serves as the Foreign Key on the BookTable. The Foreign Key serves as the link and therefore the connection between the two "related" tables in this sample database.

In a relational database, a **unique key** index can uniquely identify each row of data values in a database table. A unique key index comprises a single column or a set of columns in a single database table. No two distinct rows or data records in a database table can have the same data value (or combination of data values) in those unique key index columns if NULL values are not used. Depending on its design, a database table may have many unique key

indexes but at most one primary key index.

A unique key constraint does not imply the `NOT NULL` constraint in practice. Because NULL is not an actual value (it represents the lack of a value), when two rows are compared, and both rows have NULL in a column, the column values are not considered to be equal. Thus, in order for a unique key to uniquely identify each row in a table, NULL values must not be used. According to the SQL[3] standard and Relational Model theory, a unique key (unique constraint) should accept NULL in several rows/tuples — however not all RDBMS implement this feature correctly.[4][5]

A unique key should uniquely identify all *possible* rows that exist in a table and not only the currently existing rows [*citation needed*]. Examples of unique keys are Social Security numbers (associated with a specific person[6]) or ISBNs (associated with a specific book). Telephone books and dictionaries cannot use names, words, or Dewey Decimal system numbers as candidate keys because they do not uniquely identify telephone numbers or words.

A table can have at most one **primary key**, but more than one unique key. A primary key is a combination of columns which uniquely specify a row. It is a special case of unique keys. One difference is that primary keys have an implicit `NOT NULL` constraint while unique keys do not. Thus, the values in unique key columns may or may not be NULL, and in fact such a column may contain at most one NULL fields.[7] Another difference is that primary keys must be defined using another syntax.

The relational model, as expressed through relational calculus and relational algebra, does not distinguish between primary keys and other kinds of keys. Primary keys were added to the SQL standard mainly as a convenience to the application programmer.[*citation needed*]

Unique keys as well as primary keys can be referenced by foreign keys.

Defining primary keys

Primary keys are defined in the ANSI SQL Standard, through the PRIMARY KEY constraint. The syntax to add such a constraint to an existing table is defined in SQL:2003 like this:

```
ALTER TABLE <table identifier>
    ADD [ CONSTRAINT <constraint identifier> ]
    PRIMARY KEY ( <column expression> {, <column expression>}... )
```

The primary key can also be specified directly during table creation. In the SQL Standard, primary keys may consist of one or multiple columns. Each column participating in the primary key is implicitly defined as NOT NULL. Note that some DBMS require explicitly marking primary-key columns as `NOT NULL`.[*citation needed*]

```
CREATE TABLE table_name (

   ...
)
```

If the primary key consists only of a single column, the column can be marked as such using the following syntax:

```
CREATE TABLE table_name (
   id_col  INT  PRIMARY KEY,
   col2    CHARACTER VARYING(20),
   ...
)
```

Differences between Primary Key and Unique Key:

Primary Key

1. A primary key *cannot allow* null values. (You cannot define a primary key on columns that allow nulls.)

2. Each table can have *at most one* primary key.
3. On some RDBMS a primary key automatically generates a *clustered* table index by default.

Unique Key

1. A unique key *can allow* null values. (You can define a unique key on columns that allow nulls.)
2. Each table can have *multiple* unique keys.
3. On some RDBMS a unique key automatically generates a *non-clustered* table index by default.

Defining unique keys

The definition of unique keys is syntactically very similar to primary keys.

```
ALTER TABLE <table identifier>
    ADD [ CONSTRAINT <constraint identifier> ]
    UNIQUE ( <column expression> {, <column expression>}... )
```

Likewise, unique keys can be defined as part of the `CREATE TABLE` SQL statement.

```
CREATE TABLE table_name (
   id_col   INT,
   col2     CHARACTER VARYING(20),
   key_col  SMALLINT,
   ...
   CONSTRAINT key_unique UNIQUE(key_col),
   ...
)
```

```
CREATE TABLE table_name (
   id_col  INT  PRIMARY KEY,
   col2    CHARACTER VARYING(20),
   ...
   key_col  SMALLINT UNIQUE,
   ...
)
```

Surrogate keys

In some design situations the natural key that uniquely identifies a tuple in a relation is difficult to use for software development. For example, it may involve multiple columns or large text fields. A surrogate key can be used as the primary key. In other situations there may be more than one candidate key for a relation, and no candidate key is obviously preferred. A surrogate key may be used as the primary key to avoid giving one candidate key artificial primacy over the others.

Since primary keys exist primarily as a convenience to the programmer, surrogate primary keys are often used—in many cases exclusively—in database application design.

Due to the popularity of surrogate primary keys, many developers and in some cases even theoreticians have come to regard surrogate primary keys as an inalienable part of the relational data model. This is largely due to a migration of principles from the Object-Oriented Programming model to the relational model, creating the hybrid object-relational model. In the ORM, these additional restrictions are placed on primary keys:

- Primary keys should be immutable, that is, not changed until the record is destroyed.
- Primary keys should be anonymous integer or numeric identifiers.

However, neither of these restrictions is part of the relational model or any SQL standard. Due diligence should be applied when deciding on the immutability of primary key values during database and application design. Some database systems even imply that values in primary key columns cannot be changed using the `UPDATE` SQL statement[*citation needed*].

Alternate key

It is commonplace in SQL databases to declare a single **primary key**, the most important unique key. However, there could be further unique keys that could serve the same purpose. These should be marked as 'unique' keys. This is done to prevent incorrect data from entering a table (a duplicate entry is not valid in a unique column) and to make the database more complete and useful. These could be called alternate keys.[8]

Natural key

In relational model database design, a **natural key** is a key that is formed of attributes that already exist in the real world. For example, a USA citizen's social security number could be used as a natural key. In other words, a natural key is a candidate key that has a logical relationship to the attributes within that row. A natural key is sometimes called *domain key*.

The main advantage of a natural key over a surrogate key, which has no meaning outside the database environment, is that it already exists; there is no need to add a new, artificial column to the schema. Using a natural key (when one can be identified) also simplifies data quality: It ensures that there can only be one row for a key; this "one version of the truth" can be verified, because the natural key is based on a real-world observation.

The main disadvantage of choosing a natural key is that its value may change and the relational database engine may not be able to propagate that change across the related foreign keys. For example, if `person_name` is used as the primary key for the person table, and a person gets married and changes name, then all of the one-to-many related tables need to be updated also. The secondary disadvantage of choosing a natural key is identifying uniqueness. The primary key must consist of the attributes that uniquely identify a row. However, it may be difficult (or it may add constraints) to create a natural key on a table. For example, if `person_name` is used as a primary key for the person table, many persons may share the same name and all but the first entry will be rejected as a duplication. The uniqueness constraint may be overcome by adding an additional column to the primary key, like `street_address`, to increase the likelihood of uniqueness.

Key field

A **unique key** or **primary key** is a key that uniquely defines the characteristics of each row. The **primary key** has to consist of characteristics that cannot collectively be duplicated by any other row. A Primary and Foreign key is needed in order to link tables.

In an entity relationship diagram of a data model, one or more **unique keys** may be declared for each data entity. Each unique key is composed from one or more data attributes of that data entity. The set of unique keys declared for a data entity is often referred to as the candidate keys for that data entity. From the set of candidate keys, a single unique key is selected and declared the primary key for that data entity. In an entity relationship diagram, each entity relationship uses a unique key, most often the primary key, of one data entity and copies the unique key data attributes to another data entity to which it relates. This inheritance of the unique key data attributes is referred to as a foreign key and is used to provide data access paths between data entities. Once the data model is instantiated into a database, each data entity usually becomes a database table, unique keys become unique indexes associated with their assigned database tables, and entity relationships become foreign key constraints. In integrated data models,[1] commonality relationships[2] do not become foreign key constraints since commonality relationships are a peer-to-peer type of relationship.

The primary key may consist of a single attribute or a multiple attributes in combination. For example, a birthday could be shared by many people and so would not be a prime candidate for the Primary Key, but a social security number or Driver's License number would be ideal since it correlates to one single data value. Another unique characteristic of a Primary Key as it pertains to a relational database, is that a Primary Key must also serve as a Foreign Key on a related table[*citation needed*]. For example:

```
Author Table Schema:

AuthorTable(AUTHOR_ID,AuthorName,CountryBorn,YearBorn)

Book Table Schema:

Book(ISBN,Author_ID,Title,Publisher,Price)
```

Here we can see that AUTHOR_ID serves as the Primary Key in AuthorTable but also serves as the Foreign Key on the BookTable. The Foreign Key serves as the link and therefore the connection between the two "related" tables in this sample database.

In a relational database, a **unique key** index can uniquely identify each row of data values in a database table. A unique key index comprises a single column or a set of columns in a single database table. No two distinct rows or data records in a database table can have the same data value (or combination of data values) in those unique key index columns if NULL values are not used. Depending on its design, a database table may have many unique key indexes but at most one primary key index.

A unique key constraint does not imply the `NOT NULL` constraint in practice. Because NULL is not an actual value (it represents the lack of a value), when two rows are compared, and both rows have NULL in a column, the column values are not considered to be equal. Thus, in order for a unique key to uniquely identify each row in a table, NULL values must not be used. According to the SQL[3] standard and Relational Model theory, a unique key (unique constraint) should accept NULL in several rows/tuples — however not all RDBMS implement this feature correctly.[4][5]

A unique key should uniquely identify all *possible* rows that exist in a table and not only the currently existing rows [*citation needed*]. Examples of unique keys are Social Security numbers (associated with a specific person[6]) or ISBNs (associated with a specific book). Telephone books and dictionaries cannot use names, words, or Dewey Decimal

system numbers as candidate keys because they do not uniquely identify telephone numbers or words.

A table can have at most one **primary key**, but more than one unique key. A primary key is a combination of columns which uniquely specify a row. It is a special case of unique keys. One difference is that primary keys have an implicit `NOT NULL` constraint while unique keys do not. Thus, the values in unique key columns may or may not be NULL, and in fact such a column may contain at most one NULL fields.[7] Another difference is that primary keys must be defined using another syntax.

The relational model, as expressed through relational calculus and relational algebra, does not distinguish between primary keys and other kinds of keys. Primary keys were added to the SQL standard mainly as a convenience to the application programmer.[*citation needed*]

Unique keys as well as primary keys can be referenced by foreign keys.

Defining primary keys

Primary keys are defined in the ANSI SQL Standard, through the PRIMARY KEY constraint. The syntax to add such a constraint to an existing table is defined in SQL:2003 like this:

```
ALTER TABLE <table identifier>
    ADD [ CONSTRAINT <constraint identifier> ]
    PRIMARY KEY ( <column expression> {, <column expression>}... )
```

The primary key can also be specified directly during table creation. In the SQL Standard, primary keys may consist of one or multiple columns. Each column participating in the primary key is implicitly defined as NOT NULL. Note that some DBMS require explicitly marking primary-key columns as `NOT NULL`.[*citation needed*]

```
CREATE TABLE table_name (

   ...
)
```

If the primary key consists only of a single column, the column can be marked as such using the following syntax:

```
CREATE TABLE table_name (
   id_col  INT  PRIMARY KEY,
   col2    CHARACTER VARYING(20),
   ...
)
```

Differences between Primary Key and Unique Key:

Primary Key

1. A primary key *cannot allow* null values. (You cannot define a primary key on columns that allow nulls.)
2. Each table can have *at most one* primary key.
3. On some RDBMS a primary key automatically generates a *clustered* table index by default.

Unique Key

1. A unique key *can allow* null values. (You can define a unique key on columns that allow nulls.)
2. Each table can have *multiple* unique keys.
3. On some RDBMS a unique key automatically generates a *non-clustered* table index by default.

Defining unique keys

The definition of unique keys is syntactically very similar to primary keys.

```
ALTER TABLE <table identifier>
    ADD [ CONSTRAINT <constraint identifier> ]
    UNIQUE ( <column expression> {, <column expression>}... )
```

Likewise, unique keys can be defined as part of the `CREATE TABLE` SQL statement.

```
CREATE TABLE table_name (
   id_col   INT,
   col2     CHARACTER VARYING(20),
   key_col  SMALLINT,
   ...
   CONSTRAINT key_unique UNIQUE(key_col),
   ...
)
```

```
CREATE TABLE table_name (
   id_col  INT  PRIMARY KEY,
   col2    CHARACTER VARYING(20),
   ...
   key_col  SMALLINT UNIQUE,
   ...
)
```

Surrogate keys

In some design situations the natural key that uniquely identifies a tuple in a relation is difficult to use for software development. For example, it may involve multiple columns or large text fields. A surrogate key can be used as the primary key. In other situations there may be more than one candidate key for a relation, and no candidate key is obviously preferred. A surrogate key may be used as the primary key to avoid giving one candidate key artificial primacy over the others.

Since primary keys exist primarily as a convenience to the programmer, surrogate primary keys are often used—in many cases exclusively—in database application design.

Due to the popularity of surrogate primary keys, many developers and in some cases even theoreticians have come to regard surrogate primary keys as an inalienable part of the relational data model. This is largely due to a migration of principles from the Object-Oriented Programming model to the relational model, creating the hybrid object-relational model. In the ORM, these additional restrictions are placed on primary keys:

Compound key

In database design, a **compound key** is a key that consists of 2 or more attributes that uniquely identify an entity occurrence. Each attribute that makes up the compound key is a **simple key** in its own right.

This is often confused with a **composite key** whereby even though this is also a key that consists of 2 or more attributes that uniquely identify an entity occurrence, at least one attribute that makes up the composite key is not a **simple key** in its own right.

An example might be an entity that represents the modules each student is attending at University. The entity has a studentId and a moduleCode as its primary key. Each of the attributes that make up the primary key are simple keys because each represents a unique reference when identifying a student in one instance and a module in the other.

In contrast, using the same example, imagine we identified a student by their firstName + lastName. In our table representing students on modules our primary key would now be firstName + lastName + moduleCode. Because firstName + lastName represent a unique reference to a student, it is not a simple key, it is a combination of attributes used to uniquely identify a student. Therefore the primary key for this entity is a composite key.

No restriction is applied to the attributes regarding their (initial) ownership within the data model. This means that any one, none, or all, of the multiple attributes within the compound key can be foreign keys. Indeed, a foreign key may itself be a compound key.

Compound keys almost always originate from attributive or an associative entity (tables) within the model, but this is not an absolute.

Foreign key

In the context of relational databases, a **foreign key** is a field (or collection of fields) in one table that uniquely identifies a row of another table. In other words, a foreign key is a column or a combination of columns that is used to establish and enforce a link between two tables.

The table containing the foreign key is called the **referencing** or **child table**, and the table containing the candidate key is called the **referenced** or **parent table**.

Since the purpose of the foreign key is to identify a particular row of the referenced table, it is generally required that the foreign key is equal to the candidate key in some row of the primary table, or else have no value (the NULL value.). This rule is called a **referential integrity constraint** between the two tables. Because violations of these constraints can be the source of many database problems, most database management systems provide mechanisms to ensure that every non-null foreign key corresponds to a row of the referenced table.

For example, consider a database with two tables: a CUSTOMER table that includes all customer data and an ORDER table that includes all customer orders. Suppose the business requires that each order must refer to a single customer. To reflect this in the database, a foreign key column is added to the ORDER table (e.g., CUSTOMERID), which references the primary key of CUSTOMER (e.g. ID). Because the primary key of a table must be unique, and because CUSTOMERID only contains values from that primary key field, we may assume that, when it has a value, CUSTOMERID will identify the particular customer which placed the order. However, this can no longer be assumed if the ORDER table is not kept up to date when rows of the CUSTOMER table are deleted or the ID column altered, and working with these tables may become more difficult. Many real world databased work around this problem by 'inactivating' rather than physically deleting master table foreign keys, or by complex update programs that modify all references to a foreign key when a change is needed.

Foreign keys play an essential role in database design. One important part of database design is making sure that relationships between real-world entities are reflected in the database by references, using foreign keys to refer from one table to another. Another important part of database design is database normalization, in which tables are broken apart and foreign keys make it possible for them to be reconstructed.

Multiple rows in the referencing (or child) table may refer to the same row in the referenced (or parent) table. In this case, the relationship between the two tables is called a one to many relationship between the referenced table and the referencing table.

In addition, the child and parent table may, in fact, be the same table, i.e. the foreign key refers back to the same table. Such a foreign key is known in SQL:2003 as a **self-referencing** or **recursive** foreign key. In database management systems, this is often accomplished by linking a first and second reference to the same table.

A table may have multiple foreign keys, and each foreign key can have a different parent table. Each foreign key is enforced independently by the database system. Therefore, cascading relationships between tables can be established using foreign keys.

Defining foreign keys

Foreign keys are defined in the ISO SQL Standard, through a FOREIGN KEY constraint. The syntax to add such a constraint to an existing table is defined in SQL:2003 as shown below. Omitting the column list in the REFERENCES clause implies that the foreign key shall reference the primary key of the referenced table.

```
ALTER TABLE <table identifier>
   ADD [ CONSTRAINT <constraint identifier> ]
      FOREIGN KEY ( <column expression> )
      REFERENCES <table identifier> [ ( <column expression> {, <column expression>}... ) ]
      [ ON UPDATE <referential action> ]
      [ ON DELETE <referential action> ]
```

Likewise, foreign keys can be defined as part of the `CREATE TABLE` SQL statement.

```
CREATE TABLE table_name (
   id    INTEGER  PRIMARY KEY,
   col2  CHARACTER VARYING(20),
   col3  INTEGER,
   ...
   FOREIGN KEY(col3)
      REFERENCES other_table(key_col) ON DELETE CASCADE,
   ... )
```

If the foreign key is a single column only, the column can be marked as such using the following syntax:

```
CREATE TABLE table_name (
   id    INTEGER  PRIMARY KEY,
   col2  CHARACTER VARYING(20),
   col3  INTEGER REFERENCES other_table(column_name),
   ... )
```

Foreign keys can be defined with a stored procedure statement.Wikipedia:Please clarify

```
sp_foreignkey tabname, pktabname, col1 [, col2] ...  [, col8]
```

- **tabname**: the name of the table or view that contains the foreign key to be defined.
- **pktabname**: the name of the table or view that has the primary key to which the foreign key applies. The primary key must already be defined.
- **col1**: the name of the first column that makes up the foreign key. The foreign key must have at least one column and can have a maximum of eight columns.

Referential actions

Because the database management system enforces referential constraints, it must ensure data integrity if rows in a referenced table are to be deleted (or updated). If dependent rows in referencing tables still exist, those references have to be considered. SQL:2003 specifies 5 different **referential actions** that shall take place in such occurrences:

- CASCADE
- RESTRICT
- NO ACTION
- SET NULL
- SET DEFAULT

CASCADE

Whenever rows in the master (referenced) table are deleted (resp. updated), the respective rows of the child (referencing) table with a matching foreign key column will get deleted (resp. updated) as well. This is called a cascade delete (resp. update).

RESTRICT

A value cannot be updated or deleted when a row exists in a referencing or child table that references the value in the referenced table.

Similarly, a row cannot be deleted as long as there is a reference to it from a referencing or child table.

To understand RESTRICT (and CASCADE) better, it may be helpful to notice the following difference, which might not be immediately clear. The referential action CASCADE modifies the "behavior" of the (child) table itself where the word CASCADE is used. For example, ON DELETE CASCADE effectively says "When the referenced row is deleted from the other table (master table), then delete *also from me*". However, the referential action RESTRICT modifies the "behavior" of the master table, *not* the child table, although the word RESTRICT appears in the child table and not in the master table! So, ON DELETE RESTRICT effectively says: "When someone tries to delete the row from the other table (master table), prevent deletion *from that other table* (and of course, also don't delete from me, but that's not the main point here)."

RESTRICT is not supported by Microsoft SQL 2012 and earlier.

NO ACTION

NO ACTION and RESTRICT are very much alike. The main difference between NO ACTION and RESTRICT is that with NO ACTION the referential integrity check is done after trying to alter the table. RESTRICT does the check before trying to execute the UPDATE or DELETE statement. Both referential actions act the same if the referential integrity check fails: the UPDATE or DELETE statement will result in an error.

In other words, when an UPDATE or DELETE statement is executed on the referenced table using the referential action NO ACTION, the DBMS verifies at the end of the statement execution that none of the referential relationships are violated. This is different from RESTRICT, which assumes at the outset that the operation will violate the constraint. Using NO ACTION, the triggers or the semantics of the statement itself may yield an end state in which no foreign key relationships are violated by the time the constraint is finally checked, thus allowing the statement to complete successfully.

SET DEFAULT , SET NULL

In general, the action taken by the DBMS for SET NULL or SET DEFAULT is the same for both ON DELETE or ON UPDATE: The value of the affected referencing attributes is changed to NULL for SET NULL, and to the specified default value for SET DEFAULT.

Triggers

Referential actions are generally implemented as implied triggers (i.e. triggers with system-generated names, often hidden.) As such, they are subject to the same limitations as user-defined triggers, and their order of execution relative to other triggers may need to be considered; in some cases it may become necessary to replace the referential action with its equivalent user-defined trigger to ensure proper execution order, or to work around mutating-table limitations.

Another important limitation appears with transaction isolation: your changes to a row may not be able to fully cascade because the row is referenced by data your transaction cannot "see", and therefore cannot cascade onto. An example: while your transaction is attempting to renumber a customer account, a simultaneous transaction is attempting to create a new invoice for that same customer; while a CASCADE rule may fix all the invoice rows your transaction can see to keep them consistent with the renumbered customer row, it won't reach into another transaction to fix the data there; because the database cannot guarantee consistent data when the two transactions commit, one of them will be forced to roll back (often on a first-come-first-served basis.)

Example

As a first example to illustrate foreign keys, suppose an accounts database has a table with invoices and each invoice is associated with a particular supplier. Supplier details (such as name and address) are kept in a separate table; each supplier is given a 'supplier number' to identify it. Each invoice record has an attribute containing the supplier number for that invoice. Then, the 'supplier number' is the primary key in the Supplier table. The foreign key in the Invoices table points to that primary key. The relational schema is the following. Primary keys are marked in bold, and foreign keys are marked in italics.

```
Supplier ( SupplierNumber, Name, Address, Type )
Invoices ( InvoiceNumber, SupplierNumber, Text )
```

The corresponding Data Definition Language statement is as follows.

```
CREATE TABLE Supplier (
   SupplierNumber  INTEGER NOT NULL,
   Name            VARCHAR(20) NOT NULL,
   Address         VARCHAR(50) NOT NULL,
   Type            VARCHAR(10),

Persistent Object Identifier

In database design, a **Persistent Object Identifier** (**POID**) is a unique identifier of a record on a table, used as the primary key. Important characteristics of a POID are that it does not carry business information and are not generally exported or otherwise made visible to data users; as such a POID has many of the characteristics of a surrogate key. The only purpose of the POID is to act as the primary key on the table where it is defined and to be referenced as the foreign key by other tables. Because POIDs, like surrogate keys, do not carry business information, they are immune to changes in the form or meaning of business data.

Cardinality (data modeling)

In database design, the **cardinality** or fundamental principle of one data table with respect to another is a critical aspect. The relationship of one to the other must be precise and exact between each other in order to explain how each table links together.

In the relational model, tables can be related as any of "one to many" or "many-to-many." This is said to be the **cardinality** of a given table in relation to another.

For example, consider a database designed to keep track of hospital records. Such a database could have many tables like:

- a *doctor* table with information about physicians;
- a *patient* table for medical subjects undergoing treatment;
- and a *department* table with an entry for each division of a hospital.

In that model:

- There is a **many-to-many** relationship between the records in the doctor table and records in the patient table because doctors have many patients, and a patient could have several doctors;
- A **one-to-many** relation between the department table and the doctor table because each doctor may work for only one department, but one department could have many doctors.

A "one-to-one" relationship is mostly used to split a table in two in order to provide information concisely and make it more understandable. In the hospital example, such a relationship could be used to keep apart doctors' own unique professional information from administrative details.

In data modeling, collections of data elements are grouped into "data tables" which contain groups of data field names called "database attributes". Tables are linked by "key fields". A "primary key" assigns a field to its "special order table". For example, the "Doctor Last Name" field might be assigned as a primary key of the Doctor table with all people having same last name organized alphabetically according to the first three letters of their first name. A table can also have a **foreign key** which indicates that field is linked to the primary key of another table.

A complex data model can involve hundreds of related tables. A renowned computer scientist, C.J. Date, created a systematic method to organize database models. Date's steps for organizing database tables and their keys is called **Database Normalization**. Database normalization avoids certain hidden database design errors (**delete anomalies** or **update anomalies**). In real life the process of database normalization ends up breaking tables into a larger number of smaller tables, so there are common sense data modeling tactics called **de-normalization** which combine tables in practical ways.

In real world data models careful design is critical because as the data grows voluminous, tables linked by keys must be used to speed up programmed retrieval of data. If data modeling is poor, even a computer applications system with just a million records will give the end-users unacceptable response time delays. For this reason data modeling is a keystone in the skills needed by a modern software developer.

Formal Database Modeling Technologies

UML class diagram may be used for data modeling. In that case, relationship are modeled using UML associations, and multiplicity is used on those associations to denote **cardinality**. Here are some examples:

left	right		example
1	**1**	one-to-one	person <-> weight
0..1	**1**	*optional on one side* one-to-one	date of death <-> person
0..* or *****	**0..*** or *****	*optional on both sides* many-to-many	person <-> book
1	**1..***	one-to-many	person <-> language

As an alternative to UML, Entity Relationship Diagrams (ERDs) can be used to capture information about data model cardinality. A crow's foot shows a **one-to-many** relationship. Alternatively a single line represents a one-to-one relationship.

Recordset

A **recordset** is a data structure that consists of a group of database records, and can either come from a base table or as the result of a query to the table.

The concept is common to a number of platforms, notably Microsoft's Data Access Objects (DAO) and ActiveX Data Objects (ADO). The Recordset object contains a Fields collection, and a Properties collection. At any time, the Recordset object refers to only a single record within the set as the current record.

Superkey

A **superkey** is defined in the relational model of database organization as a set of attributes of a relation variable for which it holds that in all relations assigned to that variable, there are no two distinct tuples (rows) that have the same values for the attributes in this set. Equivalently a superkey can also be defined as a set of attributes of a relation schema upon which all attributes of the schema are functionally dependent.

Note that the set of **all** attributes is a trivial superkey, because in relational algebra duplicate rows are not permitted.

Also note that if attribute set *K* is a superkey of relation *R*, then at all times it is the case that the projection of *R* over *K* has the same cardinality as *R* itself.

Informally, a superkey is a set of attributes within a table whose values can be used to uniquely identify a tuple. A candidate key is a minimal set of attributes necessary to identify a tuple, this is also called a minimal superkey. For example, given an employee schema, consisting of the attributes employeeID, name, job, and departmentID, we could use the employeeID in combination with any or all other attributes of this table to uniquely identify a tuple in the table. Examples of superkeys in this schema would be {employeeID, Name}, {employeeID, Name, job}, and {employeeID, Name, job, departmentID}. The last example is known as trivial superkey, because it uses all attributes of this table to identify the tuple.

In a real database we do not need values for all of those attributes to identify a tuple. We only need, per our example, the set {employeeID}. This is a **minimal superkey –** that is, a minimal set of attributes that can be used to identify a single tuple. So, employeeID is a candidate key.

Example

English Monarchs

Monarch Name	Monarch Number	Royal House
Edward	II	Plantagenet
Edward	III	Plantagenet
Richard	III	Plantagenet
Henry	IV	Lancaster

First, list out all the (non-empty) sets of attributes:

- {Monarch Name}
- {Monarch Number}
- {Royal House}
- {Monarch Name, Monarch Number}
- {Monarch Name, Royal House}
- {Monarch Number, Royal House}
- {Monarch Name, Monarch Number, Royal House}

Second, eliminate all the sets which **do not** meet superkey's requirement. For example, {Monarch Name, Royal House} cannot be a superkey because for the same attribute values (Edward, Plantagenet), there are two distinct tuples:

- (Edward, **II**, Plantagenet)
- (Edward, **III**, Plantagenet)

Finally, after elimination, the remaining sets of attributes are the only possible superkeys in this example:

- {Monarch Name, Monarch Number} **(Candidate Key)**
- {Monarch Name, Monarch Number, Royal House}

In real situations, however, superkeys are normally not determined by this method, which is very tedious and time-consuming, but by analyzing functional dependencies.

Integrity constraints

Integrity constraints are used to ensure accuracy and consistency of data in a relational database.[*citation needed*]

Types

Codd initially defined two sets of constraints but, in his second version of the relational model, he came up with four integrity constraints: [*citation needed*]

Entity Integrity

The entity integrity constraint states that no primary key value can be null. This is because the primary key value is used to identify individual tuples in a relation. Having null value for the primary key implies that we cannot identify some tuples.This also specifies that there may not be any duplicate entries in primary key column key word.

Referential Integrity

The referential integrity constraint is specified between two relations and is used to maintain the consistency among tuples in the two relations. Informally, the referential integrity constraint states that a tuple in one relation that refers to another relation must refer to an existing tuple in that relation. It is a rule that maintains consistency among the rows of the two relations in dbms.

Domain Integrity

Domain constraints allows us to test the values inserted into the database and to test the queries to make sure comparisons made are appropriate.

User Defined Integrity

A business rule is a statement that defines or constrains some aspect of the business. It is intended to assert business structure or to control or influence the behavior of the business. E.g.: Age>=18 && Age<=60

Check Constraint

A **check constraint** is applied to each row in the table.Wikipedia:Please clarify The constraint must be a predicate. It can refer to a single or multiple columns of the table. The result of the predicate can be either `TRUE`, `FALSE`, or `UNKNOWN`, depending on the presence of NULLs. If the predicate evaluates to `UNKNOWN`, then the constraint is not violated and the row can be inserted or updated in the table. This is contrary to predicates in WHERE clauses in SELECT or UPDATE statements.

For example, in a table containing products, one could add a check constraint such that the price of a product and quantity of a product is a non-negative value:

```
PRICE >= 0
```

```
QUANTITY >= 0
```

If these constraints were not in place, it would be possible to have a negative price (-$30) or quantity (-3 items).

Check constraints are used to ensure the validity of data in a database and to provide data integrity. If they are used at the database level, applications that use the database will not be able to add invalid data or modify valid data so the data becomes invalid, even if the application itself accepts invalid data.

Definition

Each check constraint has to be defined in the `CREATE TABLE` or `ALTER TABLE` statement using the syntax:

```
CREATE TABLE table_name (
   ...,
   CONSTRAINT constraint_name CHECK ( predicate ),
   ...
)
```

```
ALTER TABLE table_name
   ADD CONSTRAINT constraint_name CHECK ( predicate )
```

If the check constraint refers to a single column only, it is possible to specify the constraint as part of the column definition.

```
CREATE TABLE table_name (
   ...
   column_name type CHECK ( predicate ),
   ...
)
```

NOT NULL constraint

A `NOT NULL` constraint is functionally equivalent to the following check constraint with an `IS NOT NULL` predicate:

```
CHECK (column IS NOT NULL)
```

Some relational database management systems are able to optimize performance when the `NOT NULL` constraint syntax is used as opposed to the `CHECK` constraint syntax given above.[1]

Common restrictions

Most database management systems restrict check constraints to a single row, with access to constants and deterministic functions, but not to data in other tables, or to data invisible to the current transaction because of transaction isolation.

Such constraints are not truly *table check constraints* but rather *row check constraints*. Because these constraints are generally only verified when a row is directly updated (for performance reasons,) and often implemented as implied `INSERT` or `UPDATE` triggers, integrity constraints could be violated by indirect action were it not for these limitations. Furthermore, otherwise-valid modifications to these records would then be prevented by the `CHECK` constraint. Some examples of dangerous constraints include:

- `CHECK ((select count(*) from invoices where invoices.customerId = customerId) < 1000)`
- `CHECK (dateInserted = CURRENT_DATE)`
- `CHECK (countItems = RAND())`

User-defined triggers can be used to work around these restrictions. Although similar in implementation, it is semantically clear that triggers will only be fired when the table is directly modified, and that it is the designer's responsibility to handle indirect, important changes in other tables; constraints on the other hand are intended to be "true at all times" regardless of the user's actions or the designer's lack of foresight.

Propagation constraint

In database systems, a **propagation constraint** "details what should happen to a related table when we update a row or rows of a target table" (Paul Beynon-Davies, 2004, p.108). Tables are linked using primary key to foreign key relationships. It is possible for users to update one table in a relationship in such a way that the relationship is no longer consistent and this is known as breaking referential integrity. An example of breaking referential integrity: if a table of employees includes a department number for 'Housewares' which is a foreign key to a table of departments and a user deletes that department from the department table then Housewares employees records would refer to a non-existent department number.

Propagation constraints are methods used by relational database management systems (RDBMS) to solve this problem by ensuring that relationships between tables are preserved without error. In his database textbook, Beynon-Davies explains the three ways that RDBMS handle deletions of target and related tuples:

- Restricted Delete - the user cannot delete the target row until all rows that point to it (via foreign keys) have been deleted. This means that all Housewares employees would need to be deleted, or their departments changed, before removing the department from the departmental table.
- Cascades Delete - can delete the target row and all rows that point to it (via foreign keys) are also deleted. The process is the same as a restricted delete, except that the RDBMS would delete the Houseware employees automatically before removing the department.
- Nullifies Delete - can delete the target row and all foreign keys (pointing to it) are set to null. In this case, after removing the housewares department, employees who worked in this department would have a NULL (unknown) value for their department.

Transition constraint

A **transition constraint** is a way of enforcing that the data does not enter an impossible state because of a previous state. For example, it should not be possible for a person to change from being "married" to being "single, never married". The only valid states after "married" might be "divorced", "widowed", or "deceased".

Transition constraint is commonly used in database models such as relational databases.

Wide and narrow data

Wide and **narrow** (sometimes un-stacked and stacked) are terms used to describe two different presentations for tabular data.[1][2][3]

Wide

Wide, or unstacked data is presented with each different data variable in a separate column.

Person	Age	Weight
Bob	32	128
Alice	24	86
Steve	64	95

Narrow

Narrow, or stacked data is presented with one column containing all the values and another column listing the context of the value

Person	Variable	Value
Bob	Age	32
Bob	Weight	128
Alice	Age	24
Alice	Weight	86
Steve	Age	64
Steve	Weight	95

This is often easier to implement, addition of a new field does not require any changes to the structure of the table, however it can be harder for people to understand.

Implementations

Many statistical and data processing systems have functions to convert between these two presentations, for instance the R programming language has several packages such as the reshape [4] package

Universal relation assumption

In relational databases, the **universal relation assumption** states that one can place all data attributes into a (possibly very wide) table, which may then be decomposed into smaller tables as needed.[1]

However, the assumption that a single large table can capture real database designs is often plagued with a number of difficulties.[2] The "nested universal relation" model has attempted to address some of the problems and offer improvements.[3]

Reference table

A **reference table** (or table of reference) may mean a set of references that an author may have cited or gained inspiration from whilst writing an article, similar to a bibliography.

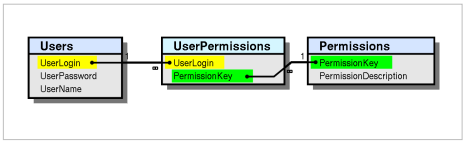
It can also mean an information table that is used as a quick and easy reference for things that are difficult to remember such as comparing imperial with metric measurements.

In the context of database design a reference table is a table into which an enumerated set of possible values of a certain field data type is divested. For example, in a relational database model of a warehouse the entity 'Item' may have a field called 'status' with a predefined set of values such as 'sold', 'reserved', 'out of stock'. In a purely designed database these values would be divested into an extra entity or Reference Table called 'status' in order to achieve database normalisation. The entity 'status' in this case has no true representative in the real world but rather would an exceptional case where the attribute of a certain database entity is divested into its own table. The advantage of doing this is that internal functionality and optional conditions within the database and the software which utilizes it are easier to modify and extend on that particular aspect. Establishing an enterprise-wide view of reference tables is called master data management.

Junction table

In database management systems following the relational model, a **junction table** is a database table that contains common fields from two or more other database tables within the same database. It is on the many side of a one-to-many relationship with each of the other tables. Junction tables are known under many names, among them **cross-reference table**, **bridge table**, **join table**, **map table**, **intersection table**, **linking table**, **many-to-many resolver**, **link table**, **pairing table**, **pivot table**, **transition table**, or **association table**.

Junction tables are employed when dealing with many-to-many relationships in a database. A practical use of a junction table would be to assign permissions to users. There can be multiple users, and each user can be assigned 0 or more permissions.



```sql
CREATE TABLE Users (
    UserLogin varchar(50) PRIMARY KEY,
    UserPassword varchar(50) NOT NULL,
    UserName varchar(50) NOT NULL
)

CREATE TABLE Permissions (
    PermissionKey varchar(50) PRIMARY KEY,
    PermissionDescription varchar(500) NOT NULL
)

-- This is the junction table.
CREATE TABLE UserPermissions (
    UserLogin varchar(50) REFERENCES Users (UserLogin),
    PermissionKey varchar(50) REFERENCES Permissions (PermissionKey),
```

```
    PRIMARY KEY (UserLogin, PermissionKey)
)
```

Using junction tables

A SELECT-statement on a junction table usually involves joining the main table with the junction table:

```
SELECT * FROM Users
JOIN UserPermissions USING (UserLogin);
```

This will return a list of all users and their permissions.

Inserting into a junction table involves two steps: first inserting into the main table (for example, a new User), then updating the junction table.

```
-- Creating a new User
INSERT INTO Users (UserLogin, UserPassword, UserName)
VALUES ('SomeUser', 'SecretPassword', 'UserName');

-- Creating a new Permission
INSERT INTO Permissions (PermissionKey, PermissionDescription)
VALUES ('TheKey', 'A key used for several permissions');

-- Finally, updating the junction
INSERT INTO UserPermissions (UserLogin, PermissionKey)
VALUES ('SomeUser', 'TheKey');
```

Using foreign keys, the database will automatically dereference the values of the UserPermissions table to their own table.

Nested set model

The **nested set model** is a particular technique for representing nested sets (also known as trees or hierarchies) in relational databases. The term was apparently introduced by Joe Celko; others describe the same technique without naming it [1] or using different terms.[2]

Motivation

The technique is an answer to the problem that the standard relational algebra and relational calculus, and the SQL operations based on them, are unable to express all desirable operations on hierarchies directly. A hierarchy can be expressed in terms of a parent-child relation - Celko calls this the adjacency list model - but if it can have arbitrary depth, this does not allow the expression of operations such as comparing the contents of hierarchies of two elements, or determining whether an element is somewhere in the subhierarchy of another element. When the hierarchy is of fixed or bounded depth, the operations are possible, but expensive, due to the necessity of performing one relational join per level. This is often known as the bill of materials problem.[*citation needed*]

Several resolutions exist and are available in some relational database management systems:

- support for a dedicated hierarchy data type, such as in SQL's hierarchical query facility;
- extending the relational language with hierarchy manipulations, such as in the nested relational algebra.
- extending the relational language with transitive closure, such as SQL's CONNECT statement; this allows a parent-child relation to be used, but execution remains expensive;
- the queries can be expressed in a language that supports iteration and is wrapped around the relational operations, such as PL/SQL, T-SQL or a general-purpose programming language

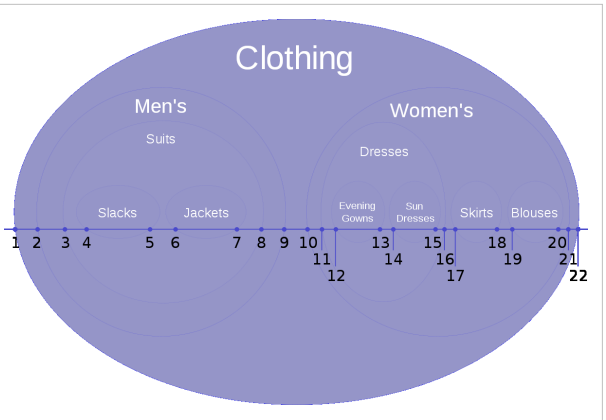
When these solutions are not available or not feasible, another approach must be taken.

The technique

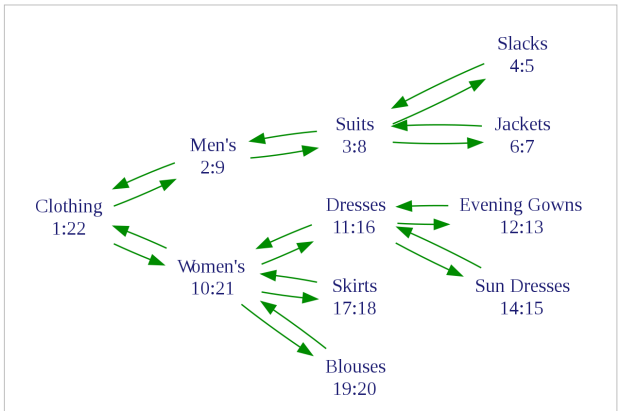
The **nested set model** is to number the nodes according to a tree traversal, which visits each node twice, assigning numbers in the order of visiting, and at both visits. This leaves two numbers for each node, which are stored as two attributes. Querying becomes inexpensive: hierarchy membership can be tested by comparing these numbers. Updating requires renumbering and is therefore expensive. Refinements that use rational numbers instead of integers can avoid renumbering, and so are faster to update, although much more complicated.

Example

In a clothing store catalog, clothing may be categorized according to the hierarchy given on the left:



A hierarchy: types of clothing



The numbering assigned by tree traversal

Node	Left	Right
Clothing	1	22
Men's	2	9
Women's	10	21
Suits	3	8
Slacks	4	5
Jackets	6	7
Dresses	11	16
Skirts	17	18
Blouses	19	20
Evening Gowns	12	13
Sun Dresses	14	+ The resulting representation

The "Clothing" category, with the highest position in the hierarchy, encompasses all subordinating categories. It is therefore given left and right domain values of 1 and 22, the latter value being the double of the total number of nodes being represented. The next hierarchical level contains "Men's" and "Women's", both containing levels within themselves that must be accounted for. Each level's data node is assigned left and right domain values according to the number of sublevels contained within, as shown in the table data.

Performance

Queries using nested sets can be expected to be faster than queries using a stored procedure to traverse an adjacency list, and so are the faster option for databases which lack native recursive query constructs, such as MySQL. However, recursive SQL queries can be expected to perform comparably for 'find immediate descendants' queries, and much faster for other depth search queries, and so are the faster option for databases which provide them, such as PostgreSQL, Oracle, and Microsoft SQL Server.

Drawbacks

Nested sets are very slow for inserts because it requires updating left and right domain values for all records in the table after the insert. This can cause a lot of database thrash[*citation needed*] as many rows are rewritten and indexes rebuilt.

The nested interval model does not suffer from this problem, but is more complex to implement, and is not as well known. The nested interval model stores the position of the nodes as rational numbers expressed as quotients (n/d). [3]

Variations

Using the nested set model as described above has some performance limitations during certain tree traversal operations. For example, trying to find the immediate child nodes given a parent node requires pruning the subtree to a specific level as in the following SQL code example:

```
SELECT Child.Node, Child.Left, Child.Right
FROM Tree as Parent, Tree as Child
WHERE
      Child.Left BETWEEN Parent.Left AND Parent.Right
      AND NOT EXISTS (    -- No Middle Node
```

```
            SELECT *
            FROM Tree as Mid
            WHERE Mid.Left BETWEEN Parent.Left AND Parent.Right
                        AND Child.Left BETWEEN Mid.Left AND Mid.Right
                  AND Mid.Node NOT IN (Parent.Node AND Child.Node)
      )
      AND Parent.Left = 1  -- Given Parent Node Left Index
```

Or, equivalently:

```
SELECT DISTINCT Child.Node, Child.Left, Child.Right
FROM Tree as Child, Tree as Parent
WHERE Parent.Left < Child.Left AND Parent.Right > Child.Right  -- associate Child Nodes with ancestors
GROUP BY Child.Node
HAVING max(Parent.Left) = 1  -- Subset for those with the given Parent
Node as the nearest ancestor
```

The query will be more complicated when searching for children more than one level deep. To overcome this limitation and simplify tree traversal an additional column is added to the model to maintain the depth of a node within a tree.

Node	Left	Right	Depth
Clothing	1	22	0
Men's	2	9	1
Women's	10	21	1
Suits	3	8	2
Slacks	4	5	3
Jackets	6	7	3
Dresses	11	16	2
Skirts	17	18	2
Blouses	19	20	2
Evening Gowns	12	13	3
Sun Dresses	14	15	+ The resulting representation

In this model, finding the immediate children given a parent node can be accomplished with the following SQL code:

```
SELECT Child.Node, Child.Left, Child.Right
FROM Tree as Child, Tree as Parent
WHERE
      Child.Depth = Parent.Depth + 1
      AND Child.Left > Parent.Left
      AND Child.Right < Parent.Right
      AND Parent.Left = 1  -- Given Parent Node Left Index
```

Information schema

In relational databases, the **information schema** is an ANSI standard set of read-only views which provide information about all of the tables, views, columns, and procedures in a database. It can be used as a source of the information which some databases make available through non-standard commands, such as the `SHOW` command of MySQL, the `DESCRIBE` command of Oracle, and the `\d` command of PostgreSQL.

```
=> select count(table_name) from information_schema.tables;
 count
-------
    99
(1 row)
=> select column_name, data_type, column_default, is_nullable
      from information_schema.columns where table_name='alpha';
 column_name | data_type | column_default | is_nullable
-------------+-----------+----------------+-------------
 foo         | integer   |                | YES

Codd's 12 rules

Codd's twelve rules are a set of thirteen rules (numbered zero to twelve) proposed by Edgar F. Codd worked under a pioneer of the relational model for databases, designed to define what is required from a database management system in order for it to be considered *relational*, i.e., a relational database management system (RDBMS). They are sometimes jokingly referred to as "Codd's Twelve Commandments".

Details

Codd produced these rules as part of a personal campaign to prevent his vision of the relational database being diluted, as database vendors scrambled in the early 1980s to repackage existing products with a relational veneer. Rule 12 was particularly designed to counter such a positioning. Even if such repackaged non-relational products eventually gave way to SQL DBMSs, no popular "relational" DBMSs are actually relational, be it by Codd's twelve rules or by the more formal definitions in his papers, in his books or in succeeding works in the academia or by its coworkers and successors, Christopher J. Date, Hugh Darwen, David McGoveran and Fabian Pascal. Only less known DBMSs, most of them academic, strive to comply. The only commercial example, as of December 2010[1], is Dataphor. Some rules are controversial, especially rule three, because of the debate on three-valued logic.

Rules

Rule 0: The *Foundation rule*:

> A relational database management system must manage its stored data using only its relational capabilities. The system must qualify as *relational*, as a *database*, and as a *management system*. For a system to qualify as a relational database management system (RDBMS), that system must use its *relational* facilities (exclusively) to *manage* the *database*.

Rule 1: The *information rule*:

> All information in a relational database (including table and column names) is represented in only one way, namely as a value in a table.

Rule 2: The *guaranteed access rule*:

> All data must be accessible. This rule is essentially a restatement of the fundamental requirement for primary keys. It says that every individual scalar value in the database must be logically addressable by specifying the name of the containing table, the name of the containing column and the primary key value of the containing

row.

Rule 3: *Systematic treatment of null values*:

The DBMS must allow each field to remain null (or empty). Specifically, it must support a representation of "missing information and inapplicable information" that is systematic, distinct from all regular values (for example, "distinct from zero or any other number", in the case of numeric values), and independent of data type. It is also implied that such representations must be manipulated by the DBMS in a systematic way.

Rule 4: *Active online catalog based on the relational model*:

The system must support an online, inline, relational catalog that is accessible to authorized users by means of their regular query language. That is, users must be able to access the database's structure (catalog) using the same query language that they use to access the database's data.

Rule 5: The *comprehensive data sublanguage rule*:

The system must support at least one relational language that

1. Has a linear syntax
2. Can be used both interactively and within application programs,
3. Supports data definition operations (including view definitions), data manipulation operations (update as well as retrieval), security and integrity constraints, and transaction management operations (begin, commit, and rollback).

Rule 6: The *view updating rule*:

All views that are theoretically updatable must be updatable by the system.

Rule 7: *High-level insert, update, and delete*:

The system must support set-at-a-time *insert*, *update*, and *delete* operators. This means that data can be retrieved from a relational database in sets constructed of data from multiple rows and/or multiple tables. This rule states that insert, update, and delete operations should be supported for any retrievable set rather than just for a single row in a single table.

Rule 8: *Physical data independence*:

Changes to the physical level (how the data is stored, whether in arrays or linked lists etc.) must not require a change to an application based on the structure.

Rule 9: *Logical data independence*:

Changes to the logical level (tables, columns, rows, and so on) must not require a change to an application based on the structure. Logical data independence is more difficult to achieve than physical data independence.

Rule 10: *Integrity independence*:

Integrity constraints must be specified separately from application programs and stored in the catalog. It must be possible to change such constraints as and when appropriate without unnecessarily affecting existing applications.

Rule 11: *Distribution independence*:

The distribution of portions of the database to various locations should be invisible to users of the database. Existing applications should continue to operate successfully:

1. when a distributed version of the DBMS is first introduced; and
2. when existing distributed data are redistributed around the system.

Rule 12: The *nonsubversion rule*:

If the system provides a low-level (record-at-a-time) interface, then that interface cannot be used to subvert the system, for example, bypassing a relational security or integrity constraint.

Edgar F. Codd

Edgar Frank "Ted" Codd	
Born	August 19, 1923 Isle of Portland, England
Died	April 18, 2003 (aged 79) Williams Island, Aventura, Florida, USA
Fields	Computer Science
Institutions	University of Oxford University of Michigan IBM
Alma mater	Exeter College, Oxford University of Michigan
Thesis	*Propagation, Computation, and Construction in Two-dimensional cellular spaces* [1] (1965)
Doctoral advisor	John Henry Holland
Known for	OLAP Relational model Codd's cellular automaton Codd's 12 rules Boyce–Codd normal form
Notable awards	Turing Award

Edgar Frank "Ted" Codd (August 19, 1923 – April 18, 2003) was an English computer scientist who, while working for IBM, invented the relational model for database management, the theoretical basis for relational databases. He made other valuable contributions to computer science, but the relational model, a very influential general theory of data management, remains his most mentioned achievement.

Biography

Edgar Frank Codd was born on the Isle of Portland in England. After attending Poole Grammar School, he studied mathematics and chemistry at Exeter College, Oxford, before serving as a pilot in the Royal Air Force during the Second World War. In 1948, he moved to New York to work for IBM as a mathematical programmer. In 1953, angered by Senator Joseph McCarthy, Codd moved to Ottawa, Canada. A decade later he returned to the U.S. and received his doctorate in computer science from the University of Michigan in Ann Arbor. Two years later he moved to San Jose, California, to work at IBM's San Jose Research Laboratory, where he continued to work until the 1980s.[2] He was appointed IBM Fellow in 1976. During the 1990s, his health deteriorated and he ceased work.

Codd received the Turing Award in 1981, and in 1994 he was inducted as a Fellow of the Association for Computing Machinery.[3]

Codd died of heart failure at his home in Williams Island, Florida, at the age of 79 on April 18, 2003.[4]

Work

Codd received a PhD in 1965 from the University of Michigan, Ann Arbor advised by John Henry Holland. His thesis was about self-replication in cellular automata, extending on work of von Neumann and showing that a set of eight states was sufficient for universal computation and construction. His design for a self-replicating computer was only implemented in 2010.

In the 1960s and 1970s he worked out his theories of data arrangement, issuing his paper "A Relational Model of Data for Large Shared Data Banks" in 1970, after an internal IBM paper one year earlier.[5] To his disappointment, IBM proved slow to exploit his suggestions until commercial rivals started implementing them.

Initially, IBM refused to implement the relational model in order to preserve revenue from IMS/DB. Codd then showed IBM customers the potential of the implementation of its model, and they in turn pressured IBM. Then IBM included in its Future Systems project a System R subproject — but put in charge of it developers who were not thoroughly familiar with Codd's ideas, and isolated the team from Codd[*citation needed*]. As a result, they did not use Codd's own Alpha language but created a non-relational one, SEQUEL. Even so, SEQUEL was so superior to pre-relational systems that it was copied, in 1979, based on pre-launch papers presented at conferences, by Larry Ellison, of Relational software Inc, in his Oracle Database, which actually reached market before SQL/DS — because of the then-already proprietary status of the original name, SEQUEL had been renamed SQL.

Codd continued to develop and extend his relational model, sometimes in collaboration with Chris Date. One of the normalized forms, the Boyce–Codd normal form, is named after him.

Codd's theorem, a result proven in his seminal work on the relational model, equates the expressive power of relational algebra and relational calculus (which, in essence, is equivalent to first-order logic).

As the relational model started to become fashionable in the early 1980s, Codd fought a sometimes bitter campaign to prevent the term being misused by database vendors who had merely added a relational veneer to older technology. As part of this campaign, he published his 12 rules to define what constituted a relational database. This made his position in IBM increasingly difficult, so he left to form his own consulting company with Chris Date and others.

Codd coined the term *Online analytical processing (OLAP)* and wrote the "twelve laws of online analytical processing".[6] Controversy erupted, however, after it was discovered that this paper had been sponsored by Arbor Software (subsequently Hyperion, now acquired by Oracle), a conflict of interest that had not been disclosed, and ComputerWorld withdrew the paper.[7]

In 2004, SIGMOD renamed its highest prize to the SIGMOD Edgar F. Codd Innovations Award, in his honour.

Relational algebra

Relational algebra

In computer science, **relational algebra** is an offshoot of first-order logic and of algebra of sets concerned with operations over finitary relations, usually made more convenient to work with by identifying the components of a tuple by a name (called attribute) rather than by a numeric column index, which is called a relation in database terminology.

The main application of relational algebra is providing a theoretical foundation for relational databases, particularly query languages for such databases, chief among which is SQL.

Introduction

Relational algebra received little attention outside of pure mathematics until the publication of E.F. Codd's relational model of data in 1970. Codd proposed such an algebra as a basis for database query languages. (See section Implementations.)

Both a named and an unnamed perspective are possible for relational algebra, depending on whether the tuples are endowed with component names or not. In the unnamed perspective, a tuple is simply a member of a Cartesian product. In the named perspective, tuples are functions from a finite set U of attributes (of the relation) to a domain of values (assumed distinct from U).[1] The relational algebras obtained from the two perspectives are equivalent.[2] The typical undergraduate textbooks present only the named perspective though, and this article follows suit.

Relational algebra is essentially equivalent in expressive power to relational calculus (and thus first-order logic); this result is known as Codd's theorem. One must be careful to avoid a mismatch that may arise between the two languages because negation, applied to a formula of the calculus, constructs a formula that may be true on an infinite set of possible tuples, while the difference operator of relational algebra always returns a finite result. To overcome these difficulties, Codd restricted the operands of relational algebra to finite relations only and also proposed restricted support for negation (NOT) and disjunction (OR). Analogous restrictions are found in many other logic-based computer languages. Codd defined the term ***relational completeness*** to refer to a language that is complete with respect to first-order predicate calculus apart from the restrictions he proposed. In practice the restrictions have no adverse effect on the applicability of his relational algebra for database purposes.

Primitive operations

As in any algebra, some operators are primitive and the others are derived in terms of the primitive ones. It is useful if the choice of primitive operators parallels the usual choice of primitive logical operators.

Five primitive operators of Codd's algebra are the *selection*, the *projection*, the *Cartesian product* (also called the *cross product* or *cross join*), the *set union*, and the *set difference*. Another operator, *rename* was not noted by Codd, but the need for it is shown by the inventors of ISBL. These six operators are fundamental in the sense that omitting any one of them causes a loss of expressive power. Many other operators have been defined in terms of these six. Among the most important are set intersection, division, and the natural join. In fact ISBL made a compelling case for replacing the Cartesian product with the natural join, of which the Cartesian product is a degenerate case.

Altogether, the operators of relational algebra have an expressive power identical to that of domain relational calculus or tuple relational calculus. However, for the reasons given in section Introduction, relational algebra is less expressive than first-order predicate calculus without function symbols. Relational algebra corresponds to a subset of

first-order logic, namely Horn clauses without recursion and negation.

Set operators

The relational algebra uses set union, set difference, and Cartesian product from set theory, but adds additional constraints to these operators.

For set union and set difference, the two relations involved must be *union-compatible*—that is, the two relations must have the same set of attributes. Because set intersection can be defined in terms of set difference, the two relations involved in set intersection must also be union-compatible.

For the Cartesian product to be defined, the two relations involved must have disjoint headers—that is, they must not have a common attribute name.

In addition, the Cartesian product is defined differently from the one in set theory in the sense that tuples are considered to be "shallow" for the purposes of the operation. That is, the Cartesian product of a set of *n*-tuples with a set of *m*-tuples yields a set of "flattened" $(n + m)$-tuples (whereas basic set theory would have prescribed a set of 2-tuples, each containing an *n*-tuple and an *m*-tuple). More formally, $R \times S$ is defined as follows:

$$R \times S = \{(r_1, r_2, ..., r_n, s_1, s_2, ..., s_m) \mid (r_1, r_2, ..., r_n) \in R, (s_1, s_2, ..., s_m) \in S\}$$

The cardinality of the Cartesian product is the product of the cardinalities of its factors, i.e., $|R \times S| = |R| \times |S|$.

Projection (π)

A **projection** is a unary operation written as $\pi_{a_1,\ldots,a_n}(R)$ where $a_1, \ldots, a_n$ is a set of attribute names. The result of such projection is defined as the set that is obtained when all tuples in *R* are restricted to the set $\{a_1, \ldots, a_n\}$. This specifies the specific subset of columns (attributes of each tuple) to be retrieved. To obtain the names and phone numbers from an address book, the projection might be written $\pi_{\text{contactName, contactPhoneNumber}}(\text{addressBook})$. The result of that projection would be a relation which contains only the contactName and contactPhoneNumber attributes for each unique entry in addressBook.

Selection (σ)

A **generalized selection** is a unary operation written as $\sigma_{\varphi}(R)$ where φ is a propositional formula that consists of atoms as allowed in the normal selection and the logical operators $\wedge$ (and), $\vee$ (or) and $\neg$ (negation). This selection selects all those tuples in *R* for which φ holds.

To obtain a listing of all friends or business associates in an address book, the selection might be written as $\sigma_{\text{isFriend} = \text{true} \vee \text{isBusinessContact} = \text{true}}(\text{addressBook})$. The result would be a relation containing every attribute of every unique record where isFriend is true or where isBusinessContact is true.

In Codd's 1970 paper, selection is called restriction.

Rename (ϱ)

A **rename** is a unary operation written as $\rho_{a/b}(R)$ where the result is identical to *R* except that the *b* attribute in all tuples is renamed to an *a* attribute. This is simply used to rename the attribute of a relation or the relation itself.
To rename the 'isFriend' attribute to 'isBusinessContact' in a relation, $\rho_{\text{isBusinessContact / isFriend}}(\text{addressBook})$ might be used.

Joins and join-like operators

Natural join (⋈)

Natural join (⋈) is a binary operator that is written as (*R* ⋈ *S*) where *R* and *S* are relations.[3] The result of the natural join is the set of all combinations of tuples in *R* and *S* that are equal on their common attribute names. For an example consider the tables *Employee* and *Dept* and their natural join:

Name	EmpId	DeptName
Harry	3415	Finance
Sally	2241	Sales
George	3401	Finance
Harriet	2202	Sales

DeptName	Manager
Finance	George
Sales	Harriet
Production	Charles

Name	EmpId	DeptName	Manager
Harry	3415	Finance	George
Sally	2241	Sales	Harriet
George	3401	Finance	George
Harriet	2202	Sales	Harriet

This can also be used to define composition of relations. For example, the composition of *Employee* and *Dept* is their join as shown above, projected on all but the common attribute *DeptName*. In category theory, the join is precisely the fiber product.

The natural join is arguably one of the most important operators since it is the relational counterpart of logical AND. Note carefully that if the same variable appears in each of two predicates that are connected by AND, then that variable stands for the same thing and both appearances must always be substituted by the same value. In particular, natural join allows the combination of relations that are associated by a foreign key. For example, in the above example a foreign key probably holds from *Employee.DeptName* to *Dept.DeptName* and then the natural join of *Employee* and *Dept* combines all employees with their departments. Note that this works because the foreign key holds between attributes with the same name. If this is not the case such as in the foreign key from *Dept.manager* to *Employee.Name* then we have to rename these columns before we take the natural join. Such a join is sometimes also referred to as an **equijoin** (see θ-join).

More formally the semantics of the natural join are defined as follows:

$$R \bowtie S = \{t \cup s \mid t \in R \ \wedge \ s \in S \ \wedge \ Fun(t \cup s)\}$$

where *Fun* is a predicate that is true for a relation *r* if and only if *r* is a function. It is usually required that *R* and *S* must have at least one common attribute, but if this constraint is omitted, and *R* and *S* have no common attributes, then the natural join becomes exactly the Cartesian product.

The natural join can be simulated with Codd's primitives as follows. Assume that $c_1,...,c_m$ are the attribute names common to *R* and *S*, $r_1,...,r_n$ are the attribute names unique to *R* and $s_1,...,s_k$ are the attribute unique to *S*. Furthermore assume that the attribute names $x_1,...,x_m$ are neither in *R* nor in *S*. In a first step we can now rename the common attribute names in *S*:

$$T = \rho_{x_1/c_1,\ldots,x_m/c_m}(S) = \rho_{x_1/c_1}(\rho_{x_2/c_2}(\ldots \rho_{x_m/c_m}(S)\ldots))$$

Then we take the Cartesian product and select the tuples that are to be joined:

$$P = \sigma_{c_1=x_1,\ldots,c_m=x_m}(R \times T) = \sigma_{c_1=x_1}(\sigma_{c_2=x_2}(\ldots \sigma_{c_m=x_m}(R \times T)\ldots))$$

Finally we take a projection to get rid of the renamed attributes:

$$U = \pi_{r_1,\ldots,r_n,c_1,\ldots,c_m,s_1,\ldots,s_k}(P)$$

θ-join and equijoin

Consider tables *Car* and *Boat* which list models of cars and boats and their respective prices. Suppose a customer wants to buy a car and a boat, but she does not want to spend more money for the boat than for the car. The θ-join ($\bowtie_\theta$) on the relation *CarPrice* ≥ *BoatPrice* produces a table with all the possible options. When using a condition where the attributes are equal, for example Price, then the condition may be specified as *Price=Price* or alternatively *(Price)* itself.

CarModel	CarPrice
CarA	20,000
CarB	30,000
CarC	50,000

BoatModel	BoatPrice
Boat1	10,000
Boat2	40,000
Boat3	60,000

CarModel	CarPrice	BoatModel	BoatPrice
CarA	20,000	Boat1	10,000
CarB	30,000	Boat1	10,000
CarC	50,000	Boat1	10,000
CarC	50,000	Boat2	40,000

If we want to combine tuples from two relations where the combination condition is not simply the equality of shared attributes then it is convenient to have a more general form of join operator, which is the θ-join (or theta-join). The θ-join is a binary operator that is written as $R \underset{a\ \theta\ b}{\bowtie} S$ or $R \underset{a\ \theta\ v}{\bowtie} S$ where *a* and *b* are attribute names, θ is a binary relation in the set {<, ≤, =, >, ≥}, *v* is a value constant, and *R* and *S* are relations. The result of this operation consists of all combinations of tuples in *R* and *S* that satisfy the relation θ. The result of the θ-join is defined only if the headers of *S* and *R* are disjoint, that is, do not contain a common attribute.

The simulation of this operation in the fundamental operations is therefore as follows:

$$R \bowtie_\theta S = \sigma_\theta(R \times S)$$

In case the operator θ is the equality operator (=) then this join is also called an **equijoin**.

Note, however, that a computer language that supports the natural join and rename operators does not need θ-join as well, as this can be achieved by selection from the result of a natural join (which degenerates to Cartesian product when there are no shared attributes).

Semijoin (▯)(▯)

The left semijoin is joining similar to the natural join and written as $R \ltimes S$ where *R* and *S* are relations.[4] The result of this semijoin is the set of all tuples in *R* for which there is a tuple in *S* that is equal on their common attribute names. For an example consider the tables *Employee* and *Dept* and their semi join:

Name	EmpId	DeptName
Harry	3415	Finance
Sally	2241	Sales
George	3401	Finance
Harriet	2202	Production

DeptName	Manager
Sales	Bob
Sales	Thomas
Production	Katie
Production	Mark

Name	EmpId	DeptName
Sally	2241	Sales
Harriet	2202	Production

More formally the semantics of the semijoin can be defined as follows:

$$R \ltimes S = \{\, t : t \in R \wedge \exists\, s \in S(Fun\,(t \cup s)) \,\}$$

where $Fun(r)$ is as in the definition of natural join.

The semijoin can be simulated using the natural join as follows. If a_1, ..., a_n are the attribute names of R, then

$$R \ltimes S = \pi_{a1,..,a_n}(R \bowtie S).$$

Since we can simulate the natural join with the basic operators it follows that this also holds for the semijoin.

Antijoin (▷)

The antijoin, written as $R \triangleright S$ where R and S are relations, is similar to the semijoin, but the result of an antijoin is only those tuples in R for which there is *no* tuple in S that is equal on their common attribute names.[5]

For an example consider the tables *Employee* and *Dept* and their antijoin:

Name	EmpId	DeptName
Harry	3415	Finance
Sally	2241	Sales
George	3401	Finance
Harriet	2202	Production

DeptName	Manager
Sales	Sally
Production	Harriet

Name	EmpId	DeptName
Harry	3415	Finance
George	3401	Finance

The antijoin is formally defined as follows:

$$R \triangleright S = \{ t : t \in R \land \neg\exists\, s \in S(Fun\,(t \cup s)) \}$$

or

$$R \triangleright S = \{ t : t \in R, \text{there is no tuple } s \text{ of } S \text{ that satisfies } Fun\,(t \cup s) \}$$

where $Fun(r)$ is as in the definition of natural join.

The antijoin can also be defined as the complement of the semijoin, as follows:

$$R \triangleright S = R - R \ltimes S$$

Given this, the antijoin is sometimes called the anti-semijoin, and the antijoin operator is sometimes written as semijoin symbol with a bar above it, instead of ▷.

Division (÷)

The division is a binary operation that is written as $R \div S$. The result consists of the restrictions of tuples in R to the attribute names unique to R, i.e., in the header of R but not in the header of S, for which it holds that all their combinations with tuples in S are present in R. For an example see the tables *Completed*, *DBProject* and their division:

Student	Task
Fred	Database1
Fred	Database2
Fred	Compiler1
Eugene	Database1
Eugene	Compiler1
Sarah	Database1
Sarah	Database2

Task
Database1
Database2

Student
Fred
Sarah

If *DBProject* contains all the tasks of the Database project, then the result of the division above contains exactly the students who have completed both of the tasks in the Database project.

More formally the semantics of the division is defined as follows:

$$R \div S = \{\ t[a_1,...,a_n] : t \in R \wedge \forall\ s \in S\ (\ (t[a_1,...,a_n] \cup s) \in R)\ \}$$

where $\{a_1,...,a_n\}$ is the set of attribute names unique to R and $t[a_1,...,a_n]$ is the restriction of t to this set. It is usually required that the attribute names in the header of S are a subset of those of R because otherwise the result of the operation will always be empty.

The simulation of the division with the basic operations is as follows. We assume that $a_1,...,a_n$ are the attribute names unique to R and $b_1,...,b_m$ are the attribute names of S. In the first step we project R on its unique attribute names and construct all combinations with tuples in S:

$$T := \pi_a 1,...,a_n(R) \times S$$

In the prior example, T would represent a table such that every Student (because Student is the unique key / attribute of the Completed table) is combined with every given Task. So Eugene, for instance, would have two rows, Eugene -> Database1 and Eugene -> Database2 in T.

In the next step we subtract R from this relation:

$$U := T - R$$

Note that in U we have the possible combinations that "could have" been in R, but weren't. So if we now take the projection on the attribute names unique to R then we have the restrictions of the tuples in R for which not all combinations with tuples in S were present in R:

$$V := \pi_a 1,...,a_n(U)$$

So what remains to be done is take the projection of R on its unique attribute names and subtract those in V:

$$W := \pi_a 1,...,a_n(R) - V$$

Common extensions

In practice the classical relational algebra described above is extended with various operations such as outer joins, aggregate functions and even transitive closure.

Outer joins

Whereas the result of a join (or inner join) consists of tuples formed by combining matching tuples in the two operands, an outer join contains those tuples and additionally some tuples formed by extending an unmatched tuple in one of the operands by "fill" values for each of the attributes of the other operand. Note that outer joins are not considered part of the classical relational algebra discussed so far.

The operators defined in this section assume the existence of a *null* value, ω, which we do not define, to be used for the fill values; in practice this corresponds to the NULL in SQL. In order to make subsequent selection operations on the resulting table meaningful, a semantic meaning needs to be assigned to nulls; in Codd's approach the propositional logic used by the selection is extended to a three-valued logic, although we elide those details in this article.

Three outer join operators are defined: left outer join, right outer join, and full outer join. (The word "outer" is sometimes omitted.)

Left outer join (⟕)

The left outer join is written as $R \mathbin{⟕} S$ where R and S are relations.[6] The result of the left outer join is the set of all combinations of tuples in R and S that are equal on their common attribute names, in addition (loosely speaking) to tuples in R that have no matching tuples in S.

For an example consider the tables *Employee* and *Dept* and their left outer join:

Name	EmpId	DeptName
Harry	3415	Finance
Sally	2241	Sales
George	3401	Finance
Harriet	2202	Sales
Tim	1123	Executive

DeptName	Manager
Sales	Harriet
Production	Charles

Name	EmpId	DeptName	Manager
Harry	3415	Finance	ω
Sally	2241	Sales	Harriet
George	3401	Finance	ω
Harriet	2202	Sales	Harriet
Tim	1123	Executive	ω

In the resulting relation, tuples in S which have no common values in common attribute names with tuples in R take a *null* value, ω.

Since there are no tuples in *Dept* with a *DeptName* of *Finance* or *Executive*, ωs occur in the resulting relation where tuples in *Employee* have a *DeptName* of *Finance* or *Executive*.

Let r_1, r_2, ..., r_n be the attributes of the relation R and let $\{(\omega, ..., \omega)\}$ be the singleton relation on the attributes that are *unique* to the relation S (those that are not attributes of R). Then the left outer join can be described in terms of the natural join (and hence using basic operators) as follows:

$$(R \bowtie S) \cup ((R - \pi_{r_1, r_2, \ldots, r_n}(R \bowtie S)) \times \{(\omega, \ldots \omega)\})$$

Right outer join (⟖)

The right outer join behaves almost identically to the left outer join, but the roles of the tables are switched.

The right outer join of relations R and S is written as $R \mathbin{⟖} S$.[7] The result of the right outer join is the set of all combinations of tuples in R and S that are equal on their common attribute names, in addition to tuples in S that have no matching tuples in R.

For example consider the tables *Employee* and *Dept* and their right outer join:

Name	EmpId	DeptName
Harry	3415	Finance
Sally	2241	Sales
George	3401	Finance
Harriet	2202	Sales
Tim	1123	Executive

DeptName	Manager
Sales	Harriet
Production	Charles

Name	EmpId	DeptName	Manager
Sally	2241	Sales	Harriet
Harriet	2202	Sales	Harriet
ω	ω	Production	Charles

In the resulting relation, tuples in R which have no common values in common attribute names with tuples in S take a *null* value, ω.

Since there are no tuples in *Employee* with a *DeptName* of *Production*, ωs occur in the Name attribute of the resulting relation where tuples in *DeptName* had tuples of *Production*.

Let s_1, s_2, ..., s_n be the attributes of the relation S and let $\{(\omega, ..., \omega)\}$ be the singleton relation on the attributes that are *unique* to the relation R (those that are not attributes of S). Then, as with the left outer join, the right outer join

can be simulated using the natural join as follows:

$$(R \bowtie S) \cup (\{(\omega, \ldots, \omega)\} \times (S - \pi_{s_1, s_2, \ldots, s_n}(R \bowtie S)))$$

Full outer join ( )

The **outer join** or **full outer join** in effect combines the results of the left and right outer joins.

The full outer join is written as R S where R and S are relations.[8] The result of the full outer join is the set of all combinations of tuples in R and S that are equal on their common attribute names, in addition to tuples in S that have no matching tuples in R and tuples in R that have no matching tuples in S in their common attribute names.

For an example consider the tables *Employee* and *Dept* and their full outer join:

Name	EmpId	DeptName
Harry	3415	Finance
Sally	2241	Sales
George	3401	Finance
Harriet	2202	Sales
Tim	1123	Executive

DeptName	Manager
Sales	Harriet
Production	Charles

Name	EmpId	DeptName	Manager
Harry	3415	Finance	ω
Sally	2241	Sales	Harriet
George	3401	Finance	ω
Harriet	2202	Sales	Harriet
Tim	1123	Executive	ω
ω	ω	Production	Charles

In the resulting relation, tuples in R which have no common values in common attribute names with tuples in S take a *null* value, ω. Tuples in S which have no common values in common attribute names with tuples in R also take a *null* value, ω.

The full outer join can be simulated using the left and right outer joins (and hence the natural join and set union) as follows:

R $S = (R$ $S) \cup (R$ $S)$

Operations for domain computations

There is nothing in relational algebra introduced so far that would allow computations on the data domains (other than evaluation of propositional expressions involving equality). For example, it's not possible using only the algebra introduced so far to write an expression that would multiply the numbers from two columns, e.g. a unit price with a quantity to obtain a total price. Practical query languages have such facilities, e.g. the SQL SELECT allows arithmetic operations to define new columns in the result `SELECT unit_price * quantity AS total_price FROM t`, and a similar facility is provided more explicitly by Tutorial D's `EXTEND` keyword. In database theory, this is called **extended projection**.:213

Aggregation

Furthermore, computing various functions on a column, like the summing up its elements, is also not possible using the relational algebra introduced so far. There are five aggregate functions that are included with most relational database systems. These operations are Sum, Count, Average, Maximum and Minimum. In relational algebra the aggregation operation over a schema $(A_1, A_2, \ldots A_n)$ is written as follows:

$G_1, G_2, \ldots, G_m\ g\ f_1(A_1'), f_2(A_2'), \ldots, f_k(A_k')$ (**r**)

where each A_j', $1 \le j \le k$, is one of the original attributes A_i, $1 \le i \le n$.

The attributes preceding the g are grouping attributes, which function like a "group by" clause in SQL. Then there are an arbitrary number of aggregation functions applied to individual attributes. The operation is applied to an arbitrary relation **r**. The grouping attributes are optional, and if they are not supplied, the aggregation functions are

applied across the entire relation to which the operation is applied.

Let's assume that we have a table named Account with three columns, namely Account_Number, Branch_Name and Balance. We wish to find the maximum balance of each branch. This is accomplished by ${}_{\text{Branch\_Name}}\text{G}_{\text{Max(Balance)}}$(Account). To find the highest balance of all accounts regardless of branch, we could simply write $\text{G}_{\text{Max(Balance)}}$(Account).

Transitive closure

Although relational algebra seems powerful enough for most practical purposes, there are some simple and natural operators on relations which cannot be expressed by relational algebra. One of them is the transitive closure of a binary relation. Given a domain *D*, let binary relation *R* be a subset of *D*×*D*. The transitive closure R^+ of *R* is the smallest subset of *D*×*D* containing *R* which satisfies the following condition:

$$\forall x \forall y \forall z \left((x, y) \in R^+ \wedge (y, z) \in R^+ \Rightarrow (x, z) \in R^+ \right)$$

There is no relational algebra expression *E*(*R*) taking *R* as a variable argument which produces R^+. This can be proved using the fact that, given a relational expression *E* for which it is claimed that *E*(*R*) = R^+, where *R* is a variable, we can always find an instance ***r*** of *R* (and a corresponding domain **d**) such that *E*(***r***) ≠ $\boldsymbol{r}^+$.

SQL however officially supports such fixpoint queries since 1999, and it had vendor-specific extensions in this direction well before that.

Use of algebraic properties for query optimization

Queries can be represented as a tree, where

- the internal nodes are operators,
- leaves are relations,
- subtrees are subexpressions.

Our primary goal is to transform expression trees into equivalent expression trees, where the average size of the relations yielded by subexpressions in the tree is smaller than it was before the optimization. Our secondary goal is to try to form common subexpressions within a single query, or if there is more than one query being evaluated at the same time, in all of those queries. The rationale behind the second goal is that it is enough to compute common subexpressions once, and the results can be used in all queries that contain that subexpression.

Here we present a set of rules that can be used in such transformations.

Selection

Rules about selection operators play the most important role in query optimization. Selection is an operator that very effectively decreases the number of rows in its operand, so if we manage to move the selections in an expression tree towards the leaves, the internal relations (yielded by subexpressions) will likely shrink.

Basic selection properties

Selection is idempotent (multiple applications of the same selection have no additional effect beyond the first one), and commutative (the order selections are applied in has no effect on the eventual result).

1. $\sigma_A(R) = \sigma_A\sigma_A(R)$
2. $\sigma_A\sigma_B(R) = \sigma_B\sigma_A(R)$

Breaking up selections with complex conditions

A selection whose condition is a conjunction of simpler conditions is equivalent to a sequence of selections with those same individual conditions, and selection whose condition is a disjunction is equivalent to a union of selections. These identities can be used to merge selections so that fewer selections need to be evaluated, or to split them so that the component selections may be moved or optimized separately.

1. $\sigma_{A \wedge B}(R) = \sigma_A(\sigma_B(R)) = \sigma_B(\sigma_A(R))$
2. $\sigma_{A \vee B}(R) = \sigma_A(R) \cup \sigma_B(R)$

Selection and cross product

Cross product is the costliest operator to evaluate. If the input relations have *N* and *M* rows, the result will contain NM rows. Therefore it is very important to do our best to decrease the size of both operands before applying the cross product operator.

This can be effectively done, if the cross product is followed by a selection operator, e.g. $\sigma_A (R \times P)$. Considering the definition of join, this is the most likely case. If the cross product is not followed by a selection operator, we can try to push down a selection from higher levels of the expression tree using the other selection rules.

In the above case we break up condition *A* into conditions *B*, *C* and *D* using the split rules about complex selection conditions, so that $A = B \wedge C \wedge D$ and *B* only contains attributes from *R*, *C* contains attributes only from *P* and *D* contains the part of *A* that contains attributes from both *R* and *P*. Note, that *B*, *C* or *D* are possibly empty. Then the following holds:

$$\sigma_A(R \times P) = \sigma_{B \wedge C \wedge D}(R \times P) = \sigma_D(\sigma_B(R) \times \sigma_C(P))$$

Selection and set operators

Selection is distributive over the setminus, intersection, and union operators. The following three rules are used to push selection below set operations in the expression tree. Note, that in the setminus and the intersection operators it is possible to apply the selection operator to only one of the operands after the transformation. This can make sense in cases, where one of the operands is small, and the overhead of evaluating the selection operator outweighs the benefits of using a smaller relation as an operand.

1. $\sigma_A(R \setminus P) = \sigma_A(R) \setminus \sigma_A(P) = \sigma_A(R) \setminus P$
2. $\sigma_A(R \cup P) = \sigma_A(R) \cup \sigma_A(P)$
3. $\sigma_A(R \cap P) = \sigma_A(R) \cap \sigma_A(P) = \sigma_A(R) \cap P = R \cap \sigma_A(P)$

Selection and projection

Selection commutes with projection if and only if the fields referenced in the selection condition are a subset of the fields in the projection. Performing selection before projection may be useful if the operand is a cross product or join. In other cases, if the selection condition is relatively expensive to compute, moving selection outside the projection may reduce the number of tuples which must be tested (since projection may produce fewer tuples due to the elimination of duplicates resulting from omitted fields).

$$\pi_{a_1,\ldots,a_n}(\sigma_A(R)) = \sigma_A(\pi_{a_1,\ldots,a_n}(R)) \text{ where fields in } A \subseteq \{a_1, \ldots, a_n\}$$

Projection

Basic projection properties

Projection is idempotent, so that a series of (valid) projections is equivalent to the outermost projection.

$$\pi_{a_1,\ldots,a_n}(\pi_{b_1,\ldots,b_m}(R)) = \pi_{a_1,\ldots,a_n}(R) \text{ where } \{a_1,\ldots,a_n\} \subseteq \{b_1,\ldots,b_m\}$$

Projection and set operators

Projection is distributive over set union.

$$\pi_{a_1,\ldots,a_n}(R \cup P) = \pi_{a_1,\ldots,a_n}(R) \cup \pi_{a_1,\ldots,a_n}(P).$$

Projection does not distribute over intersection and set difference. Counterexamples are given by:

$$\pi_A(\{\langle A=a, B=b\rangle\} \cap \{\langle A=a, B=b'\rangle\}) = \emptyset$$
$$\pi_A(\{\langle A=a, B=b\rangle\}) \cap \pi_A(\{\langle A=a, B=b'\rangle\}) = \{\langle A=a\rangle\}$$

and

$$\pi_A(\{\langle A=a, B=b\rangle\} \setminus \{\langle A=a, B=b'\rangle\}) = \{\langle A=a\}$$
$$\pi_A(\{\langle A=a, B=b\rangle\}) \setminus \pi_A(\{\langle A=a, B=b'\rangle\}) = \emptyset\,,$$

where *b* is assumed to be distinct from *b′*.

Rename

Basic rename properties

Successive renames of a variable can be collapsed into a single rename. Rename operations which have no variables in common can be arbitrarily reordered with respect to one another, which can be exploited to make successive renames adjacent so that they can be collapsed.

1. $\rho_{a/b}(\rho_{b/c}(R)) = \rho_{a/c}(R)$
2. $\rho_{a/b}(\rho_{c/d}(R)) = \rho_{c/d}(\rho_{a/b}(R))$

Rename and set operators

Rename is distributive over set difference, union, and intersection.

1. $\rho_{a/b}(R \setminus P) = \rho_{a/b}(R) \setminus \rho_{a/b}(P)$
2. $\rho_{a/b}(R \cup P) = \rho_{a/b}(R) \cup \rho_{a/b}(P)$
3. $\rho_{a/b}(R \cap P) = \rho_{a/b}(R) \cap \rho_{a/b}(P)$

Implementations

The first query language to be based on Codd's algebra was ISBL, and this pioneering work has been acclaimed by many authorities as having shown the way to make Codd's idea into a useful language. Business System 12 was a short-lived industry-strength relational DBMS that followed the ISBL example.

In 1998 Chris Date and Hugh Darwen proposed a language called **Tutorial D** intended for use in teaching relational database theory, and its query language also draws on ISBL's ideas. Rel is an implementation of **Tutorial D**.

Even the query language of SQL is loosely based on a relational algebra, though the operands in SQL (tables) are not exactly relations and several useful theorems about the relational algebra do not hold in the SQL counterpart (arguably to the detriment of optimisers and/or users). The SQL table model is a bag (multiset), rather than a set. For example, the expression (R ∪ S) − T = (R − T) ∪ (S − T) is a theorem for relational algebra on sets, but not for relational algebra on bags; for a treatment of relational algebra on bags see chapter 5 of the "Complete" textbook by Garcia-Molina, Ullman and Widom.

Projection (relational algebra)

In relational algebra, a **projection** is a unary operation written as $\Pi_{a_1,\ldots,a_n}(R)$ where $a_1, \ldots, a_n$ is a set of attribute names. The result of such projection is defined as the set obtained when the components of the tuple R are restricted to the set $\{a_1, \ldots, a_n\}$ – it *discards* (or *excludes*) the other attributes.[1]
In practical terms, it can be roughly thought of as picking a sub-set of all available columns. For example, if the attributes are (name, age), then projection of the relation {(Alice, 5), (Bob, 8)} onto attribute list (age) yields {5,8} – we have discarded the names, and only know what ages are present.

In addition, projection can be used to modify an attribute's value: if relation R has attributes a, b, and c, and b is a number, then $\Pi_{a,\ b*0.5,\ c}(R)$ will return a relation nearly the same as R, but with all values for 'b' shrunk by half.[2]

Related concepts

The closely related concept in set theory (see: projection (set theory)) differs from that of relational algebra in that, in set theory, one projects onto ordered components, not onto attributes. For instance, projecting $(3, 7)$ onto the second component yields 7.
Projection is relational algebra's counterpart of existential quantification in predicate logic. The attributes *not* included correspond to existentially quantified variables in the predicate whose extension the operand relation represents. The example below illustrates this point.

Because of the correspondence with existential quantification, some authorities prefer to define projection in terms of the excluded attributes. In a computer language it is of course possible to provide notations for both, and that was done in ISBL and several languages that have taken their cue from ISBL.

A nearly identical concept occurs in the category of monoids, called a string projection, which consists of removing all of the letters in the string that do not belong to a given alphabet.

Example

For an example, consider the relations depicted in the following two tables which are the relation $Person$ and its projection on (some say "over") the attributes Age and $Weight$:

$Person$ $\Pi_{Age,Weight}(Person)$

Name	Age	Weight
Harry	34	180
Sally	28	164
George	29	170
Helena	54	154
Peter	34	180

Age	Weight
34	180
28	164
29	170
54	154

Suppose the predicate of Person is "*Name* is *age* years old and weighs *weight*." Then the given projection represents the predicate, "There exists *Name* such that *Name* is *age* years old and weighs *weight*."

Note that Harry and Peter have the same age and weight, but since the result is a relation, and therefore a set, this combination only appears once in the result.

More formally the semantics of projection are defined as follows:

$$\Pi_{a_1,...,a_n}(R) = \{\ t[a_1, ..., a_n] :\ t \in R\ \}$$

where $t[a_1, ..., a_n]$ is the restriction of the tuple t to the set $\{a_1, ..., a_n\}$ so that

$$t[a_1, ..., a_n] = \{\ (a', v) \mid (a', v) \in t,\ a' \in a_1, ..., a_n\ \}$$

The result of a projection $\Pi_{a_1,...,a_n}(R)$ is defined only if $\{a_1, ..., a_n\}$ is a subset of the header of R.

It is interesting to note that projection over no attributes at all is possible, yielding a relation of degree zero. In this case the cardinality of the result is zero if the operand is empty, otherwise one. The two relations of degree zero are the only ones that cannot be depicted as tables.

Rename (relational algebra)

In relational algebra, a **rename** is a unary operation written as $\rho_{a/b}(R)$ where:

- R is a relation
- a and b are attribute names
- b is an attribute of R

The result is identical to R except that the b attribute in all tuples is renamed to a. For an example, consider the following invocation of ρ on an $Employee$ relation and the result of that invocation:

$Employee$ $\rho_{EmployeeName/Name}(Employee)$

Name	EmployeeId
Harry	3415
Sally	2241

EmployeeName	EmployeeId
Harry	3415
Sally	2241

Formally the semantics of the rename operator is defined as follows:

$$\rho_{a/b}(R) = \{\ t[a/b] : t \in R\ \}$$

where $t[a/b]$ is defined as the tuple t with the b attribute renamed to a so that:

$$t[a/b] = \{\ (c, v) \mid (c, v) \in t,\ c \neq b\ \} \cup \{\ (a,\ t(b))\ \}$$

Selection (relational algebra)

In relational algebra, a **selection** (sometimes called a **restriction** to avoid confusion with SQL's use of SELECT) is a unary operation written as $\sigma_{a\theta b}(R)$ or $\sigma_{a\theta v}(R)$ where:

- a and b are attribute names
- θ is a binary operation in the set $\{ <, \leq, =, \geq, > \}$
- v is a value constant
- R is a relation

The selection $\sigma_{a\theta b}(R)$ selects all those tuples in R for which θ holds between the a and the b attribute.

The selection $\sigma_{a\theta v}(R)$ selects all those tuples in R for which θ holds between the a attribute and the value v.

For an example, consider the following tables where the first table gives the relation $Person$, the second table gives the result of $\sigma_{Age \geq 34}(Person)$ and the third table gives the result of $\sigma_{Age=Weight}(Person)$.

$Person$

Name	Age	Weight
Harry	34	80
Sally	28	64
George	29	70
Helena	54	54
Peter	34	80

$\sigma_{Age \geq 34}(Person)$

Name	Age	Weight
Harry	34	80
Helena	54	54
Peter	34	80

$\sigma_{Age=Weight}(Person)$

Name	Age	Weight
Helena	54	54

More formally the semantics of the selection is defined as follows:

$$\sigma_{a\theta b}(R) = \{ t : t \in R,\ t(a)\ \theta\ t(b) \}$$
$$\sigma_{a\theta v}(R) = \{ t : t \in R,\ t(a)\ \theta\ v \}$$

The result of the selection is only defined if the attribute names that it mentions are in the heading of the relation that it operates upon.

In computer languages it is expected that any truth-valued expression be permitted as the selection condition rather than restricting it to be a simple comparison.

In SQL, selections are performed by using `WHERE` definitions in `SELECT`, `UPDATE`, and `DELETE` statements, but note that the selection condition can result in any of three truth values (*true*, *false* and *unknown*) instead of the usual two.

Generalized selection

In relational algebra, a **generalized selection** is a unary operation written as $\sigma_{\varphi}(R)$ where φ is a propositional formula that consists of atoms as allowed in the normal selection and the logical operators $\wedge$ (and), $\vee$ (or) and $\neg$ (negation). This selection selects all those tuples in R for which φ holds.
For an example, consider the following tables where the first table gives the relation $Person$ and the second the result of $\sigma_{Age \geq 30 \ \wedge \ Weight \leq 60}(Person)$.

$Person$

Name	Age	Weight
Harry	34	80
Sally	28	64
George	29	70
Helena	54	54
Peter	34	80

$\sigma_{Age \geq 30 \ \wedge \ Weight \leq 60}(Person)$

Name	Age	Weight
Helena	54	54

Formally the semantics of the generalized selection is defined as follows:

$$\sigma_{\varphi}(R) = \{\ t : t \in R,\ \varphi(t)\ \}$$

The result of the selection is only defined if the attribute names that it mentions are in the header of the relation that it operates upon.

The simulation of a generalized selection that is not a fundamental selection with the fundamental operators is defined by the following rules:

$$\sigma_{\varphi \wedge \psi}(R) = \sigma_{\varphi}(R) \cap \sigma_{\psi}(R)$$
$$\sigma_{\varphi \vee \psi}(R) = \sigma_{\varphi}(R) \cup \sigma_{\psi}(R)$$
$$\sigma_{\neg \varphi}(R) = R - \sigma_{\varphi}(R)$$

The generalized selection is expressible with other basic algebraic operations.

In SQL, general selections are performed by using `WHERE` definitions with `AND`, `OR`, or `NOT` operands in `SELECT`, `UPDATE`, and `DELETE` statements.

Range query

A **range query** is a common database operation that retrieves all records where some value is between an upper and lower boundary. For example, list all employees with 3 to 5 years experience. Range queries are unusual because it is not generally known in advance how many entries a range query will return, or if it will return any at all. Many other queries, such as the top ten most senior employees, or the newest employee, can be done more efficiently because there is an upper bound to the number of results they will return. A query that returns exactly one result is sometimes called a singleton.

Partial match query

Match at least one of the requested keys

Data structures for range query

Range tree

K-D tree

Monotonic query

In database theory and systems, a **monotonic query** is one whose result size does not decrease with the addition of new tuples in the database. Formally, a query q over a schema R is monotonic if and only if for every two instances I, J of R, $I \subseteq J \Rightarrow q(I) \subseteq q(J)$ (q must be a monotonic function).

An example of a monotonic query is a select-project-join query containing only conditions of equality (also known as conjunctive queries). Examples of non-monotonic queries are aggregation queries, or queries with set difference.

Identifying whether a query is monotonic can be crucial for query optimization, especially in view maintenance and data stream management. Since the answer set for a monotonic query can only grow as more tuples are added to the database, query processing may be optimized by executing only the new portions of the database and adding the new results to the existing answer set.

Applications

Data streams

A data stream is a real-time, continuous, ordered (implicitly by arrival time or explicitly by timestamp) sequence of items. The number of items is considered to be infinite and therefore cannot feasibly be stored in its entirety. Queries over data streams are often called *continuous* or *long-running* queries, and are mostly run over a limited window of tuples in the stream. To evaluate a continuous query, one can simply reevaluate the query over newly arrived tuples, and append the new tuples to the existing result set. More formally, let $A(Q, t)$ be the answer set of a continuous query Q at time t, τ be the current time, and 0 the start time. Then, if Q is monotonic, its result set at time τ is

$$A(Q,\tau) = \bigcup_{t=1}^{\tau} (A(Q,t) - A(Q,t-1)) \cup A(Q,0)$$

In contrast, non-montonic queries have the following answer semantics:

$$A(Q,\tau) = \bigcup_{t=0}^{\tau} A(Q,t)$$

View maintenance

Recursive join

The **recursive join** is an operation used in relational databases, also sometimes called a "fixed-point join". It is a compound operation that involves repeating the join operation, typically accumulating more records each time, until a repetition makes no change to the results (as compared to the results of the previous iteration).

For example, if a database of family relationships is to be searched, and the record for each person has "mother" and "father" fields, a recursive join would be one way to retrieve all of a person's known ancestors: first the person's direct parents' records would be retrieved, then the parents' information would be used to retrieve the grandparents' records, and so on until no new records are being found.

In this example, as in many real cases, the repetition involves only a single database table, and so is more specifically a "recursive self-join".

Recursive joins can be very time-consuming unless optimized through indexing, the addition of extra key fields, or other techniques.

Recursive joins are highly characteristic of hierarchical data, and therefore become a serious issue with XML data. In XML, operations such as determining whether one element contains another are extremely common, and the recursive join is perhaps the most obvious way to implement them when the XML data is stored in a relational database.

The standard way to define recursive joins in the SQL:1999 standard is by way of recursive common table expressions. Database management systems that support recursive CTEs include Microsoft SQL Server, Oracle, PostgreSQL and others.

Relvar

In relational databases, **relvar** is a term introduced by C. J. Date and Hugh Darwen as an abbreviation for relation variable in their 1995 paper *The Third Manifesto*, to avoid the confusion sometimes arising from the use of the term **relation**, by the inventor of the relational model, E. F. Codd, for a variable to which a relation is assigned as well as for the relation itself. The term is used in Date's well-known database textbook *An Introduction to Database Systems* and in various other books authored or coauthored by him.

Relvar is not universally accepted as a term, and it is not used in the context of existing database management system products that support SQL[*citation needed*], whose counterpart concept (but not exact equivalent) is the **base table**, this being something that, like computer language variables in general, has a name and is subject to update (i.e., being assigned different values from time to time). Other database textbooks continue to use the term **relation** for both the variable and the data it contains. Similarly, texts on SQL tend to use the term *table* for both purposes, though the qualified term *base table* is used in the standard for the variable.

A closely related term often used in academic texts is relation schema, this being a set of attributes paired with a set of constraints, together defining a set of relations for the purpose of some discussion (typically, database normalization). Constraints that mention just one relvar are termed *relvar constraints*, so relation schema can be regarded as a single term encompassing a relvar and its relvar constraints.

Relational calculus

Relational calculus consists of two calculi, the tuple relational calculus and the domain relational calculus, that are part of the relational model for databases and provide a declarative way to specify database queries. This in contrast to the relational algebra which is also part of the relational model but provides a more procedural way for specifying queries.

The relational algebra might suggest these steps to retrieve the phone numbers and names of book stores that supply *Some Sample Book*:

1. Join book stores and titles over the BookstoreID.
2. Restrict the result of that join to tuples for the book *Some Sample Book*.
3. Project the result of that restriction over StoreName and StorePhone.

The relational calculus would formulate a descriptive, declarative way:

> Get StoreName and StorePhone for supplies such that there exists a title BK with the same BookstoreID value and with a BookTitle value of *Some Sample Book*.

The relational algebra and the relational calculus are essentially logically equivalent: for any algebraic expression, there is an equivalent expression in the calculus, and vice versa. This result is known as Codd's theorem.

Tuple relational calculus

Tuple calculus is a calculus that was introduced by Edgar F. Codd as part of the relational model, in order to provide a declarative database-query language for this data model. It formed the inspiration for the database-query languages QUEL and SQL, of which the latter, although far less faithful to the original relational model and calculus, is now the de-facto-standard database-query language; a dialect of SQL is used by nearly every relational-database-management system. Lacroix and Pirotte proposed domain calculus, which is closer to first-order logic and which showed that both of these calculi (as well as relational algebra) are equivalent in expressive power. Subsequently, query languages for the relational model were called *relationally complete* if they could express at least all of these queries.

Definition of the calculus

Relational database

Since the calculus is a query language for relational databases we first have to define a relational database. The basic relational building block is the domain, or data type. A tuple is an ordered multiset of attributes, which are ordered pairs of domain and value; or just a row. A relvar (relation variable) is a set of ordered pairs of domain and name, which serves as the header for a relation. A relation is a set of tuples. Although these relational concepts are mathematically defined, those definitions map loosely to traditional database concepts. A table is an accepted visual representation of a relation; a tuple is similar to the concept of *row*.

We first assume the existence of a set C of column names, examples of which are "name", "author", "address" et cetera. We define *headers* as finite subsets of C. A *relational database schema* is defined as a tuple $S = (D, R, h)$ where D is the domain of atomic values (see relational model for more on the notions of *domain* and *atomic value*),

R is a finite set of relation names, and

$$h : R \to 2^C$$

a function that associates a header with each relation name in R. (Note that this is a simplification from the full relational model where there is more than one domain and a header is not just a set of column names but also maps these column names to a domain.) Given a domain D we define a *tuple* over D as a partial function

$$t : C \to D$$

that maps some column names to an atomic value in D. An example would be (name : "Harry", age : 25).

The set of all tuples over D is denoted as T_D. The subset of C for which a tuple t is defined is called the *domain* of t (not to be confused with the domain in the schema) and denoted as $dom(t)$.

Finally we define a *relational database* given a schema $S = (D, R, h)$ as a function

$$db : R \to 2^T D$$

that maps the relation names in R to finite subsets of T_D, such that for every relation name r in R and tuple t in $db(r)$ it holds that

$$dom(t) = h(r).$$

The latter requirement simply says that all the tuples in a relation should contain the same column names, namely those defined for it in the schema.

Atoms

For the construction of the formulae we will assume an infinite set V of tuple variables. The formulas are defined given a database schema $S = (D, R, h)$ and a partial function $type : V \to 2^C$ that defines a *type assignment* that assigns headers to some tuple variables. We then define the *set of atomic formulas* $A[S,type]$ with the following rules:

1. if v and w in V, a in $type(v)$ and b in $type(w)$ then the formula " $v.a = w.b$ " is in $A[S,type]$,
2. if v in V, a in $type(v)$ and k denotes a value in D then the formula " $v.a = k$ " is in $A[S,type]$, and
3. if v in V, r in R and $type(v) = h(r)$ then the formula " $r(v)$ " is in $A[S,type]$.

Examples of atoms are:

- (t.age = s.age) — t has an age attribute and s has an age attribute with the same value
- (t.name = "Codd") — tuple t has a name attribute and its value is "Codd"
- Book(t) — tuple t is present in relation Book.

The formal semantics of such atoms is defined given a database db over S and a tuple variable binding $val : V \to T_D$ that maps tuple variables to tuples over the domain in S:

1. " $v.a = w.b$ " is true if and only if $val(v)(a) = val(w)(b)$
2. " $v.a = k$ " is true if and only if $val(v)(a) = k$
3. " $r(v)$ " is true if and only if $val(v)$ is in $db(r)$

Formulas

The atoms can be combined into formulas, as is usual in first-order logic, with the logical operators $\wedge$ (and), $\vee$ (or) and $\neg$ (not), and we can use the existential quantifier ($\exists$) and the universal quantifier ($\forall$) to bind the variables. We define the *set of formulas* $F[S,type]$ inductively with the following rules:

1. every atom in $A[S,type]$ is also in $F[S,type]$
2. if f_1 and f_2 are in $F[S,type]$ then the formula " $f_1 \wedge f_2$ " is also in $F[S,type]$
3. if f_1 and f_2 are in $F[S,type]$ then the formula " $f_1 \vee f_2$ " is also in $F[S,type]$
4. if f is in $F[S,type]$ then the formula " $\neg f$ " is also in $F[S,type]$
5. if v in V, H a header and f a formula in $F[S,type_{[v->H]}]$ then the formula " $\exists\, v : H\,(f)$ " is also in $F[S,type]$, where $type_{[v->H]}$ denotes the function that is equal to $type$ except that it maps v to H,

6. if v in V, H a header and f a formula in $F[S,type_{[v->H]}]$ then the formula " $\forall\ v : H\ (f)$ " is also in $F[S,type]$

Examples of formulas:

- t.name = "C. J. Date" $\vee$ t.name = "H. Darwen"
- Book(t) $\vee$ Magazine(t)
- $\forall\ t$: {author, title, subject} ($\neg$ (Book(t) $\wedge$ t.author = "C. J. Date" $\wedge$ $\neg$ (t.subject = "relational model")))

Note that the last formula states that all books that are written by C. J. Date have as their subject the relational model. As usual we omit brackets if this causes no ambiguity about the semantics of the formula.

We will assume that the quantifiers quantify over the universe of all tuples over the domain in the schema. This leads to the following formal semantics for formulas given a database *db* over S and a tuple variable binding $val : V -> T_D$:

1. " $f_1 \wedge f_2$ " is true if and only if " f_1 " is true and " f_2 " is true,
2. " $f_1 \vee f_2$ " is true if and only if " f_1 " is true or " f_2 " is true or both are true,
3. " $\neg f$ " is true if and only if " f " is not true,
4. " $\exists\ v : H\ (f)$ " is true if and only if there is a tuple t over D such that $dom(t) = H$ and the formula " f " is true for $val_{[v->t]}$, and
5. " $\forall\ v : H\ (f)$ " is true if and only if for all tuples t over D such that $dom(t) = H$ the formula " f " is true for $val_{[v->t]}$.

Queries

Finally we define what a query expression looks like given a schema $S = (D, R, h)$:

$$\{\ v : H \mid f(v)\ \}$$

where v is a tuple variable, H a header and $f(v)$ a formula in $F[S,type]$ where $type = \{\ (v, H)\ \}$ and with v as its only free variable. The result of such a query for a given database *db* over S is the set of all tuples t over D with $dom(t) = H$ such that f is true for *db* and $val = \{\ (v, t)\ \}$.

Examples of query expressions are:

- { t : {name} | $\exists\ s$: {name, wage} (Employee(s) $\wedge$ s.wage = 50.000 $\wedge$ t.name = s.name) }
- { t : {supplier, article} | $\exists\ s$: {s#, sname} (Supplier(s) $\wedge$ s.sname = t.supplier $\wedge$ $\exists\ p$: {p#, pname} (Product(p) $\wedge$ p.pname = t.article $\wedge$ $\exists\ a$: {s#, p#} (Supplies(a) $\wedge$ s.s# = a.s# $\wedge$ a.p# = p.p#) }

Semantic and syntactic restriction of the calculus

Domain-independent queries

Because the semantics of the quantifiers is such that they quantify over all the tuples over the domain in the schema it can be that a query may return a different result for a certain database if another schema is presumed. For example, consider the two schemas $S_1 = (\ D_1, R, h\ )$ and $S_2 = (\ D_2, R, h\ )$ with domains $D_1 = \{\ 1\ \}$, $D_2 = \{\ 1, 2\ \}$, relation names $R = \{\ "r_1"\ \}$ and headers $h = \{\ ("r_1", \{"a"\})\ \}$. Both schemas have a common instance:

$$db = \{\ (\ "r_1", \{\ ("a", 1)\ \}\ )\ \}$$

If we consider the following query expression

$$\{\ t : \{a\} \mid t.a = t.a\ \}$$

then its result on *db* is either { (a : 1) } under S_1 or { (a : 1), (a : 2) } under S_2. It will also be clear that if we take the domain to be an infinite set, then the result of the query will also be infinite. To solve these problems we will restrict our attention to those queries that are *domain independent*, i.e., the queries that return the same result for a database under all of its schemas.

An interesting property of these queries is that if we assume that the tuple variables range over tuples over the so-called *active domain* of the database, which is the subset of the domain that occurs in at least one tuple in the

database or in the query expression, then the semantics of the query expressions does not change. In fact, in many definitions of the tuple calculus this is how the semantics of the quantifiers is defined, which makes all queries by definition domain independent.

Safe queries

In order to limit the query expressions such that they express only domain-independent queries a syntactical notion of *safe query* is usually introduced. To determine whether a query expression is safe we will derive two types of information from a query. The first is whether a variable-column pair *t.a* is *bound* to the column of a relation or a constant, and the second is whether two variable-column pairs are directly or indirectly equated (denoted $t.v == s.w$).

For deriving boundedness we introduce the following reasoning rules:

1. in " $v.a = w.b$ " no variable-column pair is bound,
2. in " $v.a = k$ " the variable-column pair $v.a$ is bound,
3. in " $r(v)$ " all pairs $v.a$ are bound for a in $type(v)$,
4. in " $f_1 \wedge f_2$ " all pairs are bound that are bound either in f_1 or in f_2,
5. in " $f_1 \vee f_2$ " all pairs are bound that are bound both in f_1 and in f_2,
6. in " $\neg f$ " no pairs are bound,
7. in " $\exists\ v : H\ (f)$ " a pair $w.a$ is bound if it is bound in f and $w <> v$, and
8. in " $\forall\ v : H\ (f)$ " a pair $w.a$ is bound if it is bound in f and $w <> v$.

For deriving equatedness we introduce the following reasoning rules (next to the usual reasoning rules for equivalence relations: reflexivity, symmetry and transitivity):

1. in " $v.a = w.b$ " it holds that $v.a == w.b$,
2. in " $v.a = k$ " no pairs are equated,
3. in " $r(v)$ " no pairs are equated,
4. in " $f_1 \wedge f_2$ " it holds that $v.a == w.b$ if it holds either in f_1 or in f_2,
5. in " $f_1 \vee f_2$ " it holds that $v.a == w.b$ if it holds both in f_1 and in f_2,
6. in " $\neg f$ " no pairs are equated,
7. in " $\exists\ v : H\ (f)$ " it holds that $w.a == x.b$ if it holds in f and $w<>v$ and $x<>v$, and
8. in " $\forall\ v : H\ (f)$ " it holds that $w.a == x.b$ if it holds in f and $w<>v$ and $x<>v$.

We then say that a query expression { v : H | f(v) } is *safe* if

- for every column name a in H we can derive that $v.a$ is equated with a bound pair in f,
- for every subexpression of f of the form " $\forall\ w : G\ (g)$ " we can derive that for every column name a in G we can derive that $w.a$ is equated with a bound pair in g, and
- for every subexpression of f of the form " $\exists\ w : G\ (g)$ " we can derive that for every column name a in G we can derive that $w.a$ is equated with a bound pair in g.

The restriction to safe query expressions does not limit the expressiveness since all domain-independent queries that could be expressed can also be expressed by a safe query expression. This can be proven by showing that for a schema $S = (D, R, h)$, a given set K of constants in the query expression, a tuple variable v and a header H we can construct a safe formula for every pair $v.a$ with a in H that states that its value is in the active domain. For example, assume that K={1,2}, R={"r"} and h = { ("r", {"a, "b"}) } then the corresponding safe formula for v.b is:

$$v.\mathrm{b} = 1 \vee v.\mathrm{b} = 2 \vee \exists\ w\ (\ \mathrm{r(w)} \wedge (\ v.\mathrm{b} = w.\mathrm{a} \vee v.\mathrm{b} = w.\mathrm{b}\ )\ )$$

This formula, then, can be used to rewrite any unsafe query expression to an equivalent safe query expression by adding such a formula for every variable v and column name a in its type where it is used in the expression. Effectively this means that we let all variables range over the active domain, which, as was already explained, does not change the semantics if the expressed query is domain independent.

Overview

Query language

Query languages are computer languages used to make queries into databases and information systems.

Broadly, query languages can be classified according to whether they are database query languages or information retrieval query languages. The difference is that a database query language attempts to give factual answers to factual questions, while an information retrieval query language attempts to find documents containing information that is relevant to an area of inquiry.

Examples include:

- .QL is a proprietary object-oriented query language for querying relational databases; successor of Datalog;
- Contextual Query Language (CQL) a formal language for representing queries to information retrieval systems such as web indexes or bibliographic catalogues.
- CQLF (CODASYL Query Language, Flat) is a query language for CODASYL-type databases;
- Concept-Oriented Query Language (COQL) is used in the concept-oriented model (COM). It is based on a novel data modeling construct, concept, and uses such operations as projection and de-projection for multi-dimensional analysis, analytical operations and inference;
- DMX is a query language for Data Mining models;
- Datalog is a query language for deductive databases;
- F-logic is a declarative object-oriented language for deductive databases and knowledge representation.
- FQL enables you to use a SQL-style interface to query the data exposed by the Graph API. It provides advanced features not available in the Graph API.[1]
- Gellish English is a language that can be used for queries in Gellish English Databases, for dialogues (requests and responses) as well as for information modeling and knowledge modeling;[2]
- HTSQL is a query language that translates HTTP queries to SQL;
- ISBL is a query language for PRTV, one of the earliest relational database management systems;
- LINQ query-expressions is a way to query various data sources from .NET languages
- LDAP is an application protocol for querying and modifying directory services running over TCP/IP;
- MQL is a cheminformatics query language for a substructure search allowing beside nominal properties also numerical properties;
- MDX is a query language for OLAP databases;
- OQL is Object Query Language;
- OCL (Object Constraint Language). Despite its name, OCL is also an object query language and an OMG standard;
- OPath, intended for use in querying WinFS *Stores*;
- OttoQL, intended for querying tables, XML, and databases;
- Poliqarp Query Language is a special query language designed to analyze annotated text. Used in the Poliqarp search engine;
- QUEL is a relational database access language, similar in most ways to SQL;
- RDQL is a RDF query language;
- SMARTS is the cheminformatics standard for a substructure search;
- SPARQL is a query language for RDF graphs;
- SPL is a search language for machine-generated big data, based upon Unix Piping and SQL.

- SQL is a well known query language and Data Manipulation Language for relational databases;
- SuprTool is a proprietary query language for SuprTool, a database access program used for accessing data in *Image/SQL* (formerly TurboIMAGE) and Oracle databases;
- TMQL Topic Map Query Language is a query language for Topic Maps;
- Tutorial D is a query language for truly relational database management systems (TRDBMS);
- XQuery is a query language for XML data sources;
- XPath is a declarative language for navigating XML documents;
- XSPARQL is an integrated query language combining XQuery with SPARQL to query both XML and RDF data sources at once;
- YQL is an SQL-like query language created by Yahoo!

Data Definition Language

A **data definition language** or **data description language** (**DDL**) is a syntax similar to a computer programming language for defining data structures, especially database schemas.

History

The data definition language concept and name was first introduced in relation to the Codasyl database model, where the schema of the database was written in a language syntax describing the records, fields, and sets of the user data model. Later it was used to refer to a subset of Structured Query Language (SQL) for creating tables and constraints. SQL-92 introduced a schema manipulation language and schema information tables to query schemas. These information tables were specified as SQL/Schemata in SQL:2003. The term DDL is also used in a generic sense to refer to any formal language for describing data or information structures.

SQL

Many data description languages use a declarative syntax to define fields and data types. SQL, however, uses a collection of imperative verbs whose effect is to modify the schema of the database by adding, changing, or deleting definitions of tables or other objects. These statements can be freely mixed with other SQL statements, so the DDL is not truly a separate language.

CREATE statements

Create - To make a new database, table, index, or stored procedure.

A `CREATE` statement in SQL creates an object in a relational database management system (RDBMS). In the SQL 1992 specification, the types of objects that can be created are schemas, tables, views, domains, character sets, collations, translations, and assertions. Many implementations extend the syntax to allow creation of additional objects, such as indexes and user profiles. Some systems (such as PostgreSQL) allow `CREATE`, and other DDL commands, inside a transaction and thus they may be rolled back.

CREATE TABLE statement

A commonly used `CREATE` command is the `CREATE TABLE` command. The typical usage is:

`CREATE TABLE` *`[table name]`* `(` *`[column definitions]`* `)` *`[table parameters]`*.

column definitions: A comma-separated list consisting of any of the following

- Column definition: *[column name] [data type] {`NULL` | `NOT NULL`} {column options}*
- Primary key definition: *`PRIMARY KEY`* (*[comma separated column list]*)
- Constraints: *{`CONSTRAINT`} [constraint definition]*
- RDBMS specific functionality

For example, the command to create a table named **employees** with a few sample columns would be:

```
CREATE TABLE employees (
    id              INTEGER       PRIMARY KEY,
    first_name      VARCHAR(50)   null,
    last_name       VARCHAR(75)   not null,
    fname           VARCHAR(50)   not null,
    dateofbirth     DATE          null
);
```

Note that some forms of `CREATE TABLE` DDL may incorporate DML (data manipulation language)-like constructs as well, such as the `CREATE TABLE AS SELECT` (CTAS) syntax of SQL.

DROP statements

Drop - To destroy an existing database, table, index, or view.

A **`DROP`** statement in SQL removes an object from a relational database management system (RDBMS). The types of objects that can be dropped depends on which RDBMS is being used, but most support the dropping of tables, users, and databases. Some systems (such as PostgreSQL) allow `DROP` and other DDL commands to occur inside of a transaction and thus be rolled back. The typical usage is simply:

`DROP` *`objecttype objectname`*.

For example, the command to drop a table named **employees** would be:

```
DROP employees;
```

The `DROP` statement is distinct from the `DELETE` and `TRUNCATE` statements, in that `DELETE` and `TRUNCATE` do not remove the table itself. For example, a `DELETE` statement might delete some (or all) data from a table while leaving the table itself in the database, whereas a `DROP` statement would remove the entire table from the database.

ALTER statements

Alter - To modify an existing database object.

An `ALTER` statement in SQL changes the properties of an object inside of a relational database management system (RDBMS). The types of objects that can be altered depends on which RDBMS is being used. The typical usage is:

`ALTER` *`objecttype objectname parameters`*.

For example, the command to add (then remove) a column named **bubbles** for an existing table named **sink** would be:

```
ALTER TABLE sink ADD bubbles INTEGER;
ALTER TABLE sink DROP COLUMN bubbles;
```

Referential integrity statements

Finally, another kind of DDL sentence in SQL is one used to define referential integrity relationships, usually implemented as primary key and foreign key tags in some columns of the tables.

These two statements can be included inside a `CREATE TABLE` or an `ALTER TABLE` sentence.

Other languages

- XML Schema is an example of a DDL for XML.
- Simple Declarative Language

Varchar

A **varchar** or **Variable Character Field** is a set of character data of indeterminate length. The term **varchar** refers to a data type of a field (or column) in a database management system which can hold letters and numbers. Varchar fields can be of any size up to a limit, which varies by databases: an Oracle 9i database has a limit of 4000 bytes, a MySQL database has a limit of 65,535 bytes (for the entire row) and Microsoft SQL Server 2005 has a limit of 8000 bytes (unless varchar(max) is used, which has a maximum storage capacity of 2 gigabytes).

Data Manipulation Language

A **data manipulation language** (**DML**) is a family of syntax elements similar to a computer programming language used for inserting, deleting and updating data in a database. Performing read-only queries of data is sometimes also considered a component of DML.

A popular data manipulation language is that of Structured Query Language (SQL), which is used to retrieve and manipulate data in a relational database.[1] Other forms of DML are those used by IMS/DLI, CODASYL databases, such as IDMS and others.

Data manipulation language comprises the SQL data change statements, which modify stored data but not the schema or database objects. Manipulation of persistent database objects, e.g., tables or stored procedures, via the SQL schema statements,[] rather than the data stored within them, is considered to be part of a separate data definition language. In SQL these two categories are similar in their detailed syntax, data types, expressions etc., but distinct in their overall function.

Data manipulation languages have their functional capability organized by the initial word in a statement, which is almost always a verb. In the case of SQL, these verbs are:

- `SELECT ... FROM ... WHERE ...`
- `INSERT INTO ... VALUES ...`
- `UPDATE ... SET ... WHERE ...`
- `DELETE FROM ... WHERE ...`

The purely read-only `SELECT` query statement is classed with the 'SQL-data' statements and so is considered by the standard to be outside of DML. The `SELECT ... INTO` form is considered to be DML because it manipulates (i.e. modifies) data. In common practice though, this distinction is not made and `SELECT` is widely considered to be part of DML.

Most SQL database implementations extend their SQL capabilities by providing imperative, i.e. procedural languages. Examples of these are Oracle's PL/SQL and DB2's SQL PL.

Data manipulation languages tend to have many different flavors and capabilities between database vendors. There have been a number of standards established for SQL by ANSI, but vendors still provide their own extensions to the standard while not implementing the entire standard.

Data manipulation languages are divided into two types, procedural programming and declarative programming.

Data manipulation languages were initially only used within computer programs, but with the advent of SQL have come to be used interactively by database administrators.

Create, read, update and delete

In computer programming, **create, read, update and delete** (**CRUD**) (Sometimes called SCRUD with an "S" for Search) are the four basic functions of persistent storage. Sometimes *CRUD* is expanded with the words *retrieve* instead of *read*, *modify* instead of *update*, or *destroy* instead of *delete*. It is also sometimes used to describe user interface conventions that facilitate viewing, searching, and changing information; often using computer-based forms and reports. The term was likely first popularized by James Martin in his 1983 book *Managing the Data-base Environment*. The acronym may be extended to CRUDL to cover *listing* of large data sets which bring additional complexity such as pagination when the data sets are too large to hold easily in memory.

Another variation of CRUD is BREAD, an acronym for "Browse, Read, Edit, Add, Delete".

Database applications

The acronym CRUD refers to all of the major functions that are implemented in relational database applications. Each letter in the acronym can map to a standard SQL statement and HTTP method:

Operation	SQL	HTTP
Create	INSERT	PUT / POST
Read (Retrieve)	SELECT	GET
Update (Modify)	UPDATE	PUT / PATCH
Delete (Destroy)	DELETE	DELETE

Although a relational database provides a common persistence layer in software applications, numerous other persistence layers exist. CRUD functionality can be implemented with an object database, an XML database, flat text files, custom file formats, tape, or card, for example.

User interface

CRUD is also relevant at the user interface level of most applications. For example, in address book software, the basic storage unit is an individual *contact entry*. As a bare minimum, the software must allow the user to:

- Create or add new entries
- Read, retrieve, search, or view existing entries
- Update or edit existing entries
- Delete/deactivate existing entries

Without at least these four operations, the software cannot be considered complete. Because these operations are so fundamental, they are often documented and described under one comprehensive heading, such as "contact management", "content management" or "contact maintenance" (or "document management" in general, depending on the basic storage unit for the particular application).

Notes

SQL

SQL

Paradigm(s)	Multi-paradigm
Appeared in	1974
Designed by	Donald D. Chamberlin Raymond F. Boyce
Developer	ISO/IEC
Stable release	SQL:2011 (2011)
Typing discipline	Static, strong
Major implementations	Many
Dialects	SQL-86, SQL-89, SQL-92, SQL:1999, SQL:2003, SQL:2008, SQL:2011
Influenced by	Datalog
Influenced	CQL, LINQ, SOQL, Windows PowerShell, JPQL, jOOQ
OS	Cross-platform
File format details	
Filename extension	`.sql`
Internet media type	`application/sql`
Developed by	ISO/IEC
Initial release	1986
Latest release	SQL:2898 / 2011
Type of format	Database
Standard(s)	ISO/IEC 9075
Open format?	Yes

SQL (/ˈɛsHelp:IPA for English#KeykjuːHelp:IPA for English#Keyˈɛl/, or /ˈsiːkwəl/; **Structured Query Language**[1][2]) is a special-purpose programming language designed for managing data held in a relational database management system (RDBMS).

Originally based upon relational algebra and tuple relational calculus, SQL consists of a data definition language and a data manipulation language. The scope of SQL includes data insert, query, update and delete, schema creation and modification, and data access control. Although SQL is often described as, and to a great extent is, a declarative language (4GL), it also includes procedural elements.

SQL was one of the first commercial languages for Edgar F. Codd's relational model, as described in his influential 1970 paper, "A Relational Model of Data for Large Shared Data Banks." Despite not entirely adhering to the relational model as described by Codd, it became the most widely used database language.

SQL became a standard of the American National Standards Institute (ANSI) in 1986, and of the International Organization for Standardization (ISO) in 1987. Since then, the standard has been enhanced several times with added features. Despite these standards, code is not completely portable among different database systems, which can lead to vendor lock-in. The different makers do not perfectly adhere to the standard, for instance by adding extensions, and the standard itself is sometimes ambiguous.

History

SQL was initially developed at IBM by Donald D. Chamberlin, Donald C. Messerly, and Raymond F. Boyce in the early 1970s.[3] This version, initially called *SEQUEL* (*Structured English Query Language*), was designed to manipulate and retrieve data stored in IBM's original quasi-relational database management system, System R, which a group at IBM San Jose Research Laboratory had developed during the 1970s. The acronym SEQUEL was later changed to SQL because "SEQUEL" was a trademark of the UK-based Hawker Siddeley aircraft company.

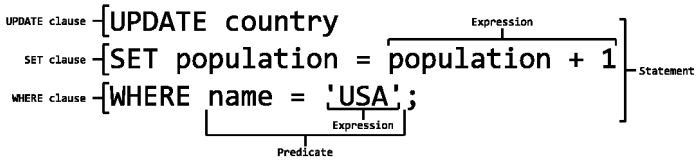
In the late 1970s, Relational Software, Inc. (now Oracle Corporation) saw the potential of the concepts described by Codd, Chamberlin, and Boyce and developed their own SQL-based RDBMS with aspirations of selling it to the U.S. Navy, Central Intelligence Agency, and other U.S. government agencies. In June 1979, Relational Software, Inc. introduced the first commercially available implementation of SQL, Oracle V2 (Version2) for VAX computers.

After testing SQL at customer test sites to determine the usefulness and practicality of the system, IBM began developing commercial products based on their System R prototype including System/38, SQL/DS, and DB2, which were commercially available in 1979, 1981, and 1983, respectively.

Syntax

Language elements

The SQL language is subdivided into several language elements, including:



A chart showing several of the SQL language elements that compose a single statement

- *Clauses*, which are constituent components of statements and queries. (In some cases, these are optional.)[4]
- *Expressions*, which can produce either scalar values, or tables consisting of columns and rows of data.
- *Predicates*, which specify conditions that can be evaluated to SQL three-valued logic (3VL) (true/false/unknown) or Boolean truth values and which are used to limit the effects of statements and queries, or to change program flow.
- *Queries*, which retrieve the data based on specific criteria. This is an important element of *SQL*.
- *Statements*, which may have a persistent effect on schemata and data, or which may control transactions, program flow, connections, sessions, or diagnostics.
  - SQL statements also include the semicolon (";") statement terminator. Though not required on every platform, it is defined as a standard part of the SQL grammar.
- *Insignificant whitespace* is generally ignored in SQL statements and queries, making it easier to format SQL code for readability.

Operators

Operator	Description	Example
=	Equal to	`Author = 'Alcott'`
<>	Not equal to (most DBMS also accept != instead of <>)	`Dept <> 'Sales'`
>	Greater than	`Hire_Date > '2012-01-31'`
<	Less than	`Bonus < 50000.00`
>=	Greater than or equal	`Dependents >= 2`
<=	Less than or equal	`Rate <= 0.05`
BETWEEN	Between an inclusive range	`Cost BETWEEN 100.00 AND 500.00`
LIKE	Match a character pattern	`First_Name LIKE 'Will%'`
IN	Equal to one of multiple possible values	`DeptCode IN (101, 103, 209)`
IS *or* IS NOT	Compare to null (missing data)	`Address IS NOT NULL`
IS NOT DISTINCT FROM	Is equal to value or both are nulls (missing data)	`Debt IS NOT DISTINCT FROM Receivables`
AS	Used to change a field name when viewing results	`SELECT employee AS 'department1'`

Conditional (CASE) expressions

SQL has the `case/when/then/else/end` expression, which was introduced in SQL-92. In its most general form, which is called a "searched case" in the SQL standard, it works like else if in other programming languages:

```
CASE WHEN n > 0
          THEN 'positive'
     WHEN n < 0
          THEN 'negative'
     ELSE 'zero'
END
```

The `WHEN` conditions are tested in the order in which they appear in the source. If no `ELSE` expression is specified, it defaults to `ELSE NULL`. An abbreviated syntax exists mirroring switch statements; it is called "simple case" in the SQL standard:

```
CASE n WHEN 1
            THEN 'one'
       WHEN 2
          THEN 'two'
       ELSE 'i cannot count that high'
END
```

This syntax uses implicit equality comparisons, with the usual caveats for comparing with NULL.

For the Oracle-SQL dialect, the latter can be shortened to an equivalent `DECODE` construct:

```
SELECT DECODE(n, 1, 'one',
               2, 'two',
                 'i cannot count that high')
FROM   some_table;
```

The last value is the default; if none is specified, it also defaults to NULL. However, unlike the standard's "simple case", Oracle's DECODE considers two NULLs to be equal with each other.

Queries

The most common operation in SQL is the query, which is performed with the declarative SELECT statement. SELECT retrieves data from one or more tables, or expressions. Standard SELECT statements have no persistent effects on the database. Some non-standard implementations of SELECT can have persistent effects, such as the SELECT INTO syntax that exists in some databases.

Queries allow the user to describe desired data, leaving the database management system (DBMS) responsible for planning, optimizing, and performing the physical operations necessary to produce that result as it chooses.

A query includes a list of columns to be included in the final result immediately following the SELECT keyword. An asterisk ("*") can also be used to specify that the query should return all columns of the queried tables. SELECT is the most complex statement in SQL, with optional keywords and clauses that include:

- The FROM clause which indicates the table(s) from which data is to be retrieved. The FROM clause can include optional JOIN subclauses to specify the rules for joining tables.
- The WHERE clause includes a comparison predicate, which restricts the rows returned by the query. The WHERE clause eliminates all rows from the result set for which the comparison predicate does not evaluate to True.
- The GROUP BY clause is used to project rows having common values into a smaller set of rows. GROUP BY is often used in conjunction with SQL aggregation functions or to eliminate duplicate rows from a result set. The WHERE clause is applied before the GROUP BY clause.
- The HAVING clause includes a predicate used to filter rows resulting from the GROUP BY clause. Because it acts on the results of the GROUP BY clause, aggregation functions can be used in the HAVING clause predicate.
- The ORDER BY clause identifies which columns are used to sort the resulting data, and in which direction they should be sorted (options are ascending or descending). Without an ORDER BY clause, the order of rows returned by an SQL query is undefined.

The following is an example of a SELECT query that returns a list of expensive books. The query retrieves all rows from the *Book* table in which the *price* column contains a value greater than 100.00. The result is sorted in ascending order by *title*. The asterisk (*) in the *select list* indicates that all columns of the *Book* table should be included in the result set.

```
SELECT *
 FROM  Book
 WHERE price > 100.00
 ORDER BY title;
```

The example below demonstrates a query of multiple tables, grouping, and aggregation, by returning a list of books and the number of authors associated with each book.

```
SELECT Book.title AS Title,
       count(*) AS Authors
 FROM  Book
 JOIN  Book_author
   ON  Book.isbn = Book_author.isbn
 GROUP BY Book.title;
```

Example output might resemble the following:

```
Title                  Authors
---------------------- -------
```

```
SQL Examples and Guide 4
The Joy of SQL         1
An Introduction to SQL 2
Pitfalls of SQL        1
```

Under the precondition that *isbn* is the only common column name of the two tables and that a column named *title* only exists in the *Books* table, the above query could be rewritten in the following form:

```
SELECT title,
       count(*) AS Authors
 FROM  Book
 NATURAL JOIN Book_author
 GROUP BY title;
```

However, many vendors either do not support this approach, or require certain column naming conventions in order for natural joins to work effectively.

SQL includes operators and functions for calculating values on stored values. SQL allows the use of expressions in the *select list* to project data, as in the following example which returns a list of books that cost more than 100.00 with an additional *sales_tax* column containing a sales tax figure calculated at 6% of the *price*.

```
SELECT isbn,
       title,
       price,
       price * 0.06 AS sales_tax
 FROM  Book
 WHERE price > 100.00
 ORDER BY title;
```

Subqueries

Queries can be nested so that the results of one query can be used in another query via a relational operator or aggregation function. A nested query is also known as a *subquery*. While joins and other table operations provide computationally superior (i.e. faster) alternatives in many cases, the use of subqueries introduces a hierarchy in execution which can be useful or necessary. In the following example, the aggregation function `AVG` receives as input the result of a subquery:

```
SELECT isbn,
       title,
       price
 FROM  Book
 WHERE price < (SELECT AVG(price) FROM Book)
 ORDER BY title;
```

A subquery can use values from the outer query, in which case it is known as a correlated subquery.

Since 1999 the SQL standard allows named subqueries called common table expression (named and designed after the IBM DB2 version 2 implementation; Oracle calls these subquery factoring). CTEs can be also be recursive by referring to themselves; the resulting mechanism allows tree or graph traversals (when represented as relations), and more generally fixpoint computations.

Null and three-valued logic (3VL)

The concept of Null was introduced into SQL to handle missing information in the relational model. The word `NULL` is a reserved keyword in SQL, used to identify the Null special marker. Comparisons with Null, for instance equality (=) in WHERE clauses, results in an Unknown truth value. In SELECT statements SQL returns only results for which the WHERE clause returns a value of True; i.e. it excludes results with values of False and also excludes those whose value is Unknown.

Along with True and False, the Unknown resulting from direct comparisons with Null thus brings a fragment of three-valued logic to SQL. The truth tables SQL uses for AND, OR, and NOT correspond to a common fragment of the Kleene and Lukasiewicz three-valued logic (which differ in their definition of implication, however SQL defines no such operation).

p AND q		p		
		True	**False**	**Unknown**
q	**True**	True	False	Unknown
	False	False	False	False
	Unknown	Unknown	False	Unknown

p OR q		p		
		True	**False**	**Unknown**
q	**True**	True	True	True
	False	True	False	Unknown
	Unknown	True	Unknown	Unknown

q	NOT q
True	False
False	True
Unknown	Unknown

p = q		p		
		True	**False**	**Unknown**
q	**True**	True	False	Unknown
	False	False	True	Unknown
	Unknown	Unknown	Unknown	Unknown

There are however disputes about the semantic interpretation of Nulls in SQL because of its treatment outside direct comparisons. As seen in the table above direct equality comparisons between two NULLs in SQL (e.g. `NULL = NULL`) returns a truth value of Unknown. This is in line with the interpretation that Null does not have a value (and is not a member of any data domain) but is rather a placeholder or "mark" for missing information. However, the principle that two Nulls aren't equal to each other is effectively violated in the SQL specification for the `UNION` and `INTERSECT` operators, which do identify nulls with each other. Consequently, these set operations in SQL may produce results not representing sure information, unlike operations involving explicit comparisons with NULL (e.g. those in a `WHERE` clause discussed above). In Codd's 1979 proposal (which was basically adopted by SQL92) this semantic inconsistency is rationalized by arguing that removal of duplicates in set operations happens "at a lower level of detail than equality testing in the evaluation of retrieval operations." However, computer science professor Ron van der Meyden concluded that "The inconsistencies in the SQL standard mean that it is not possible to ascribe any intuitive logical semantics to the treatment of nulls in SQL."[]

Additionally, since SQL operators return Unknown when comparing anything with Null directly, SQL provides two Null-specific comparison predicates: `IS NULL` and `IS NOT NULL` test whether data is or is not Null. Universal quantification is not explicitly supported by SQL, and must be worked out as a negated existential quantification.[5][6][7] There is also the "<row value expression> IS DISTINCT FROM <row value expression>" infixed comparison operator which returns TRUE unless both operands are equal or both are NULL. Likewise, IS NOT DISTINCT FROM is defined as "NOT (<row value expression> IS DISTINCT FROM <row value expression>)". SQL:1999 also introduced `BOOLEAN` type variables, which according to the standard can also hold Unknown values. In practice, a number of systems (e.g. PostgreSQL) implement the BOOLEAN Unknown as a

BOOLEAN NULL.

Data manipulation

The Data Manipulation Language (DML) is the subset of SQL used to add, update and delete data:

- `INSERT` adds rows (formally tuples) to an existing table, e.g.:

```
INSERT INTO example
 (field1, field2, field3)
 VALUES
 ('test', 'N', NULL);
```

- `UPDATE` modifies a set of existing table rows, e.g.:

```
UPDATE example
 SET field1 = 'updated value'
 WHERE field2 = 'N';
```

- `DELETE` removes existing rows from a table, e.g.:

```
DELETE FROM example
 WHERE field2 = 'N';
```

- `MERGE` is used to combine the data of multiple tables. It combines the `INSERT` and `UPDATE` elements. It is defined in the SQL:2003 standard; prior to that, some databases provided similar functionality via different syntax, sometimes called "upsert".

```
 MERGE INTO table_name USING table_reference ON (condition)
 WHEN MATCHED THEN
 UPDATE SET column1 = value1 [, column2 = value2 ...]
 WHEN NOT MATCHED THEN
 INSERT (column1 [, column2 ...]) VALUES (value1 [, value2 ...
```

Transaction controls

Transactions, if available, wrap DML operations:

- `START TRANSACTION` (or `BEGIN WORK`, or `BEGIN TRANSACTION`, depending on SQL dialect) marks the start of a database transaction, which either completes entirely or not at all.
- `SAVE TRANSACTION` (or `SAVEPOINT`) saves the state of the database at the current point in transaction

```
CREATE TABLE tbl_1(id int);
 INSERT INTO tbl_1(id) VALUES(1);
 INSERT INTO tbl_1(id) VALUES(2);
COMMIT;
 UPDATE tbl_1 SET id=200 WHERE id=1;
SAVEPOINT id_1upd;
 UPDATE tbl_1 SET id=1000 WHERE id=2;
ROLLBACK to id_1upd;
 SELECT id from tbl_1;
```

- `COMMIT` causes all data changes in a transaction to be made permanent.
- `ROLLBACK` causes all data changes since the last `COMMIT` or `ROLLBACK` to be discarded, leaving the state of the data as it was prior to those changes.

Once the `COMMIT` statement completes, the transaction's changes cannot be rolled back.

`COMMIT` and `ROLLBACK` terminate the current transaction and release data locks. In the absence of a `START TRANSACTION` or similar statement, the semantics of SQL are implementation-dependent. The following example shows a classic transfer of funds transaction, where money is removed from one account and added to another. If either the removal or the addition fails, the entire transaction is rolled back.

```
START TRANSACTION;
 UPDATE Account SET amount=amount-200 WHERE account_number=1234;
 UPDATE Account SET amount=amount+200 WHERE account_number=2345;

IF ERRORS=0 COMMIT;
IF ERRORS<>0 ROLLBACK;
```

Data definition

The Data Definition Language (DDL) manages table and index structure. The most basic items of DDL are the `CREATE`, `ALTER`, `RENAME`, `DROP` and `TRUNCATE` statements:

- `CREATE` creates an object (a table, for example) in the database, e.g.:

```
CREATE TABLE example(
 field1 INTEGER,
 field2 VARCHAR(50),
 field3 DATE NOT NULL,
 PRIMARY KEY (field1, field2)
);
```

- `ALTER` modifies the structure of an existing object in various ways, for example, adding a column to an existing table or a constraint, e.g.:

```
ALTER TABLE example ADD field4 NUMBER(3) NOT NULL;
```

- `TRUNCATE` deletes all data from a table in a very fast way, deleting the data inside the table and not the table itself. It usually implies a subsequent COMMIT operation, i.e., it cannot be rolled back (data is not written to the logs for rollback later, unlike DELETE).

```
TRUNCATE TABLE example;
```

- `DROP` deletes an object in the database, usually irretrievably, i.e., it cannot be rolled back, e.g.:

```
DROP TABLE example;
```

Data types

Each column in an SQL table declares the type(s) that column may contain. ANSI SQL includes the following data types.[8]

Character strings

- `CHARACTER(n)` or `CHAR(n)`: fixed-width `n`-character string, padded with spaces as needed
- `CHARACTER VARYING(n)` or `VARCHAR(n)`: variable-width string with a maximum size of `n` characters
- `NATIONAL CHARACTER(n)` or `NCHAR(n)`: fixed width string supporting an international character set
- `NATIONAL CHARACTER VARYING(n)` or `NVARCHAR(n)`: variable-width `NCHAR` string

Bit strings

- `BIT(n)`: an array of `n` bits
- `BIT VARYING(n)`: an array of up to `n` bits

Numbers

- `INTEGER` and `SMALLINT`
- `FLOAT`, `REAL` and `DOUBLE PRECISION`
- `NUMERIC(precision, scale)` or `DECIMAL(precision, scale)`

For example, the number 123.45 has a precision of 5 and a scale of 2. The `precision` is a positive integer that determines the number of significant digits in a particular radix (binary or decimal). The `scale` is a non-negative integer. A scale of 0 indicates that the number is an integer. For a decimal number with scale S, the exact numeric value is the integer value of the significant digits divided by 10^S.

SQL provides a function to round numerics or dates, called `TRUNC` (in Informix, DB2, PostgreSQL, Oracle and MySQL) or `ROUND` (in Informix, SQLite, Sybase, Oracle, PostgreSQL and Microsoft SQL Server)[9]

Date and time

- `DATE`: for date values (e.g. `2011-05-03`)
- `TIME`: for time values (e.g. `15:51:36`). The granularity of the time value is usually a *tick* (100 nanoseconds).
- `TIME WITH TIME ZONE` or `TIMETZ`: the same as `TIME`, but including details about the time zone in question.
- `TIMESTAMP`: This is a `DATE` and a `TIME` put together in one variable (e.g. `2011-05-03 15:51:36`).
- `TIMESTAMP WITH TIME ZONE` or `TIMESTAMPTZ`: the same as `TIMESTAMP`, but including details about the time zone in question.

SQL provides several functions for generating a date / time variable out of a date / time string (`TO_DATE`, `TO_TIME`, `TO_TIMESTAMP`), as well as for extracting the respective members (seconds, for instance) of such variables. The current system date / time of the database server can be called by using functions like `NOW`.

Data control

The Data Control Language (DCL) authorizes users to access and manipulate data. Its two main statements are:

- `GRANT` authorizes one or more users to perform an operation or a set of operations on an object.
- `REVOKE` eliminates a grant, which may be the default grant.

Example:

```
GRANT SELECT, UPDATE
 ON example
 TO some_user, another_user;

REVOKE SELECT, UPDATE
 ON example
 FROM some_user, another_user;
```

Procedural extensions

SQL is designed for a specific purpose: to query data contained in a relational database. SQL is a set-based, declarative query language, not an imperative language like C or BASIC. However, there are extensions to Standard SQL which add procedural programming language functionality, such as control-of-flow constructs. These include:

Source	Common name	Full name
ANSI/ISO Standard	SQL/PSM	SQL/Persistent Stored Modules
Interbase / Firebird	PSQL	Procedural SQL
IBM DB2	SQL PL	SQL Procedural Language (implements SQL/PSM)
IBM Informix	SPL	Stored Procedural Language
IBM Netezza	NZPLSQL[10]	(based on Postgres PL/pgSQL)
Microsoft / Sybase	T-SQL	Transact-SQL
Mimer SQL	SQL/PSM	SQL/Persistent Stored Module (implements SQL/PSM)
MySQL	SQL/PSM	SQL/Persistent Stored Module (implements SQL/PSM)
Oracle	PL/SQL	Procedural Language/SQL (based on Ada)
PostgreSQL	PL/pgSQL	Procedural Language/PostgreSQL (based on Oracle PL/SQL)
PostgreSQL	PL/PSM	Procedural Language/Persistent Stored Modules (implements SQL/PSM)
Sybase	Watcom-SQL	SQL Anywhere Watcom-SQL Dialect
Teradata	SPL	Stored Procedural Language

In addition to the standard SQL/PSM extensions and proprietary SQL extensions, procedural and object-oriented programmability is available on many SQL platforms via DBMS integration with other languages. The SQL standard defines SQL/JRT extensions (SQL Routines and Types for the Java Programming Language) to support Java code in SQL databases. SQL Server 2005 uses the SQLCLR (SQL Server Common Language Runtime) to host managed .NET assemblies in the database, while prior versions of SQL Server were restricted to using unmanaged extended stored procedures that were primarily written in C. PostgreSQL allows functions to be written in a wide variety of languages including Perl, Python, Tcl, and C.

Criticism

SQL deviates in several ways from its theoretical foundation, the relational model and its tuple calculus. In that model, a table is a set of tuples, while in SQL, tables and query results are lists of rows: the same row may occur multiple times, and the order of rows can be employed in queries (e.g. in the LIMIT clause). Furthermore, additional features (such as NULL and views) were introduced without founding them directly on the relational model, which makes them more difficult to interpret.

Critics argue that SQL should be replaced with a language that strictly returns to the original foundation: for example, see *The Third Manifesto*. Other critics suggest that Datalog has two advantages over SQL: it has a cleaner semantics which facilitates program understanding and maintenance, and it is more expressive, in particular for recursive queries.[11]

Another criticism is that SQL implementations are incompatible between vendors. In particular date and time syntax, string concatenation, `NULL`s, and comparison case sensitivity vary from vendor to vendor. A particular exception is PostgreSQL, which strives for compliance.

Popular implementations of SQL commonly omit support for basic features of Standard SQL, such as the `DATE` or `TIME` data types. The most obvious such examples, and incidentally the most popular commercial and proprietary

SQL DBMSs, are Oracle (whose `DATE` behaves as `DATETIME`, and lacks a `TIME` type) and MS SQL Server (before the 2008 version). As a result, SQL code can rarely be ported between database systems without modifications.

There are several reasons for this lack of portability between database systems:

- The complexity and size of the SQL standard means that most implementors do not support the entire standard.
- The standard does not specify database behavior in several important areas (e.g. indexes, file storage...), leaving implementations to decide how to behave.
- The SQL standard precisely specifies the syntax that a conforming database system must implement. However, the standard's specification of the semantics of language constructs is less well-defined, leading to ambiguity.
- Many database vendors have large existing customer bases; where the SQL standard conflicts with the prior behavior of the vendor's database, the vendor may be unwilling to break backward compatibility.
- There is little commercial incentive for vendors to make it easier for users to change database suppliers (see vendor lock-in).
- Users evaluating database software tend to place other factors such as performance higher in their priorities than standards conformance.

Standardization

SQL was adopted as a standard by the American National Standards Institute (ANSI) in 1986 as SQL-86 and the International Organization for Standardization (ISO) in 1987. Nowadays the standard is subject to continuous improvement by the Joint Technical Committee *ISO/IEC JTC 1, Information technology, Subcommittee SC 32, Data management and interchange* which affiliate to ISO as well as IEC. It is commonly denoted by the pattern: *ISO/IEC 9075-n:yyyy Part n: title*, or, as a shortcut, *ISO/IEC 9075*.

ISO/IEC 9075 is complemented by *ISO/IEC 13249: SQL Multimedia and Application Packages* (SQL/MM) which defines SQL based interfaces and packages to widely spread applications like video, audio and spatial data.

Until 1996, the National Institute of Standards and Technology (NIST) data management standards program certified SQL DBMS compliance with the SQL standard. Vendors now self-certify the compliance of their products.

The original SQL standard declared that the official pronunciation for SQL is "es queue el". Many English-speaking database professionals still use the original pronunciation /ˈsiːkwəl/ (like the word "sequel"), including Donald Chamberlin himself.

The SQL standard has gone through a number of revisions:

Year	Name	Alias	Comments
1986	SQL-86	SQL-87	First formalized by ANSI.
1989	SQL-89	FIPS 127-1	Minor revision, in which the major addition were integrity constraints. Adopted as FIPS 127-1.
1992	SQL-92	SQL2, FIPS 127-2	Major revision (ISO 9075), *Entry Level* SQL-92 adopted as FIPS 127-2.
1999	SQL:1999	SQL3	Added regular expression matching, recursive queries (e.g. transitive closure), triggers, support for procedural and control-of-flow statements, non-scalar types, and some object-oriented features (e.g. structured types). Support for embedding SQL in Java (SQL/OLB) and vice-versa (SQL/JRT).
2003	SQL:2003	SQL 2003	Introduced XML-related features (SQL/XML), *window functions*, standardized sequences, and columns with auto-generated values (including identity-columns).

2006	SQL:2006	SQL 2006	ISO/IEC 9075-14:2006 defines ways in which SQL can be used in conjunction with XML. It defines ways of importing and storing XML data in an SQL database, manipulating it within the database and publishing both XML and conventional SQL-data in XML form. In addition, it enables applications to integrate into their SQL code the use of XQuery, the XML Query Language published by the World Wide Web Consortium (W3C), to concurrently access ordinary SQL-data and XML documents.
2008	SQL:2008	SQL 2008	Legalizes ORDER BY outside cursor definitions. Adds INSTEAD OF triggers. Adds the TRUNCATE statement.
2011	SQL:2011		

Interested parties may purchase SQL standards documents from ISO, IEC or ANSI. A draft of SQL:2008 is freely available as a zip archive.

The SQL standard is divided into nine parts.

- ISO/IEC 9075-1:2011 Part 1: *Framework* (SQL/Framework). It provides logical concepts.
- ISO/IEC 9075-2:2011 Part 2: *Foundation* (SQL/Foundation). It contains the most central elements of the language and consists of both *mandatory and optional* features.
- ISO/IEC 9075-3:2008 Part 3: *Call-Level Interface* (SQL/CLI). It defines interfacing components (structures, procedures, variable bindings) that can be used to execute SQL statements from applications written in Ada, C respectively C++, COBOL, Fortran, MUMPS, Pascal or PL/I. (For Java see part 10.) SQL/CLI is defined in such a way that SQL statements and SQL/CLI procedure calls are treated as separate from the calling application's source code. Open Database Connectivity is a well-known superset of SQL/CLI. This part of the standard consists solely of *mandatory* features.
- ISO/IEC 9075-4:2011 Part 4: *Persistent Stored Modules* (SQL/PSM) It standardizes procedural extensions for SQL, including flow of control, condition handling, statement condition signals and resignals, cursors and local variables, and assignment of expressions to variables and parameters. In addition, SQL/PSM formalizes declaration and maintenance of persistent database language routines (e.g., "stored procedures"). This part of the standard consists solely of *optional* features.
- ISO/IEC 9075-9:2008 Part 9: *Management of External Data* (SQL/MED). It provides extensions to SQL that define foreign-data wrappers and datalink types to allow SQL to manage external data. External data is data that is accessible to, but not managed by, an SQL-based DBMS. This part of the standard consists solely of *optional* features.
- ISO/IEC 9075-10:2008 Part 10: *Object Language Bindings* (SQL/OLB). It defines the syntax and semantics of SQLJ, which is SQL embedded in Java (see also part 3). The standard also describes mechanisms to ensure binary portability of SQLJ applications, and specifies various Java packages and their contained classes. This part of the standard consists solely of optional features, as opposed to SQL/OLB JDBC, which is not part of the SQL standard, which defines an API.[*citation needed*]
- ISO/IEC 9075-11:2011 Part 11: *Information and Definition Schemas* (SQL/Schemata). It defines the Information Schema and Definition Schema, providing a common set of tools to make SQL databases and objects self-describing. These tools include the SQL object identifier, structure and integrity constraints, security and authorization specifications, features and packages of ISO/IEC 9075, support of features provided by SQL-based DBMS implementations, SQL-based DBMS implementation information and sizing items, and the values supported by the DBMS implementations. This part of the standard contains both *mandatory and optional* features.
- ISO/IEC 9075-13:2008 Part 13: *SQL Routines and Types Using the Java Programming Language* (SQL/JRT). It specifies the ability to invoke static Java methods as routines from within SQL applications ('Java-in-the-database'). It also calls for the ability to use Java classes as SQL structured user-defined types. This part of the standard consists solely of *optional* features.
- ISO/IEC 9075-14:2011 Part 14: *XML-Related Specifications* (SQL/XML). It specifies SQL-based extensions for using XML in conjunction with SQL. The *XMLType* data type is introduced, as well as several routines,

functions, and XML-to-SQL data type mappings to support manipulation and storage of XML in an SQL database. This part of the standard consists solely of *optional* features.[*citation needed*]

ISO/IEC 9075 is complemented by ISO/IEC 13249 *SQL Multimedia and Application Packages*. This closely related but separate standard is developed by the same committee. It defines interfaces and packages which are based on SQL. The aim is a unified access to typical database applications like text, pictures, data mining or spatial data.

- ISO/IEC 13249-1:2007 Part 1: *Framework*
- ISO/IEC 13249-2:2003 Part 2: *Full-Text*
- ISO/IEC 13249-3:2011 Part 3: *Spatial*
- ISO/IEC 13249-5:2003 Part 5: *Still image*
- ISO/IEC 13249-6:2006 Part 6: *Data mining*
- ISO/IEC 13249-8:xxxx Part 8: *Metadata registries (MDR)* (work in progress)

Alternatives

A distinction should be made between alternatives to SQL as a language, and alternatives to the relational model itself. Below are proposed relational alternatives to the SQL language. See navigational database and NoSQL for alternatives to the relational model.

- .QL: object-oriented Datalog
- 4D Query Language (4D QL)
- Datalog
- HTSQL: URL based query method
- IBM Business System 12 (IBM BS12): one of the first fully relational database management systems, introduced in 1982
- ISBL
- jOOQ: SQL implemented in Java as an internal internal domain-specific language
- Java Persistence Query Language (JPQL): The query language used by the Java Persistence API and Hibernate persistence library
- LINQ: Runs SQL statements written like language constructs to query collections directly from inside .Net code.
- Object Query Language
- OttoQL
- QBE (Query By Example) created by Moshè Zloof, IBM 1977
- Quel introduced in 1974 by the U.C. Berkeley Ingres project.
- Tutorial D
- XQuery

Chamberlin also briefly discusses his more recent research on XML query languages.
- Comparison of Different SQL Implementations (http://troels.arvin.dk/db/rdbms/) This comparison of various SQL implementations is intended to serve as a guide to those interested in porting SQL code between various RDBMS products, and includes comparisons between SQL:2008, PostgreSQL, DB2, MS SQL Server, MySQL, Oracle, and Informix.

SQL-92

SQL-92 was the third revision of the SQL database query language. Unlike SQL-89, it was a major revision of the standard. For all but a few minor incompatibilities, the SQL-89 standard is forward compatible with SQL-92.

The standard specification itself grew about five times compared to SQL-89. Much of it was due more precise specifications of existing features; the increase due to new features was only by a factor of 1.5–2. Many of the new features had already been implemented by vendors before the new standard was adopted. However, most of the new features were added to the "intermediate" and "full" tiers of the specification, meaning that conformance with SQL-92 entry level was scarcely any more demanding than conformance with SQL-89.

Later revisions of the standard include SQL:1999 (SQL3), SQL:2003, SQL:2008, and SQL:2011.

New Features

Significant new features include:[1]

- New data types defined: `DATE`, `TIME`, `TIMESTAMP`, `INTERVAL`, `BIT` string, `VARCHAR` strings, and `NATIONAL CHARACTER` strings.
- Support for additional character sets beyond the base requirement for representing SQL statements.
- New scalar operations such as string concatenation and substring extraction, date and time mathematics, and conditional statements.
- New set operations such as `UNION JOIN`, `NATURAL JOIN`, set differences, and set intersections.
- Conditional expressions with `CASE`. For an example, see Case (SQL).
- Support for alterations of schema definitions via `ALTER` and `DROP`.
- Bindings for C, Ada, and MUMPS.
- New features for user privileges.
- New integrity-checking functionality such as within a `CHECK` constraint.
- A new *information schema*—read-only views about database metadata like what tables it contains, etc. For example, `SELECT * FROM INFORMATION_SCHEMA.TABLES;`.
- Dynamic execution of queries (as opposed to prepared).
- Better support for remote database access.
- Temporary tables; `CREATE TEMP TABLE` etc.
- Transaction isolation levels.
- New operations for changing data types on the fly via `CAST (expr AS type)`.
- Scrolled cursors.
- Compatibility flagging for backwards and forwards compatibility with other SQL standards.

Extensions

Two significant extension were published after standard (but before the next major iteration.)

- SQL/CLI (Call Level Interface) in 1995
- SQL/PSM (stored procedures) in 1996

SQL:1999

SQL:1999 (also called SQL 3) was the fourth revision of the SQL database query language. It introduced a large number of new features, many of which required clarifications in the subsequent SQL:2003. The latest revision of the standard is SQL:2011.

Summary

The ISO standard documents were published between 1999 and 2002 in several installments, the first one consisting of multiple parts. Unlike previous editions, the standard's name used a colon instead of a hyphen for consistency with the names of other ISO standards. The first installment of SQL:1999 had five parts:

- SQL/Framework ISO/IEC 9075-1:1999 [1]
- SQL/Foundation ISO/IEC 9075-2:1999 [2]
- SQL/CLI : an updated definition of the extension Call Level Interface, originally published in 1995, also known as CLI-95 ISO/IEC 9075-3:1999 [3]
- SQL/PSM : an updated definition of the extension Persistent Stored Modules, originally published in 1996, also known as PSM-96 ISO/IEC 9075-4:1999 [4]
- SQL/Bindings ISO/IEC 9075-5:1999 [5]

Three more parts, also considered part of SQL:1999 were published subsequently:

- SQL/MED Management of External Data (SQL:1999 part 9) ISO/IEC 9075-9:2001 [6]
- SQL/OLB Object Language Bindings (SQL:1999 part 10) ISO/IEC 9075-10:2000 [7]
- SQL/JRT SQL Routines and Types using the Java Programming Language (SQL:1999 part 13) ISO/IEC 9075-13:2002 [8]

New features

Data types

Boolean data types

The SQL:1999 standard calls for a Boolean type,[9] but many commercial SQL Servers (Microsoft SQL Server 2005, Oracle 9i, IBM DB2) do not support it as a column type, variable type or allow it in the results set. MySQL interprets "BOOLEAN" as a synonym for TINYINT (8-bit signed integer).

Distinct user-defined types of power

Sometimes called just *distinct types*, these were introduced as an optional feature (S011) to allow existing atomic types to be extended with a distinctive meaning to create a new type and thereby enabling the type checking mechanism to detect some logical errors, e.g. accidentally adding an age to a salary. For example:

```
create type age as integer FINAL;
create type salary as integer FINAL;
```

creates two different and incompatible types. The SQL distinct types use name equivalence not structural equivalence like typedefs in C. It's still possible to perform compatible operations on (columns or data) of distinct types by using an explicit type `CAST`.

Few SQL systems support these. IBM DB2 is one those supporting them. Oracle database does not currently support them, recommending instead to emulate them by a one-place structured type.

Structured user-defined types

These are the backbone of the object-relational database extension in SQL:1999. They are analogous to classes in objected-oriented programming languages. SQL:1999 allows only single inheritance.

Common table expressions and recursive queries

SQL:1999 added a WITH [RECURSIVE] construct allowing recursive queries, like transitive closure, to be specified in the query language itself; see common table expressions.

Some OLAP capabilities

GROUP BY was extended with ROLLUP, CUBE, and GROUPING SETS.

Role-based access control

Full support for RBAC via CREATE ROLE.

SQL:2003

SQL:2003 is the fifth revision of the SQL database query language. The latest revision of the standard is SQL:2011.

Summary

The SQL:2003 standard makes minor modifications to all parts of SQL:1999 (also known as SQL3), and officially introduces a few new features such as:

- XML-related features (SQL/XML)
- Window functions
- the sequence generator, which allows standardized sequences
- two new column types: auto-generated values and identity-columns
- the new MERGE statement
- extensions to the CREATE TABLE statement, to allow "CREATE TABLE AS" and "CREATE TABLE LIKE"
- removal of the poorly implemented "BIT" and "BIT VARYING" data types
- OLAP capabilities (initially added in SQL:1999) were extended with a window function.

Documentation availability

The SQL standard is not freely available. SQL:2003 may be purchased from ISO [1] or ANSI [2]. A late draft is available as a zip archive [3] from Whitemarsh Information Systems Corporation [4]. The zip archive contains a number of PDF files that define the parts of the SQL:2003 specification.

SQL:2008

SQL:2008 is the sixth revision of the ISO and ANSI standard for the SQL database query language. It was formally adopted in July 2008.[1]

Summary

The SQL:2008 standard is split into several parts, covering the Framework, the Foundation, the Call-Level Interface, Persistent Stored Modules, Management of External Data, Object Language Bindings, Information and Definition Schemas, Routines and Types Using Java, and various "Related Specifications."

Additions to the Foundation include

- enhanced MERGE and DIAGNOSTIC statements,
- the TRUNCATE TABLE statement,
- comma-separated WHEN clauses in a CASE expression,
- INSTEAD OF database triggers
- partitioned JOIN tables,
- support for various XQuery regular expression/pattern-matching features, and
- enhancements to derived column names.

The Related Specifications for XML defines ways in which SQL can be used in conjunction with XML, including importing and storing XML data in an SQL database, manipulating it within the database and publishing both XML and conventional SQL-data in XML form.[2]

Documentation

The SQL standard is not freely available. The whole standard may be purchased from the ISO as *ISO/IEC 9075(1-4,9-11,13,14):2008*. The standard consists of the following parts:

- ISO/IEC 9075-1:2008 [3] Framework (SQL/Framework)
- ISO/IEC 9075-2:2008 [4] Foundation (SQL/Foundation)
- ISO/IEC 9075-3:2008 [5] Call-Level Interface (SQL/CLI)
- ISO/IEC 9075-4:2008 [6] Persistent Stored Modules (SQL/PSM)
- ISO/IEC 9075-9:2008 [7] Management of External Data (SQL/MED)
- ISO/IEC 9075-10:2008 [8] Object Language Bindings (SQL/OLB)
- ISO/IEC 9075-11:2008 [9] Information and Definition Schemas (SQL/Schemata)
- ISO/IEC 9075-13:2008 [10] SQL Routines and Types Using the Java TM Programming Language (SQL/JRT)
- ISO/IEC 9075-14:2008 [11] XML-Related Specifications (SQL/XML)

Claims of conformance

The minimum level of conformance to SQL:2008 that a product can claim is called "Core SQL:2008" and is limited to definitions specified in two parts of the standard: the Foundation and the Information and Definition Schemas.[12]

SQL:2011

SQL:2011 or **ISO/IEC 9075:2011** (under the general title "Information technology – Database languages – SQL") is the seventh revision of the ISO (1987) and ANSI (1986) standard for the SQL database query language. It was formally adopted in December 2011.

Parts

The standard is split into these parts:

- Part 1: Framework (SQL/Framework)
- Part 2: Foundation (SQL/Foundation)
- Part 3: Call-Level Interface (SQL/CLI)
- Part 4: Persistent Stored Modules (SQL/PSM)
- Part 9: Management of External Data (SQL/MED)
- Part 10: Object Language Bindings (SQL/OLB)
- Part 11: Information and Definition Schemas (SQL/Schemata)
- Part 13: SQL Routines and Types Using the Java™ Programming Language (SQL/JRT)
- Part 14: XML-Related Specifications (SQL/XML)

New features

Temporal support

One of the main new features is improved support for temporal databases.[1][2] Language enhancements for temporal data definition and manipulation include:

- **Time Period definitions** use two standard table columns as the start and end of a named time period, with closed-open semantics. This provides compatibility with existing data models, application code, and tools
- Definition of **application time period tables** (elsewhere called valid time tables), using the `PERIOD FOR` annotation
- Update and deletion of application time rows with **automatic time period splitting**
- **Temporal primary keys** incorporating application time periods with optional non-overlapping constraints via the `WITHOUT OVERLAPS` clause
- **Temporal referential integrity** constraints for application time tables
- Application time tables are queried using regular query syntax or using new **temporal predicates** for time periods including `CONTAINS`, `OVERLAPS`, `EQUALS`, `PRECEDES`, `SUCCEEDS`, `IMMEDIATELY PRECEDES`, and `IMMEDIATELY SUCCEEDS` (which are modified versions of Allen's interval relations)
- Definition of **system-versioned tables** (elsewhere called transaction time tables), using the `PERIOD FOR SYSTEM_TIME` annotation and `WITH SYSTEM VERSIONING` modifier. System time periods are maintained automatically. Constraints for system-versioned tables are not required to be temporal and are only enforced on current rows
- Syntax for **time-sliced** and **sequenced** queries on system time tables via the `AS OF SYSTEM TIME` and `VERSIONS BETWEEN SYSTEM TIME ... AND ...` clauses
- Application time and system versioning can be used together to provide **bitemporal tables**

IBM DB2 version 10 claims to be the first database to have a conforming implementation of this feature in what they call "Time Travel Queries".,[3][4] although they use the alternative syntax `FOR SYSTEM_TIME AS OF`.

Oracle (version 10 and above) has similar functionality in what they call **Flashback Queries**, using the alternative syntax `AS OF TIMESTAMP`.[5]

Data

Data (/ˈdeɪtə/ ***DAY***-*tə* or /ˈdætə/ ***DA***-*tə*, also /ˈdɑːtə/ ***DAH***-*tə*) is a set of values of qualitative or quantitative variables; restated, data are individual pieces of information. Data in computing (or data processing) are represented in a structure that is often tabular (represented by rows and columns), a tree (a set of nodes with parent-children relationship), or a graph (a set of connected nodes). Data are typically the results of measurements and can be visualised using graphs or images.

Data as an abstract concept can be viewed as the lowest level of abstraction, from which information and then knowledge are derived.

Raw data, i.e., unprocessed data, refers to a collection of numbers, characters and is a relative term; data processing commonly occurs by stages, and the "processed data" from one stage may be considered the "raw data" of the next. Field data refers to raw data that is collected in an uncontrolled in situ environment. Experimental data refers to data that is generated within the context of a scientific investigation by observation and recording.

The word *data* is the traditional plural form of the now-archaic *datum*, neuter past participle of the Latin *dare*, "to give", hence "something given". In discussions of problems in geometry, mathematics, engineering, and so on, the terms *givens* and *data* are used interchangeably. This usage is the origin of *data* as a concept in computer science or data processing: data are accepted numbers, words, images, etc.

Data is also increasingly used in humanities (particularly in the growing digital humanities) the highly interpretive nature whereof might oppose the ethos of data as "given". Peter Checkland introduced the term *capta* (from the Latin *capere*, “to take”) to distinguish between an immense number of possible data and a sub-set of them, to which attention is oriented. Johanna Drucker has argued that the humanities affirm knowledge production as “situated, partial, and constitutive” and that using *data* may therefore introduce assumptions that are counterproductive, for example that phenomena are discrete or observer-independent. The term *capta*, which emphasizes the act of observation as constitutive, is offered as an alternative to *data* for visual representations in the humanities.

Usage in English

Datum means "an item given". In cartography, geography, nuclear magnetic resonance and technical drawing it often refers to a reference datum wherefrom distances to all other data are measured. Any measurement or result is a *datum*, though *data point* is now far more common.

In one sense, *datum* is a count noun with the plural *datums* (see usage in datum article) that can be used with cardinal numbers (e.g. "80 datums"); *data* (originally a Latin plural) is not used like a normal count noun with cardinal numbers and can be plural with such plural determiners as *these* and *many* or as a singular abstract mass noun with a verb in the singular form. Even when a very small quantity of data is referenced (one number, for example) the phrase *piece of data* is often used, as opposed to *datum*. The debate over appropriate usage continues.

The IEEE Computer Society allows usage of *data* as either a mass noun or plural based on author preference. Some professional organizations and style guidesWikipedia:Link rot require that authors treat *data* as a plural noun. For example, the Air Force Flight Test Center specifically states that the word *data* is always plural, never singular.

Data is most often used as a singular mass noun in educated everyday usage.[1][2] Some major newspapers such as *The New York Times* use it either in the singular or plural. In the *New York Times* the phrases "the survey data are still being analyzed" and "the first year for which data is available" have appeared within one day. The *Wall Street Journal* explicitly allows this usage in its style guide. The Associated Press style guide classifies *data* as a collective noun that is singular when a unit and plural when referring to individual items ("The data is sound.", and "The data have been carefully collected.").

In scientific writing *data* is often treated as a plural, as in *These data do not support the conclusions*, and as a singular mass entity like *information*, for instance in computing and related disciplines. British usage now widely accepts treating *data* as singular in standard English, including everyday newspaper usage at least in non-scientific use. UK scientific publishing still prefers treating it as a plural. Some UK university style guides recommend using *data* for both singular and plural use and some recommend treating it only as a singular in connection with computers.

Meaning of data, information and knowledge

Data, information and knowledge frequently overlap, mainly differing in abstraction. Data is least abstract, information next least, and knowledge most. Data becomes information by interpretation; e.g., the height of Mt. Everest is generally considered as "data", a book on Mt. Everest geological characteristics may be considered as "information", and a report containing practical information on the best way to reach Mt. Everest's peak may be considered as "knowledge".

'Information' bears a diversity of meanings that ranges from everyday to technical. Generally speaking, the concept of information is closely related to notions of constraint, communication, control, data, form, instruction, knowledge, meaning, mental stimulus, pattern, perception, and representation.

Beynon-Davies uses the concept of a sign to distinguish between data and information; data are symbols while information occurs when the symbols are used to refer to something.

It is people and computers who collect data and impose patterns on it. These patterns are seen as information which can be used to enhance knowledge. These patterns can be interpreted as truth, and are authorized as aesthetic and ethical criteria. Events that leave behind perceivable physical or virtual remains can be traced back through data. Marks are no longer considered data once the link between the mark and observation is broken.

Mechanical computing devices are classified according to the means by which they represent data. An analog computer represents a datum as a voltage, distance, position, or other physical quantity. A digital computer represents a datum as a sequence of symbols drawn from a fixed alphabet. The most common digital computers use a binary alphabet, that is, an alphabet of two characters, typically denoted "0" and "1". More familiar representations, such as numbers or letters, are then constructed from the binary alphabet.

Some special forms of data are distinguished. A computer program is a collection of data, which can be interpreted as instructions. Most computer languages make a distinction between programs and the other data on which programs operate, but in some languages, notably Lisp and similar languages, programs are essentially indistinguishable from other data. It is also useful to distinguish metadata, that is, a description of other data. A similar yet earlier term for metadata is "ancillary data." The prototypical example of metadata is the library catalog, which is a description of the contents of books.

- Data is a singular noun (http://purl.org/nxg/note/singular-data) (a detailed assessment)

Metadata

Metadata is "data about data". The term is ambiguous, as it is used for two fundamentally different concepts (types). **Structural metadata** is about the design and specification of data structures and is more properly called "data about the containers of data"; **descriptive metadata**, on the other hand, is about individual instances of application data, the data content.

Metadata are traditionally found in the card catalogs of libraries. As information has become increasingly digital, metadata are also used to describe digital data using metadata standards specific to a particular discipline. By describing the contents and context of data files, the quality of the original data/files is greatly increased. For example, a webpage may include metadata specifying what language it is written in, what tools were used to create it, and where to go for more on the subject, allowing browsers to automatically improve the experience of users.

Definition

Metadata (metacontent) are defined as the data providing information about one or more aspects of the data, such as:

- Means of creation of the data
- Purpose of the data
- Time and date of creation
- Creator or author of the data
- Location on a computer network where the data were created
- Standards used

For example, a digital image may include metadata that describe how large the picture is, the color depth, the image resolution, when the image was created, and other data. A text document's metadata may contain information about how long the document is, who the author is, when the document was written, and a short summary of the document.

Metadata are data. As such, metadata can be stored and managed in a database, often called a metadata registry or metadata repository.[1] However, without context and a point of reference, it might be impossible to identify metadata just by looking at them. For example: by itself, a database containing several numbers, all 13 digits long could be the results of calculations or a list of numbers to plug into an equation - without any other context, the

numbers themselves can be perceived as the data. But if given the context that this database is a log of a book collection, those 13-digit numbers may now be identified as ISBNs - information that refers to the book, but is not itself the information within the book.

The term "metadata" was coined in 1968 by Philip Bagley, in his book "Extension of programming language concepts" where it is clear that he uses the term in the ISO 11179 "traditional" sense, which is "structural metadata" i.e. "data about the containers of data"; rather than the alternate sense "content about individual instances of data content" or metacontent, the type of data usually found in library catalogues.[2] Since then the fields of information management, information science, information technology, librarianship and GIS have widely adopted the term. In these fields the word *metadata* is defined as "data about data". While this is the generally accepted definition, various disciplines have adopted their own more specific explanation and uses of the term.

Libraries

Metadata have been used in various forms as a means of cataloging archived information. The Dewey Decimal System employed by libraries for the classification of library materials is an early example of metadata usage. Library catalogues used 3x5 inch cards to display a book's title, author, subject matter, and a brief plot synopsis along with an abbreviated alpha-numeric identification system which indicated the physical location of the book within the library's shelves. Such data help classify, aggregate, identify, and locate a particular book. Another form of older metadata collection is the use by US Census Bureau of what is known as the "Long Form." The Long Form asks questions that are used to create demographic data to find patterns of distribution.

Photographs

Metadata may be written into a digital photo file that will identify who owns it, copyright and contact information, what camera created the file, along with exposure information and descriptive information such as keywords about the photo, making the file searchable on the computer and/or the Internet. Some metadata are written by the camera and some is input by the photographer and/or software after downloading to a computer. However, not all digital cameras enable you to edit metadata; this functionality has been available on most Nikon DSLRs since the Nikon D3 and on most new Canon cameras since the Canon EOS 7D.

Photographic Metadata Standards are governed by organizations that develop the following standards. They include, but are not limited to:

- IPTC Information Interchange Model IIM (International Press Telecommunications Council),
- IPTC Core Schema for XMP
- XMP – Extensible Metadata Platform (an ISO standard)
- Exif – Exchangeable image file format, Maintained by CIPA (Camera & Imaging Products Association) and published by JEITA (Japan Electronics and Information Technology Industries Association)
- Dublin Core (Dublin Core Metadata Initiative – DCMI)
- PLUS (Picture Licensing Universal System).

Video

Metadata are particularly useful in video, where information about its contents (such as transcripts of conversations and text descriptions of its scenes) are not directly understandable by a computer, but where efficient search is desirable.

Web pages

Web pages often include metadata in the form of meta tags. Description and keywords meta tags are commonly used to describe the Web page's content. Most search engines use these data when adding pages to their search index.

Creation of metadata

Metadata can be created either by automated information processing or by manual work. Elementary metadata captured by computers can include information about when an object was created, who created it, when it was last updated, file size and file extension.

For the purposes of this article, an "object" refers to any of the following:

- A physical item such as a book, CD, DVD, map, chair, table, flower pot, etc.
- An electronic file such as a digital image, digital photo, document, program file, database table, etc.

Metadata types

The metadata application is manyfold covering a large variety of fields of application there are nothing but specialised and well accepted models to specify types of metadata. Bretheron & Singley (1994) distinguish between two distinct classes: structural/control metadata and guide metadata. **Structural metadata** are used to describe the structure of database objects such as tables, columns, keys and indexes. **Guide metadata** are used to help humans find specific items and are usually expressed as a set of keywords in a natural language. According to Ralph Kimball metadata can be divided into 2 similar categories: technical metadata and business metadata. **Technical metadata** correspond to internal metadata, *business metadata* - to external metadata. Kimball adds a third category named **process metadata**. On the other hand, NISO distinguishes among three types of metadata: descriptive, structural and administrative. **Descriptive metadata** are the information used to search and locate an object such as title, author, subjects, keywords, publisher; **structural metadata** give a description of how the components of the object are organised; and **administrative metadata** refer to the technical information including file type. Two sub-types of administrative metadata are rights management metadata and preservation metadata.

Metadata structures

Metadata (metacontent), or more correctly, the vocabularies used to assemble metadata (metacontent) statements, are typically structured according to a standardized concept using a well-defined metadata scheme, including: metadata standards and metadata models. Tools such as controlled vocabularies, taxonomies, thesauri, data dictionaries and metadata registries can be used to apply further standardization to the metadata. Structural metadata commonality is also of paramount importance in data model development and in database design.

Metadata syntax

Metadata (metacontent) syntax refers to the rules created to structure the fields or elements of metadata (metacontent). A single metadata scheme may be expressed in a number of different markup or programming languages, each of which requires a different syntax. For example, Dublin Core may be expressed in plain text, HTML, XML and RDF.

A common example of (guide) metacontent is the bibliographic classification, the subject, the Dewey Decimal class number. There is always an implied statement in any "classification" of some object. To classify an object as, for example, Dewey class number 514 (Topology) (i.e. books having the number 514 on their spine) the implied statement is: "<book><subject heading><514>. This is a subject-predicate-object triple, or more importantly, a class-attribute-value triple. The first two elements of the triple (class, attribute) are pieces of some structural metadata having a defined semantic. The third element is a value, preferably from some controlled vocabulary, some reference (master) data. The combination of the metadata and master data elements results in a statement which is a metacontent statement i.e. "metacontent = metadata + master data". All these elements can be thought of as "vocabulary". Both metadata and master data are vocabularies which can be assembled into metacontent statements. There are many sources of these vocabularies, both meta and master data: UML, EDIFACT, XSD, Dewey/UDC/LoC, SKOS, ISO-25964, Pantone, Linnaean Binomial Nomenclature etc. Using controlled vocabularies for the components of metacontent statements, whether for indexing or finding, is endorsed by ISO-25964 [3]: "If both the indexer and the searcher are guided to choose the same term for the same concept, then relevant documents will be retrieved." This is particularly relevant when considering the behemoth of the internet, Google. It simply indexes pages then matches text strings using its complex algorithm, there is no intelligence or "inferencing" occurring. Just the illusion thereof.

Hierarchical, linear and planar schemata

Metadata schema can be hierarchical in nature where relationships exist between metadata elements and elements are nested so that parent-child relationships exist between the elements. An example of a hierarchical metadata schema is the IEEE LOM schema where metadata elements may belong to a parent metadata element. Metadata schema can also be one-dimensional, or linear, where each element is completely discrete from other elements and classified according to one dimension only. An example of a linear metadata schema is Dublin Core schema which is one dimensional. Metadata schema are often two dimensional, or planar, where each element is completely discrete from other elements but classified according to two orthogonal dimensions.

Metadata hypermapping

In all cases where the metadata schemata exceed the planar depiction, some type of hypermapping is required to enable display and view of metadata according to chosen aspect and to serve special views. Hypermapping frequently applies to layering of geographical and geological information overlays.

Granularity

The degree to which the data or metadata are structured is referred to as their granularity. Metadata with a high granularity allow for deeper structured information and enable greater levels of technical manipulation however, a lower level of granularity means that metadata can be created for considerably lower costs but will not provide as detailed information. The major impact of granularity is not only on creation and capture, but moreover on maintenance. As soon as the metadata structures get outdated, the access to the referred data will get outdated. Hence granularity shall take into account the effort to create as well as the effort to maintain.

Metadata standards

International standards apply to metadata. Much work is being accomplished in the national and international standards communities, especially ANSI (American National Standards Institute) and ISO (International Organization for Standardization) to reach consensus on standardizing metadata and registries.

The core standard is ISO/IEC 11179-1:2004 and subsequent standards (see ISO/IEC 11179). All yet published registrations according to this standard cover just the definition of metadata and do not serve the structuring of metadata storage or retrieval neither any administrative standardisation. It is important to note that this standard refers to metadata as the data about containers of the data and not to metadata (metacontent) as the data about the data contents. It should also be noted that this standard describes itself originally as a "data element" registry, describing disembodied data elements, and explicitly disavows the capability of containing complex structures. Thus the original term "data element" is more applicable than the later applied buzzword "metadata".

The Dublin Core metadata terms are a set of vocabulary terms which can be used to describe resources for the purposes of discovery. The original set of 15 classic metadata terms, known as the Dublin Core Metadata Element Set are endorsed in the following standards documents:

- IETF RFC 5013
- ISO Standard 15836-2009
- NISO Standard Z39.85.

Although not a standard, Microformat (also mentioned in the section metadata on the internet below) is a web-based approach to semantic markup which seeks to re-use existing HTML/XHTML tags to convey metadata. Microformat follows XHTML and HTML standards but is not a standard in itself. One advocate of microformats, Tantek Çelik, characterized a problem with alternative approaches:

> Here's a new language we want you to learn, and now you need to output these additional files on your server. It's a hassle. (Microformats) lower the barrier to entry.

Metadata usage

Data virtualization

Data virtualization has emerged as the new software technology to complete the virtualization stack in the enterprise. Metadata are used in data virtualization servers which are enterprise infrastructure components, alongside database and application servers. Metadata in these servers are saved as persistent repository and describe business objects in various enterprise systems and applications. Structural metadata commonality is also important to support data virtualization.

Statistics and census services

Standardization work has had a large impact on efforts to build metadata systems in the statistical community[*citation needed*]. Several metadata standardsWikipedia:Avoid weasel words are described, and their importance to statistical agencies is discussed. Applications of the standardsWikipedia:Avoid weasel words at the Census Bureau, Environmental Protection Agency, Bureau of Labor Statistics, Statistics Canada, and many others are described[*citation needed*]. Emphasis is on the impact a metadata registry can have in a statistical agency.

Library and information science

Libraries employ metadata in library catalogues, most commonly as part of an Integrated Library Management System. Metadata are obtained by cataloguing resources such as books, periodicals, DVDs, web pages or digital images. These data are stored in the integrated library management system, ILMS, using the MARC metadata standard. The purpose is to direct patrons to the physical or electronic location of items or areas they seek as well as to provide a description of the item/s in question.

More recent and specialized instances of library metadata include the establishment of digital libraries including e-print repositories and digital image libraries. While often based on library principles, the focus on non-librarian use, especially in providing metadata, means they do not follow traditional or common cataloging approaches. Given the custom nature of included materials, metadata fields are often specially created e.g. taxonomic classification fields, location fields, keywords or copyright statement. Standard file information such as file size and format are usually automatically included.

Standardization for library operation has been a key topic in international standardization (ISO) for decades. Standards for metadata in digital libraries include Dublin Core, METS, MODS, DDI, ISO standard Digital Object Identifier (DOI), ISO standard Uniform Resource Name (URN), PREMIS schema, Ecological Metadata Language, and OAI-PMH. Leading libraries in the world give hints on their metadata standards strategies.

Metadata and the law

United States

Problems involving metadata in litigation in the United States are becoming widespread.Wikipedia:Manual of Style/Dates and numbers#Chronological items Courts have looked at various questions involving metadata, including the discoverability of metadata by parties. Although the Federal Rules of Civil Procedure have only specified rules about electronic documents, subsequent case law has elaborated on the requirement of parties to reveal metadata. In October 2009, the Arizona Supreme Court has ruled that metadata records are public record.

Document metadata have proven particularly important in legal environments in which litigation has requested metadata, which can include sensitive information detrimental to a party in court.

Using metadata removal tools to "clean" documents can mitigate the risks of unwittingly sending sensitive data. This process partially (see Data remanence) protects law firms from potentially damaging leaking of sensitive data through electronic discovery.

Metadata in healthcare

Australian researches in medicine started a lot of metadata definition for applications in health care. That approach offers the first recognized attempt to adhere to international standards in medical sciences instead of defining a proprietary standard under the WHO umbrella first.

The medical community yet did not approve the need to follow metadata standards despite respective research.[4]

Metadata and data warehousing

Data warehouse (DW) is a repository of an organization's electronically stored data. Data warehouses are designed to manage and store the data whereas the business intelligence (BI) focuses on the usage of the data to facilitate reporting and analysis.[5]

The purpose of a data warehouse is to house standardized, structured, consistent, integrated, correct, cleansed and timely data, extracted from various operational systems in an organization. The extracted data are integrated in the data warehouse environment in order to provide an enterprise wide perspective, one version of the truth. Data are structured in a way to specifically address the reporting and analytic requirements. The design of structural metadata

commonality using a data modeling method such as entity relationship model diagramming is very important in any data warehouse development effort.

An essential component of a data warehouse/business intelligence system is the metadata and tools to manage and retrieve the metadata. Ralph Kimball describes metadata as the DNA of the data warehouse as metadata defines the elements of the data warehouse and how they work together.

Kimball et al. refers to three main categories of metadata: Technical metadata, business metadata and process metadata. Technical metadata are primarily definitional, while business metadata and process metadata are primarily descriptive. Keep in mind that the categories sometimes overlap.

- **Technical metadata** define the objects and processes in a DW/BI system, as seen from a technical point of view. The technical metadata include the system metadata which define the data structures such as: tables, fields, data types, indexes and partitions in the relational engine, and databases, dimensions, measures, and data mining models. Technical metadata define the data model and the way it is displayed for the users, with the reports, schedules, distribution lists and user security rights.
- **Business metadata** are a content from the data warehouse described in more user-friendly terms. The business metadata tell you what data you have, where they come from, what they mean and what their relationship is to other data in the data warehouse. Business metadata may also serve as a documentation for the DW/BI system. Users who browse the data warehouse are primarily viewing the business metadata.
- **Process metadata** are used to describe the results of various operations in the data warehouse. Within the ETL process, all key data from tasks are logged on execution. This includes start time, end time, CPU seconds used, disk reads, disk writes and rows processed. When troubleshooting the ETL or query process, this sort of data becomes valuable. Process metadata are the fact measurement when building and using a DW/BI system. Some organizations make a living out of collecting and selling this sort of data to companies - in that case the process metadata becomes the business metadata for the fact and dimension tables. Collecting process metadata is in the interest of business people who can use the data to identify the users of their products, which products they are using and what level of service they are receiving.

Metadata on the Internet

The HTML format used to define web pages allows for the inclusion of a variety of types of metadata, from basic descriptive text, dates and keywords to further advanced metadata schemes such as the Dublin Core, e-GMS, and AGLS[6] standards. Pages can also be geotagged with coordinates. Metadata may be included in the page's header or in a separate file. Microformats allow metadata to be added to on-page data in a way that users do not see, but computers can readily access.

Interestingly, many search engines are cautious about using metadata in their ranking algorithms due to exploitation of metadata and the practice of search engine optimization, SEO, to improve rankings. See Meta element article for further discussion. Studies show that search engines respond to web pages with metadata implementations.[7]

Metadata in the broadcast industry

In broadcast industry, metadata are linked to audio and video Broadcast media to:

- *identify* the media: clip or playlist names, duration, timecode, etc.
- *describe* the content: notes regarding the quality of video content, rating, description (for example, during a sport event, keywords like *goal*, *red card* will be associated to some clips)
- *classify* media: metadata allow to sort the media or to easily and quickly find a video content (a TV news could urgently need some archive content for a subject). For example, the BBC have a large subject classification system, Lonclass, a customized version of the more general-purpose Universal Decimal Classification.

These metadata can be linked to the video media thanks to the video servers. All latest broadcasted sport events like FIFA World Cup or Olympic Games use these metadata to distribute their video content to TV stations through keywords. It's often the host broadcaster who is in charge of organizing metadata through its *International Broadcast Centre* and its video servers. Those metadata are recorded with the images and are entered by metadata operators (*loggers*) who associate in live metadata available in *metadata grids* through software (such as Multicam(LSM) or IPDirector used during FIFA World Cup or Olympic Games).

Geospatial metadata

Metadata that describe geographic objects (such as datasets, maps, features, or simply documents with a geospatial component) have a history dating back to at least 1994 (refer MIT Library page on FGDC Metadata [8]). This class of metadata is described more fully on the Geospatial metadata page.

Ecological and environmental metadata

Ecological and environmental metadata are intended to document the who, what, when, where, why, and how of data collection for a particular study. Metadata should be generated in a format commonly used by the most relevant science community, such as Darwin Core, Ecological Metadata Language, or Dublin Core. Metadata editing tools exist to facilitate metadata generation (e.g. Metavist, Mercury: Metadata Search System, Morpho). Metadata should describe provenance of the data (where they originated, as well as any transformations the data underwent) and how to give credit for (cite) the data products.

Digital music

CDs such as recordings of music will carry a layer of metadata about the recordings such as dates, artist, genre, copyright owner, etc. The metadata, not normally displayed by CD players, can be accessed and displayed by specialized music playback and/or editing applications.

The metadata for compressed and uncompressed digital music is often encoded in the ID3 tag. Common editors such as TagLib support MP3, Ogg Vorbis, FLAC, MPC, Speex, WavPack TrueAudio, WAV, AIFF, MP4 and ASF file formats.

Cloud applications

With the availability of Cloud applications, which include those to add metadata to content, metadata is increasingly available over the Internet.

Metadata administration and management

Metadata storage

Metadata can be stored either *internally*, in the same file as the data, or *externally*, in a separate file. Metadata that are embedded with content is called *embedded metadata*. A data repository typically stores the metadata *detached* from the data. Both ways have advantages and disadvantages:

- Internal storage allows transferring metadata together with the data they describe; thus, metadata are always at hand and can be manipulated easily. This method creates high redundancy and does not allow holding metadata together.
- External storage allows bundling metadata, for example in a database, for more efficient searching. There is no redundancy and metadata can be transferred simultaneously when using streaming. However, as most formats use URIs for that purpose, the method of how the metadata are linked to their data should be treated with care. What if a resource does not have a URI (resources on a local hard disk or web pages that are created on-the-fly using a content management system)? What if the metadata can only be evaluated if there is a connection to the Web, especially when using RDF? How to realize that a resource is replaced by another with the same name but different content?

Moreover, there is the question of data format: storing metadata in a human-readable format such as XML can be useful because users can understand and edit it without specialized tools. On the other hand, these formats are not optimized for storage capacity; it may be useful to store metadata in a binary, non-human-readable format instead to speed up transfer and save memory.

Metadata management

Metadata management is the end-to-end process and governance framework for creating, controlling, enhancing, attributing, defining and managing a metadata schema, model or other structured aggregation, either independently or within a repository and the associated supporting processes (often to enable the management of content). The world Wide Web Consortium (W3C) has identified Governance as a key challenge in the advancement of third generation Web Technologies (Web 3.0, Semantic Web), and a number of research prototypes, such as S3DB, explore the use of semantic modeling to identify practical solutions.

Database management

Each relational database system has its own mechanisms for storing metadata. Examples of relational-database metadata include:

- Tables of all tables in a database, their names, sizes and number of rows in each table.
- Tables of columns in each database, what tables they are used in, and the type of data stored in each column.

In database terminology, this set of metadata is referred to as the catalog. The SQL standard specifies a uniform means to access the catalog, called the information schema, but not all databases implement it, even if they implement other aspects of the SQL standard. For an example of database-specific metadata access methods, see Oracle metadata. Programmatic access to metadata is possible using APIs such as JDBC, or SchemaCrawler.

Database objects

Table

In relational databases and flat file databases, a **table** is an organized set of data elements (values) using a model of vertical columns (which are identified by their name) and horizontal rows, the cell being the unit where a row and column intersect. A table has a specified number of columns, but can have any number of rows. Each row is identified by the values appearing in a particular column subset which has been identified as a unique key index.

Table is another term for relation; although there is the difference in that a table is usually a multiset (bag) of rows whereas a relation is a set and does not allow duplicates. Besides the actual data rows, tables generally have associated with them some metadata, such as constraints on the table or on the values within particular columns.Wikipedia:Disputed statement|

The data in a table does not have to be physically stored in the database. Views are also relational tables, but their data are calculated at query time. Another example are nicknames[*clarify*], which represent a pointer to a table in another database.

Comparisons

In non-relational systems, hierarchical databases, the distant counterpart of a table is a structured file, representing the rows of a table in each record of the file and each column in a record.This structure implies that a record can have repeating information, Generally in the child data segments.Data are stored in sequence of records which are equivalent to table term of a relational database.with each record having equivalent rows.

Unlike a spreadsheet, the datatype of field is ordinarily defined by the schema describing the table. Some SQL systems, such as SQLite, are less strict about field datatype definitions.

Tables versus relations

In terms of the relational model of databases, a table can be considered a convenient representation of a relation, but the two are not strictly equivalent. For instance, an SQL table can potentially contain duplicate rows, whereas a true relation cannot contain duplicate tuples. Similarly, representation as a table implies a particular ordering to the rows and columns, whereas a relation is explicitly unordered. However, the database system does not guarantee any ordering of the rows unless an `ORDER BY` clause is specified in the `SELECT` statement that queries the table.

An equally valid representations of a relation is as an *n*-dimensional chart, where *n* is the number of attributes (a table's columns). For example, a relation with two attributes and three values can be represented as a table with two columns and three rows, or as a two-dimensional graph with three points. The table and graph representations are only equivalent if the ordering of rows is not significant, and the table has no duplicate rows.

Table types

Two types of tables exist:

- A relational table, which is the basic structure to hold user data in a relational database.
- An object table, which is a table that uses an object type to define a column. It is defined to hold instances of objects of a defined type.

In SQL, the `CREATE TABLE` statement creates these tables.

References

Column

In the context of a relational database table, a **column** is a set of data values of a particular simple type, one for each row of the table.[1] The columns provide the structure according to which the rows are composed.

The term *field* is often used interchangeably with *column*, although many consider it more correct to use *field* (or *field value*) to refer specifically to the single item that exists at the intersection between one row and one column.

In relational database terminology, column's equivalent is called **attribute**.

For example, a table that represents companies might have the following columns:

- ID (integer identifier, unique to each row)
- Name (text)
- Address line 1 (text)
- Address line 2 (text)
- City (integer identifier, drawn from a separate table of cities, from which any state or country information would be drawn)
- Postal code (text)
- Industry (integer identifier, drawn from a separate table of industries)
- etc.

Each row would provide a data value for each column and would then be understood as a single structured data value, in this case representing a company. More formally, each row can be interpreted as a relvar, composed of a set of tuples, with each tuple consisting of the two items: the name of the relevant column and the value this row provides for that column.

	Column 1	**Column 2**
Row 1	Row 1, Column 1	Row 1, Column 2
Row 2	Row 2, Column 1	Row 2, Column 2
Row 3	Row 3, Column 1	Row 3, Column 2

Examples of database: PostgreSQL, MySQL, SQL Server, Access, Oracle, Sybase, DB2.

Coding involved: SQL [Structured Query Language]

See more at SQL.

References

[1] The term "column" also has equivalent application in other, more generic contexts. See e.g., Flat file database, Table (information).

Field

In computer science, data that has several parts can be divided into **fields**. Relational databases arrange data as sets of database records, also called rows. Each record consists of several *fields*; the fields of all records form the columns.

In object-oriented programming, *field* (also called *data member* or *member variable*) is the data encapsulated within a class or object. In the case of a regular field (also called *instance variable*), for each instance of the object there is an instance variable: for example, an `Employee` class has a `Name` field and there is one distinct name per employee. A static field (also called *class variable*) is one variable, which is shared by all instances.

Fixed length

Fields that contain a fixed number of bits are known as fixed length fields. A four byte field for example may contain a 31 bit binary integer plus a sign bit (32 bits in all). A 30 byte name field may contain a persons name typically padded with blanks at the end. The disadvantage of using fixed length fields is that some part of the field may be wasted but space is still required for the maximum length case. Also, where fields are omitted, padding for the missing fields is still required to maintain fixed start positions within a record for instance.

Variable length

A variable length field is not always the same physical size. Such fields are nearly always used for text fields that can be large, or fields that vary greatly in length. For example, a bibliographical database like PubMed has many small fields such as publication date and author name, but also has abstracts, which vary greatly in length. Reserving a fixed-length field of some length would be inefficient because it would enforce a maximum length on abstracts, and because space would be wasted in most records (particularly if many articles lacked abstracts entirely).

Database implementations commonly store varying-length fields in special ways, in order to make all the records of a given type have a uniform small size. Doing so can help performance. On the other hand, data in serialized forms such as stored in typical file systems, transmitted across networks, and so on usually uses quite different performance strategies. The choice depends on factors such as the total size of records, performance characteristics of the storage medium, and the expected patterns of access.

Database implementations typically store variable length fields in ways such as

- a sequence of characters or bytes, followed by an *end-marker* that is prohibited within the string itself. This makes it slower to access later fields in the same record because the later fields are not always at the same physical distance from the start of the record.
- a *pointer* to data in some other location, such as a URI, a file offset (and perhaps length), or a key identifying a record in some special place. This typically speeds up processes that don't need the contents of the variable length field(s), but slows processes that do.
- a *length prefix* followed by the specified number of characters or bytes. This avoids searches for an end-marker as in the first method, and avoids the loss of locality of reference as in the second method. On the other hand, it imposes a maximum length: the biggest number that can be represented using the (generally fixed length) prefix. In addition, records still vary in length, and must be traversed in order to reach later fields.

If a varying-length field is often empty, additional optimizations come into play.

References

Row

In the context of a relational database, a **row**—also called a **record** —represents a single, implicitly structured data item in a table. In simple terms, a database table can be thought of as consisting of *rows* and columns or fields. Each row in a table represents a set of related data, and every row in the table has the same structure.

For example, in a table that represents companies, each row would represent a single company. Columns might represent things like company name, company street address, whether the company is publicly held, its VAT number, etc.. In a table that represents *the association* of employees with departments, each row would associate one employee with one department.

In a less formal usage, e.g. for a database which is not formally relational, a record is equivalent to a row as described above, but is not usually referred to as a row.

The implicit structure of a row, and the meaning of the data values in a row, requires that the row be understood as providing a succession of data values, one in each column of the table. The row is then interpreted as a relvar composed of a set of tuples, with each tuple consisting of the two items: the name of the relevant column and the value this row provides for that column.

Each column expects a data value of a particular type. For example, one column might require a unique identifier, another might require text representing a person's name, another might require an integer representing hourly pay in cents.

-	**Column 1**	**Column 2**
Row (Record) 1	Row 1, Column (Field)1	Row 1, Column 2
Row 2	Row 2, Column 1	Row 2, Column 2
Row 3	Row 3, Column 1	Row 3, Column 2

Data type

In computer science and computer programming, a **data type** or simply **type** is a classification identifying one of various types of data, such as real, integer or Boolean, that determines the possible values for that type; the operations that can be done on values of that type; the meaning of the data; and the way values of that type can be stored.[1][2]

Overview

Data types are used within type systems, which offer various ways of defining, implementing and using them. Different type systems ensure varying degrees of type safety. Formally, a type can be defined as "any property of a programme we can determine without executing the program".[3]

Almost all programming languages explicitly include the notion of data type, though different languages may use different terminology. Common data types may include:

- integers,
- booleans,
- characters,
- floating-point numbers,
- alphanumeric strings.

For example, in the Java programming language, the "int" type represents the set of 32-bit integers ranging in value from -2,147,483,648 to 2,147,483,647, as well as the operations that can be performed on integers, such as addition, subtraction, and multiplication. Colors, on the other hand, are represented by three bytes denoting the amounts each of red, green, and blue, and one string representing that color's name; allowable operations include addition and subtraction, but not multiplication.

Most programming languages also allow the programmer to define additional data types, usually by combining multiple elements of other types and defining the valid operations of the new data type. For example, a programmer might create a new data type named "complex number" that would include real and imaginary parts. A data type also represents a constraint placed upon the interpretation of data in a type system, describing representation, interpretation and structure of values or objects stored in computer memory. The type system uses data type information to check correctness of computer programs that access or manipulate the data.

Most data types in statistics have comparable types in computer programming, and vice-versa, as shown in the following table:

Statistics	Computer programming
real-valued (interval scale)	floating-point
real-valued (ratio scale)	
count data (usually non-negative)	integer
binary data	Boolean
categorical data	enumerated type
random vector	list or array
random matrix	two-dimensional array
random tree	tree

Definition of a "type"

(Parnas, Shore & Weiss 1976) identified five definitions of a "type" that were used—sometimes implicitly—in the literature:

Syntactic

: A type is a purely syntactic label associated with a variable when it is declared. Such definitions of "type" do not give any semantic meaning to types.

Representation

: A type is defined in terms of its composition of more primitive types—often machine types.

Representation and behaviour

: A type is defined as its representation and a set of operators manipulating these representations.

Value space

: A type is a set of possible values which a variable can possess. Such definitions make it possible to speak about (disjoint) unions or Cartesian products of types.

Value space and behaviour

: A type is a set of values which a variable can possess and a set of functions that one can apply to these values.

The definition in terms of a representation was often done in imperative languages such as ALGOL and Pascal, while the definition in terms of a value space and behaviour was used in higher-level languages such as Simula and CLU.

Classes of data types

Primitive data types

Machine data types

All data in computers based on digital electronics is represented as bits (alternatives 0 and 1) on the lowest level. The smallest addressable unit of data is usually a group of bits called a byte (usually an octet, which is 8 bits). The unit processed by machine code instructions is called a word (as of 2011, typically 32 or 64 bits). Most instructions interpret the word as a binary number, such that a 32-bit word can represent unsigned integer values from 0 to $2^{32} - 1$ or signed integer values from -2^{31} to $2^{31} - 1$. Because of two's complement, the machine language and machine doesn't need to distinguish between these unsigned and signed data types for the most part.

There is a specific set of arithmetic instructions that use a different interpretation of the bits in word as a floating-point number.

Machine data types need to be *exposed* or made available in systems or low-level programming languages, allowing fine-grained control over hardware. The C programming language, for instance, supplies integer types of various widths, such as `short` and `long`. If a corresponding native type does not exist on the target platform, the compiler will break them down into code using types that do exist. For instance, if a 32-bit integer is requested on a 16 bit platform, the compiler will tacitly treat it as an array of two 16 bit integers.

Several languages allow binary and hexadecimal literals, for convenient manipulation of machine data.

In higher level programming, machine data types are often hidden or *abstracted* as an implementation detail that would render code less portable if exposed. For instance, a generic `numeric` type might be supplied instead of integers of some specific bit-width.

Boolean type

The Boolean type represents the values: true and false. Although only two values are possible, they are rarely implemented as a single binary digit for efficiency reasons. Many programming languages do not have an explicit boolean type, instead interpreting (for instance) 0 as false and other values as true.

Numeric types

Such as:

- The integer data types, or "whole numbers". May be subtyped according to their ability to contain negative values (e.g. `unsigned` in C and C++). May also have a small number of predefined subtypes (such as `short` and `long` in C/C++); or allow users to freely define subranges such as 1..12 (e.g. Pascal/Ada).
- Floating point data types, sometimes misleadingly called reals, contain fractional values. They usually have predefined limits on both their maximum values and their precision. These are often represented as decimal numbers.
- Fixed point data types are convenient for representing monetary values. They are often implemented internally as integers, leading to predefined limits.
- Bignum or arbitrary precision numeric types lack predefined limits. They are not primitive types, and are used sparingly for efficiency reasons.

Composite types

Composite types are derived from more than one primitive type. This can be done in a number of ways. The ways they are combined are called data structures. Composing a primitive type into a compound type generally results in a new type, e.g. *array-of-integer* is a different type to *integer*.

- An array stores a number of elements of the same type in a specific order. They are accessed using an integer to specify which element is required (although the elements may be of almost any type). Arrays may be fixed-length or expandable.
- Record (also called tuple or struct) Records are among the simplest data structures. A record is a value that contains other values, typically in fixed number and sequence and typically indexed by names. The elements of records are usually called *fields* or *members*.
- Union. A union type definition will specify which of a number of permitted primitive types may be stored in its instances, e.g. "float or long integer". Contrast with a record, which could be defined to contain a float *and* an integer; whereas, in a union, there is only one value at a time.
- A tagged union (also called a variant, variant record, discriminated union, or disjoint union) contains an additional field indicating its current type, for enhanced type safety.
- A set is an abstract data structure that can store certain values, without any particular order, and no repeated values. Values themselves are not retrieved from sets, rather one tests a value for membership to obtain a boolean "in" or "not in".
- An object contains a number of data fields, like a record, and also a number of program code fragments for accessing or modifying them. Data structures not containing code, like those above, are called plain old data structure.

Many others are possible, but they tend to be further variations and compounds of the above.

Enumerations

The enumerated type. This has values which are different from each other, and which can be compared and assigned, but which do not necessarily have any particular concrete representation in the computer's memory; compilers and interpreters can represent them arbitrarily. For example, the four suits in a deck of playing cards may be four enumerators named *CLUB*, *DIAMOND*, *HEART*, *SPADE*, belonging to an enumerated type named *suit*. If a variable *V* is declared having *suit* as its data type, one can assign any of those four values to it. Some implementations allow programmers to assign integer values to the enumeration values, or even treat them as type-equivalent to integers.

String and text types

Such as:

- Alphanumeric character. A letter of the alphabet, digit, blank space, punctuation mark, etc.
- Alphanumeric strings, a sequence of characters. They are typically used to represent words and text.

Character and string types can store sequences of characters from a character set such as ASCII. Since most character sets include the digits, it is possible to have a numeric string, such as `"1234"`. However, many languages would still treat these as belonging to a different type to the numeric value `1234`.

Character and string types can have different subtypes according to the required character "width". The original 7-bit wide ASCII was found to be limited, and superseded by 8 and 16-bit sets, which can encode a wide variety of non-Latin alphabets (Hebrew, Chinese) and other symbols. Strings may be either stretch-to-fit or of fixed size, even in the same programming language. They may also be subtyped by their maximum size.

Note: strings are not primitive in all languages, for instance C: they may be composed from arrays of characters.

Other types

Types can be based on, or derived from, the basic types explained above. In some languages, such as C, functions have a type derived from the type of their return value.

Pointers and references

The main non-composite, derived type is the pointer, a data type whose value refers directly to (or "points to") another value stored elsewhere in the computer memory using its address. It is a primitive kind of reference. (In everyday terms, a page number in a book could be considered a piece of data that refers to another one). Pointers are often stored in a format similar to an integer; however, attempting to dereference or "look up" a pointer whose value was never a valid memory address would cause a program to crash. To ameliorate this potential problem, pointers are considered a separate type to the type of data they point to, even if the underlying representation is the same.

Abstract data types

Any type that does not specify an implementation is an abstract data type. For instance, a stack (which is an abstract type) can be implemented as an array (a contiguous block of memory containing multiple values), or as a linked list (a set of non-contiguous memory blocks linked by pointers).

Abstract types can be handled by code that does not know or "care" what underlying types are contained in them. Programming that is agnostic about concrete data types is called generic programming. Arrays and records can also contain underlying types, but are considered concrete because they specify how their contents or elements are laid out in memory.

Examples include:

- A queue is a first-in first-out list. Variations are Deque and Priority queue.
- A set can store certain values, without any particular order, and with no repeated values.
- A stack is a last-in, first out.

- A tree is a hierarchical structure.
- A graph.
- A hash or dictionary or map or Map/Associative array/Dictionary is a more flexible variation on a record, in which name-value pairs can be added and deleted freely.
- A smart pointer is the abstract counterpart to a pointer. Both are kinds of reference

Utility types

For convenience, high-level languages may supply ready-made "real world" data types, for instance *times*, *dates* and *monetary values* and *memory*, even where the language allows them to be built from primitive types.

Type systems

A type system associates types with each computed value. By examining the flow of these values, a type system attempts to prove that no *type errors* can occur. The type system in question determines what constitutes a type error, but a type system generally seeks to guarantee that operations expecting a certain kind of value are not used with values for which that operation does not make sense.

A compiler may use the static type of a value to optimize the storage it needs and the choice of algorithms for operations on the value. In many C compilers the `float` data type, for example, is represented in 32 bits, in accord with the IEEE specification for single-precision floating point numbers. They will thus use floating-point-specific microprocessor operations on those values (floating-point addition, multiplication, etc.).

The depth of type constraints and the manner of their evaluation affect the *typing* of the language. A programming language may further associate an operation with varying concrete algorithms on each type in the case of type polymorphism. Type theory is the study of type systems, although the concrete type systems of programming languages originate from practical issues of computer architecture, compiler implementation, and language design.

Type systems may be variously static or dynamic, strong or weak typing, and so forth.

Statements

Select

The SQL **SELECT** statement returns a result set of records from one or more tables.

A **SELECT** statement retrieves zero or more rows from one or more database tables or database views. In most applications, `SELECT` is the most commonly used Data Manipulation Language (DML) command. As SQL is a declarative programming language, `SELECT` queries specify a result set, but do not specify how to calculate it. The database translates the query into a "query plan" which may vary between executions, database versions and database software. This functionality is called the "query optimizer" as it is responsible for finding the best possible execution plan for the query, within applicable constraints.

The SELECT statement has many optional clauses:

- `WHERE` specifies which rows to retrieve.
- `GROUP BY` groups rows sharing a property so that an aggregate function can be applied to each group.
- `HAVING` selects among the groups defined by the GROUP BY clause.
- `ORDER BY` specifies an order in which to return the rows.
- `AS` provides an alias which can be used to temporarily rename tables or columns.

Examples

Table "T"	Query	Result
C1 | **C2** 1 | a 2 | b	`SELECT * FROM T;`	**C1** | **C2** 1 | a 2 | b
C1 | **C2** 1 | a 2 | b	`SELECT C1 FROM T;`	**C1** 1 2
C1 | **C2** 1 | a 2 | b	`SELECT * FROM T WHERE C1 = 1;`	**C1** | **C2** 1 | a
C1 | **C2** 1 | a 2 | b	`SELECT * FROM T ORDER BY C1 DESC;`	**C1** | **C2** 2 | b 1 | a

Given a table T, the *query* `SELECT * FROM T` will result in all the elements of all the rows of the table being shown.

With the same table, the query `SELECT C1 FROM T` will result in the elements from the column C1 of all the rows of the table being shown. This is similar to a *projection* in Relational algebra, except that in the general case, the result may contain duplicate rows. This is also known as a Vertical Partition in some database terms, restricting query output to view only specified fields or columns.

With the same table, the query `SELECT * FROM T WHERE C1 = 1` will result in all the elements of all the rows where the value of column C1 is '1' being shown — in Relational algebra terms, a *selection* will be performed, because of the WHERE clause. This is also known as a Horizontal Partition, restricting rows output by a query according to specified conditions.

With more than one table, the result set will be every combination of rows. So if two tables are T1 and T2, `SELECT * FROM T1, T2` will result in every combination of T1 rows with every T2 rows. E.g., if T1 has 3 rows and T2 has 5 rows, then 15 rows will result.

Limiting result rows

Often it is convenient to indicate a maximum number of rows that are returned. This can be used for testing or to prevent consuming excessive resources if the query returns more information than expected. The approach to do this often varies per vendor.

In ISO SQL:2003, result sets may be limited by using

- cursors, or
- By introducing *SQL window function* to the SELECT-statement

ISO SQL:2008 introduced the `FETCH FIRST` clause.

ROW_NUMBER() window function

`ROW_NUMBER() OVER` may be used for a *simple table* on the returned rows, e.g. to return no more than ten rows:

```
SELECT * FROM
( SELECT
    ROW_NUMBER() OVER (ORDER BY sort_key ASC) AS row_number,
    columns
  FROM tablename
) AS foo
WHERE row_number <= 11
```

ROW_NUMBER can be non-deterministic: if *sort_key* is not unique, each time you run the query it is possible to get different row numbers assigned to any rows where *sort_key* is the same. When *sort_key* is unique, each row will always get a unique row number.

RANK() window function

The `RANK() OVER` window function acts like ROW_NUMBER, but may return more than *n* rows in case of tie conditions, e.g. to return the top-10 youngest persons:

```
SELECT * FROM (
  SELECT
    RANK() OVER (ORDER BY age ASC) AS ranking,
    person_id,
    person_name,
    age
  FROM person
```

```
)AS foo
WHERE ranking <= 10
```

The above code could return more than ten rows, e.g. if there are two people of the same age, it could return eleven rows.

FETCH FIRST clause

Since ISO SQL:2008 results limits can be specified as in the following example using the `FETCH FIRST` clause.

```
SELECT * FROM T FETCH FIRST 10 ROWS ONLY
```

This clause currently is supported by CA DATACOM/DB 11,IBM DB2, Sybase SQL Anywhere, PostgreSQL, EffiProz, H2, HSQLDB version 2.0, Microsoft SQL Server 2012 and Oracle 12c.

Result limits

Not all DBMSs support the mentioned window functions, and non-standard syntax has to be used. Below, variants of the *simple limit* query for different DBMSes are listed:

`SET ROWCOUNT 10` `SELECT * FROM T`	MS SQL Server (This also works on Microsoft SQL Server 6.5 while the **Select top 10 * from T** does not)
`SELECT * FROM T LIMIT 10 OFFSET 20`	Netezza, MySQL, Sybase SQL Anywhere, PostgreSQL (also supports the standard, since version 8.4), SQLite, HSQLDB, H2, Vertica, Polyhedra
`SELECT * from T WHERE ROWNUM <= 10`	Oracle
`SELECT FIRST 10 * from T`	Ingres
`SELECT FIRST 10 * FROM T order by a`	Informix
`SELECT SKIP 20 FIRST 10 * FROM T order by c, d`	Informix (row numbers are filtered after order by is evaluated. SKIP clause was introduced in a v10.00.xC4 fixpack)
`SELECT TOP 10 * FROM T`	MS SQL Server, Sybase ASE, MS Access, Sybase IQ, Teradata
`SELECT TOP 10 START AT 20 * FROM T`	Sybase SQL Anywhere (also supports the standard, since version 9.0.1)
`SELECT FIRST 10 SKIP 20 * FROM T`	Interbase, Firebird
`SELECT * FROM T ROWS 20 TO 30`	Firebird (since version 2.1)
`SELECT * FROM T` `WHERE ID_T > 10 FETCH FIRST 10 ROWS ONLY`	DB2
`SELECT * FROM T` `WHERE ID_T > 20 FETCH FIRST 10 ROWS ONLY`	DB2 (new rows are filtered after comparing with key column of table T)

Hierarchical query

Some databases provide specialised syntax for hierarchical data.

Window function

A window function in SQL:2003 is an aggregate function applied to a partition of the result set.

For example,

```
sum(population) OVER( PARTITION BY city )
```

calculates the sum of the populations of all rows having the same *city* value as the current row.

Partitions are specified using the **OVER** clause which modifies the aggregate. Syntax:

```
<OVER_CLAUSE> :: =
   OVER ( [ PARTITION BY <expr>, ... ]
          [ ORDER BY <expression> ] )
```

The OVER clause can partition and order the result set. Ordering is used for order-relative functions such as row_number.

Query evaluation ANSI

The processing of a SELECT statement according to ANSI SQL would be the following:[1]

```
select g.*
from users u inner join groups g on g.Userid = u.Userid
where u.LastName = 'Smith'
and u.FirstName = 'John'
```

2. the FROM clause is evaluated, a cross join or Cartesian product is produced for the first two tables in the FROM clause resulting in a virtual table as Vtable1
3. the ON clause is evaluated for vtable1; only records which meet the join condition g.Userid = u.Userid are inserted into Vtable2
4. If an outer join is specified, records which were dropped from vTable2 are added into VTable 3, for instance if the above query were:

```
select u.*
from users u left join groups g on g.Userid = u.Userid
where u.LastName = 'Smith'
and u.FirstName = 'John'
```

   all users who did not belong to any groups would be added back into Vtable3
5. the WHERE clause is evaluated, in this case only group information for user John Smith would be added to vTable4
6. the GROUP BY is evaluated; if the above query were:

```
select g.GroupName, count(g.*) as NumberOfMembers
from users u inner join groups g on g.Userid = u.Userid
group by GroupName
```

   vTable5 would consist of members returned from vTable4 arranged by the grouping, in this case the GroupName

7. the HAVING clause is evaluated for groups for which the HAVING clause is true and inserted into vTable6. For example:

```
select g.GroupName, count(g.*) as NumberOfMembers
from users u inner join groups g on g.Userid = u.Userid
group by GroupName
having count(g.*) > 5
```

8. the SELECT list is evaluated and returned as Vtable 7
9. the DISTINCT clause is evaluated; duplicate rows are removed and returned as Vtable 8
10. the ORDER BY clause is evaluated, ordering the rows and returning VCursor9. This is a cursor and not a table because ANSI defines a cursor as an ordered set of rows (not relational).

Generating Data in T-SQL

Method to generate data based on the union all

```
select 1 a, 1 b union all
select 1, 2 union all
select 1, 3 union all
select 2, 1 union all
select 5, 1
```

Enhancement made in SQL Server 2008 release

```
select *
from (values (1, 1), (1, 2), (1, 3), (2, 1), (5, 1)) as x(a, b)
```

Result set

An SQL **result set** is a set of rows from a database, as well as metadata about the query such as the column names, and the types and sizes of each column. Depending on the database system, the number of rows in the result set may or may not be known. Usually, this number is not known up front because the result set is built on-the-fly. Precomputations often impose undesired performance impacts.Wikipedia:Disputed statement

A result set is effectively a table. The `ORDER BY` clause can be used in a query to impose a certain sort condition on the rows. Without that clause, there is no guarantee whatsoever on the order in which the rows are returned.

Synonym (database)

A **synonym** is an alias or alternate name for a table, view, sequence, or other schema object. They are used mainly to make it easy for users to access database objects owned by other users. They hide the underlying object's identity and make it harder for a malicious program or user to target the underlying object. Because a synonym is just an alternate name for an object, it requires no storage other than its definition. When an application uses a synonym, the DBMS forwards the request to the synonym's underlying base object. By coding your programs to use synonyms instead of database object names, you insulate yourself from any changes in the name, ownership, or object locations. If you frequently refer to a database object that has a long name, you might appreciate being able to refer to it with a shorter name without having to rename it and alter the code referring to it.

Synonyms are very powerful from the point of view of allowing users access to objects that do not lie within their schema. All synonyms have to be created explicitly with the CREATE SYNONYM command and the underlying objects can be located in the same database or in other databases that are connected by database links[*clarify*].

There are two major uses of synonyms:

- **Object invisibility**: Synonyms can be created to keep the original object hidden from the user.
- **Location invisibility**: Synonyms can be created as aliases for tables and other objects that are not part of the local database.

When you create a table or a procedure, it is created in your schema, and other users can access it only by using your schema name as a prefix to the object's name. The way around for this is for the schema owner creates a synonym with the same name as the table name.

Public synonyms

Public synonyms are owned by special schema in the Oracle Database called PUBLIC. As mentioned earlier, public synonyms can be referenced by all users in the database. Public synonyms are usually created by the application owner for the tables and other objects such as procedures and packages so the users of the application can see the objects.

The following code shows how to create a public synonym for the employee table:

```
CREATE PUBLIC SYNONYM employees for hr.employees;
```

Now any user can see the table by just typing the original table name. If you wish, you could provide a different table name for that table in the CREATE SYNONYM statement. Remember that the DBA must explicitly grant the CREATE PUBLIC SYNONYM privilege to the user HR before HR can create any public synonyms. Just because you can see a table through public (or private) synonym doesn't mean that you can also perform SELECT, INSERT, UPDATE or DELETE operations on the table. To be able to perform those operations, a user needs specific privileges for the underlying object, either directly or through roles from the application owner.

Private synonyms

A private synonym is a synonym within a database schema that a developer typically uses to mask the true name of a table, view stored procedure, or other database object in an application schema.

Private synonyms, unlike public synonyms, can be referenced only by the schema that owns the table or object. You may want to create private synonyms when you want to refer to the same table by different contexts. Private synonym overrides public synonym definitions. You create private synonyms the same way you create public synonyms, but you omit the PUBLIC keyword in the CREATE statement.

The following example shows how to create a private synonym called addresses for the locations table. Note that once you create the private synonym, you can refer to the synonym exactly as you would the original table name.

```
CREATE SYNONYM addresses FOR hr.locations;
```

Drop a synonym

Synonyms, both private and public, are dropped in the same manner by using the DROP SYNONYM command, but there is one important difference. If you are dropping a public synonym; you need to add the keyword PUBLIC after the keyword DROP.

```
DROP SYNONYM addresses;
```

The ALL_SYNONYMS (or DBA_SYNONYMS) view provides information on all synonyms in your database.

Alias (SQL)

An **alias** is a feature of SQL that is supported by most, if not all, relational database management systems (RDBMSs). Aliases provide database administrators, as well as other database users, with the ability to reduce the amount of code required for a query, and to make queries generally simpler to understand. In addition, aliasing can be used as an obfuscation technique to protect the real names of database fields.

In SQL, you can alias both tables themselves, which is called a Correlation Name,[1] or columns. A programmer can temporarily assign another name to a table or column (for the duration of the SELECT query) by using an alias. In other words, it does not actually rename the column or table. This is often useful when either tables or their columns have very long or complex names. An alias name could be anything, but usually it is kept short. For example, it might be common to use a table alias such as "pi" for a table named "price_information".

The general syntax of an alias is `SELECT * FROM table_name [AS] alias_name`. Note that the AS keyword is completely optional and is usually kept for readability purposes. Here is some sample data that the queries below will be referencing:

Department Table

DepartmentID	DepartmentName
31	Sales
33	Engineering
34	Clerical
35	Marketing

Using a table alias:

```
SELECT D.DepartmentName FROM Department AS D
```

We can also write the same query like this (Note that the AS clause is omitted this time):

```
SELECT D.DepartmentName FROM Department D
```

A column alias is similar:

```
SELECT d.DepartmentId AS Id, d.DepartmentName AS Name FROM Department d
```

In the returned result sets, the data shown above would be returned, with the only exception being "DepartmentID" would show up as "Id", and "DepartmentName" would show up as "Name".

Also, if only one table is being selected and the query is not using table joins, it is permissible to omit the table name or table alias from the column name in the SELECT statement. Example as follows:

```
SELECT DepartmentId AS Id, DepartmentName AS Name FROM Department d
```

Insert

An SQL **INSERT** statement adds one or more records to any single table in a relational database.

Basic form

Insert statements have the following form:

- INSERT INTO *table* (*column1* [, *column2*, *column3* ...]) VALUES (*value1* [, *value2*, *value3* ...])

The number of columns and values must be the same. If a column is not specified, the default value for the column is used. The values specified (or implied) by the `INSERT` statement must satisfy all the applicable constraints (such as primary keys, `CHECK` constraints, and `NOT NULL` constraints). If a syntax error occurs or if any constraints are violated, the new row is not added to the table and an error returned instead.

Example:

```
INSERT INTO phone_book (name, number) VALUES ('John Doe', '555-1212');
```

Shorthand may also be used, taking advantage of the order of the columns when the table was created. It is not required to specify all columns in the table since any other columns will take their default value or remain null:

- INSERT INTO *table* VALUES (*value1*, [*value2*, ...])

Example for inserting data into 2 columns in the phone_book table and ignoring any other columns which may be after the first 2 in the table.

```
INSERT INTO phone_book VALUES ('John Doe', '555-1212');
```

Advanced forms

Multirow inserts

A SQL feature (since SQL-92) is the use of *row value constructors* to insert multiple rows at a time in a single SQL statement:

```
INSERT INTO table (column-a, [column-b, ...])
VALUES ('value-1a', ['value-1b', ...]),
       ('value-2a', ['value-2b', ...]),
       ...
```

This feature is supported by DB2, SQL Server (since version 10.0 - i.e. 2008), PostgreSQL (since version 8.2), MySQL, sqlite (since version 3.7.11) and H2.

Example (assuming that 'name' and 'number' are the only columns in the 'phone_book' table):

```
INSERT INTO phone_book VALUES ('John Doe', '555-1212'), ('Peter Doe',
'555-2323');
```

which may be seen as a shorthand for the two statements

```
INSERT INTO phone_book VALUES ('John Doe', '555-1212');
INSERT INTO phone_book VALUES ('Peter Doe', '555-2323');
```

Note that the two separate statements may have different semantics (especially with respect to statement triggers) and may not provide the same performance as a single multi-row insert.

To insert multiple rows in MS SQL you can use such a construction:

```
INSERT INTO phone_book
SELECT 'John Doe', '555-1212'
UNION ALL
SELECT 'Peter Doe', '555-2323';
```

Note that this is not a valid SQL statement according to the SQL standard (SQL:2003) due to the incomplete subselect clause.

To do the same in Oracle use the DUAL table, which always consists of a single row only:

```
INSERT INTO phone_book
SELECT 'John Doe', '555-1212' FROM DUAL
UNION ALL
SELECT 'Peter Doe','555-2323' FROM DUAL
```

A standard-conforming implementation of this logic shows the following example, or as shown above:

```
INSERT INTO phone_book
SELECT 'John Doe', '555-1212' FROM LATERAL ( VALUES (1) ) AS t(c)
UNION ALL
SELECT 'Peter Doe','555-2323' FROM LATERAL ( VALUES (1) ) AS t(c)
```

Oracle PL/SQL supports the "INSERT ALL" statement, where multiple insert statements are terminated by a SELECT:

```
INSERT ALL
INTO phone_book VALUES ('John Doe', '555-1212')
INTO phone_book VALUES ('Peter Doe', '555-2323')
SELECT * FROM DUAL;
```

In Firebird inserting multiple rows can be achieved like this:

```
INSERT INTO phone_book ("name", "number")
SELECT 'John Doe', '555-1212' FROM RDB$DATABASE
UNION ALL
SELECT 'Peter Doe', '555-2323' FROM RDB$DATABASE;
```

Firebird however restricts the number of rows than can be inserted in this way, since there is a limit to the number contexts that can be used in a single query.

Copying rows from other tables

An INSERT statement can also be used to retrieve data from other tables, modify it if necessary and insert it directly into the table. All this is done in a single SQL statement that does not involve any intermediary processing in the client application. A subselect is used instead of the VALUES clause. The subselect can contain joins, function calls, and it can even query the same table into which the data is inserted. Logically, the select is evaluated before the actual insert operation is started. An example is given below.

```
INSERT INTO phone_book2
SELECT *
FROM   phone_book
WHERE  name IN ('John Doe', 'Peter Doe')
```

A variation is needed when some of the data from the source table is being inserted into the new table, but not the whole record. (Or when the tables' schemas are not the same.)

```
INSERT INTO phone_book2 ( [name], [phoneNumber] )
SELECT [name], [phoneNumber]
FROM   phone_book
WHERE  name IN ('John Doe', 'Peter Doe')
```

The `SELECT` statement produces a (temporary) table, and the schema of that temporary table must match with the schema of the table where the data is inserted into.

Retrieving the key

Database designers that use a surrogate key as the primary key for every table will run into the occasional scenario where they need to automatically retrieve the database generated primary key from an SQL INSERT statement for use in another SQL statements. Most systems do not allow SQL INSERT statements to return row data. Therefore, it becomes necessary to implement a workaround in such scenarios. Common implementations include:

- Using a database-specific stored procedure that generates the surrogate key, performs the INSERT operation, and finally returns the generated key. For example, in Microsoft SQL Server, the key is retrieved via the SCOPE_IDENTITY() special function, while in SQLite the function is named last_insert_rowid().
- Using a database-specific SELECT statement on a temporary table containing last inserted row(s). DB2 implements this feature in the following way:

```
SELECT *
FROM NEW TABLE (
    INSERT INTO phone_book
    VALUES ( 'Peter Doe','555-2323' )
) AS t
```

DB2 for z/OS implements this feature in the following way.

```
SELECT EMPNO, HIRETYPE, HIREDATE
FROM FINAL TABLE (
    INSERT INTO EMPSAMP (NAME, SALARY, DEPTNO, LEVEL)
    VALUES('Mary Smith', 35000.00, 11, 'Associate')
);
```

- Using a SELECT statement after the INSERT statement with a database-specific function that returns the generated primary key for the most recently inserted row. For example, LAST_INSERT_ID() for MySQL.
- Using a unique combination of elements from the original SQL INSERT in a subsequent SELECT statement.
- Using a GUID in the SQL INSERT statement and retrieving it in a SELECT statement.
- Using the OUTPUT clause in the SQL INSERT statement for MS-SQL Server 2005 and MS-SQL Server 2008.
- Using an INSERT statement with RETURNING clause for Oracle.

```
INSERT INTO phone_book VALUES ( 'Peter Doe','555-2323' )
RETURNING phone_book_id INTO v_pb_id
```

- Using an INSERT statement with RETURNING clause for PostgreSQL (since 8.2). The returned list is identical to the result of a SELECT.

Firebird has the same syntax in Data Modification Language statements (DSQL); the statement may add at most one row. In stored procedures, triggers and execution blocks (PSQL) the aforementioned Oracle syntax is used.

```
INSERT INTO phone_book VALUES ( 'Peter Doe','555-2323' )
RETURNING phone_book_id
```

- Using the IDENTITY() function in H2 returns the last identity inserted.

```
SELECT IDENTITY();
```

Triggers

If triggers are defined on the table on which the INSERT statement operates, those triggers are evaluated in the context of the operation. BEFORE INSERT triggers allow the modification of the values that shall be inserted into the table. AFTER INSERT triggers cannot modify the data anymore, but can be used to initiate actions on other tables, for example- to implement auditing mechanism.

- Oracle SQL INSERT statement (Oracle Database SQL Language Reference, 11g Release 2 (11.2) on oracle.com) (http://download.oracle.com/docs/cd/E11882_01/server.112/e10592/statements_9014.htm)
- Microsoft Access Append Query Examples and SQL INSERT Query Syntax (http://www.fmsinc.com/MicrosoftAccess/query/snytax/append-query.html)

Update

An SQL **UPDATE** statement changes the data of one or more records in a table. Either all the rows can be updated, or a subset may be chosen using a condition.

The `UPDATE` statement has the following form:[1]

`UPDATE` *table_name* **`SET`** *column_name* = *value* [, *column_name* = *value* ...] [**`WHERE`** *condition*]

For the `UPDATE` to be successful, the user must have data manipulation privileges (`UPDATE` privilege) on the table or column and the updated value must not conflict with all the applicable constraints (such as primary keys, unique indexes, `CHECK` constraints, and `NOT NULL` constraints).

In some databases, such as PostgreSQL, when a FROM clause is present, what essentially happens is that the target table is joined to the tables mentioned in the fromlist, and each output row of the join represents an update operation for the target table. When using FROM, one should ensure that the join produces at most one output row for each row to be modified. In other words, a target row shouldn't join to more than one row from the other table(s). If it does, then only one of the join rows will be used to update the target row, but which one will be used is not readily predictable.[2]

Because of this indeterminacy, referencing other tables only within sub-selects is safer, though often harder to read and slower than using a join.

Examples

Set the value of column *C1* in table *T* to 1, only in those rows where the value of column *C2* is "a".

```
UPDATE T
   SET C1 = 1
 WHERE C2 = 'a'
```

In table *T*, set the value of column *C1* to 9 and the value of *C3* to 4 for all rows for which the value of column *C2* is "a".

```
UPDATE T
   SET C1 = 9,
       C3 = 4
 WHERE C2 = 'a'
```

Increase value of column *C1* by 1 if the value in column *C2* is "a".

```
UPDATE T
   SET C1 = C1 + 1
 WHERE C2 = 'a'
```

Prepend the value in column *C1* with the string "text" if the value in column *C2* is "a".

```
UPDATE T
   SET C1 = 'text' || C1
 WHERE C2 = 'a'
```

Set the value of column *C1* in table *T1* to 2, only if the value of column *C2* is found in the sublist of values in column *C3* in table *T2* having the column *C4* equal to 0.

```
UPDATE T1
   SET C1 = 2
 WHERE C2 IN ( SELECT C3
                 FROM T2
                WHERE C4 = 0)
```

One may also update multiple columns in a single update statement:

```
UPDATE T
   SET C1 = 1,
       C2 = 2
```

Complex conditions and JOINs are also possible:

```
UPDATE T
   SET A = 1
 WHERE C1 = 1
   AND C2 = 2
```

Some databases allow the non-standard use of the FROM clause:

```
UPDATE a
   SET a.[updated_column] = updatevalue
  FROM articles a
```

```
       JOIN classification c
         ON a.articleID = c.articleID
 WHERE c.classID = 1
```

Or on Oracle systems (assuming there is an index on classification.articleID):

```
UPDATE
(
  SELECT *
    FROM articles
    JOIN classification
      ON articles.articleID = classification.articleID
   WHERE classification.classID = 1
)
SET [updated_column] = updatevalue
```

Potential issues

See Halloween Problem. It is possible for certain kinds of UPDATE statements to become an infinite loop when the WHERE clause and one or more SET clauses may utilize an intertwined index.

References

[1] http://dev.mysql.com/doc/refman/5.0/en/update.html simplified from this page
[2] http://www.postgresql.org/docs/8.1/static/sql-update.html

Merge

A relational database management system uses SQL `MERGE` (also called *upsert*) statements to `INSERT` new records or `UPDATE` existing records depending on whether or not a condition matches. It was officially introduced in the SQL:2003 standard, and expanded in the SQL:2008 standard.

Usage

```
MERGE INTO tablename USING table_reference ON (condition)
  WHEN MATCHED THEN
  UPDATE SET column1 = value1 [, column2 = value2 ...]
  WHEN NOT MATCHED THEN
  INSERT (column1 [, column2 ...]) VALUES (value1 [, value2 ...
```

Right join is employed over the Target (the INTO table) and the Source (the USING table / view / sub-query). That is:

- If rows present in the Source but missing from the Target do run the action then specifically the NOT MATCHED action
- If rows missing from the Source and present in Target are ignored then no action is performed on the Target.

If multiple Source rows match a given Target row, an error is mandated by SQL:2003 standards. You cannot update a Target row multiple times with a MERGE statement

Implementations

Database management systems Oracle Database, DB2, Teradata, EXASOL and MS SQL support the standard syntax. Some also add non-standard SQL extensions.

Synonymous

Some database implementations adopted the term "**Upsert**" (a portmanteau of *update* and *insert*) to a database statement, or combination of statements, that inserts a record to a table in a database if the record does not exist or, if the record already exists, updates the existing record. It is also used to abbreviate the "MERGE" equivalent pseudo-code.

It is used in Microsoft SQL Azure and MongoDB.

MongoDB provides an atomic upsert operation, which creates a new document by combining the criteria for the update with the fields to change.

Example

Suppose a collection is used to track the number of times each page of a website is viewed. Upserts can be used to avoid "seeding" the collection with all possible pages in advance. The collection starts off empty:

```
 > db.pages.find()
```

On each page view, the page's document is created if it doesn't exist yet and its views are incremented if it does.

```
 > db.pages.update({"_id" : "http://www.example.com"}, {"$inc" :
{"views" : 1}}, {upsert : true})
 > db.pages.find()
 { "_id" : "http://www.example.com", "views" : 1 }
 > db.pages.update({"_id" : "http://www.example.com"}, {"$inc" :
{"views" : 1}}, {upsert : true})
 { "_id" : "http://www.example.com", "views" : 2 }
```

Other non-standard implementations

Some other database management systems support this, or very similar behavior, through their own, non-standard SQL extensions.

MySQL, for example, supports the use of `INSERT ... ON DUPLICATE KEY UPDATE` syntax[1] which can be used to achieve a similar effect with the limitation that the join between target and source has to be made only on PRIMARY KEY or UNIQUE constraints, which is not required in the ANSI/ISO standard. It also supports `REPLACE INTO` syntax,[2] which first attempts an insert, and if that fails, deletes the row, if exists, and then inserts the new one. There is also an `IGNORE` clause for the `INSERT` statement, which tells the server to ignore "duplicate key" errors and go on (existing rows will not be inserted or updated, but all new rows will be inserted).

SQLite's `INSERT OR REPLACE INTO` works similarly. It also supports `REPLACE INTO` as an alias for compatibility with MySQL.

Firebird supports `MERGE INTO` though fails at throwing error when multiple Source data. Additionally a single-row version, `UPDATE OR INSERT INTO tablename (columns) VALUES (values) [MATCHING (columns)]`, but the latter does not give you the option to take different actions on insert vs. update (e.g. setting a new sequence value only for new rows, not for existing ones.)

IBM DB2 extends syntax with multiple `WHEN MATCHED` and `WHEN NOT MATCHED` clauses, distinguishing them with `... AND some-condition` guards.

Microsoft SQL extends with supporting guards and also with supporting Left Join via `WHEN NOT MATCHED BY SOURCE` clauses.

Delete

In the database structured query language (SQL), the **DELETE** statement removes one or more records from a table. A subset may be defined for deletion using a condition, otherwise all records are removed. Some DBMSs, like MySQL, allow to delete rows from multiple tables with one DELETE statement (this is sometimes called multi-table DELETE).

Usage

The `DELETE` statement follows the syntax:

> **`DELETE`** `FROM` *table_name* [**`WHERE`** condition];

Any rows that match the `WHERE` condition will be removed from the table. If the `WHERE` clause is omitted, all rows in the table are removed. The `DELETE` statement should thus be used with caution.

The `DELETE` statement does not return any rows; that is, it will not generate a result set.

Executing a `DELETE` statement can cause triggers to run that can cause deletes in other tables. For example, if two tables are linked by a foreign key and rows in the referenced table are deleted, then it is common that rows in the referencing table would also have to be deleted to maintain referential integrity.

Examples

Delete rows from table *pies* where the column *flavour* equals *Lemon Meringue*:

```
DELETE FROM pies
 WHERE flavour='Lemon Meringue';
```

Delete rows in *trees*, if the value of *height* is smaller than 80.

```
DELETE FROM trees
 WHERE height < 80;
```

Delete all rows from *mytable*:

```
DELETE FROM mytable;
```

Delete rows from *mytable* using a subquery in the where condition:

```
DELETE FROM mytable
 WHERE id IN (
       SELECT id
         FROM mytable2
      );
```

Delete rows from *mytable* using a list of values:

```
DELETE FROM mytable
 WHERE id IN (
       value1,
       value2,
       value3,
       value4,
       value5
      );
```

Example with related tables

Suppose there is a simple database that lists people and addresses. More than one person can live at a particular address and a person can live at more than one address (this is an example of a many-to-many relationship). The database only has three tables, *person*, *address*, and *pa*, with the following data:

person

pid	name
1	Joe
2	Bob
3	Ann

address

aid	description
100	2001 Main St.
200	35 Pico Blvd.

pa

pid	aid
1	100
2	100
3	100
1	200

The *pa* table relates the person and address tables, showing that Joe, Bob and Ann all live at 2001 Main Street, but Joe also takes up residence on Pico Boulevard.

In order to remove joe from the database, two deletes must be executed:

```
DELETE FROM person WHERE pid=1;
DELETE FROM pa WHERE pid=1;
```

To maintain referential integrity, Joe's records must be removed from both *person* and *pa*. The means by which integrity is sustained can happen differently in varying relational database management systems [*citation needed*]. It could be that beyond just having three tables, the database also has been set up with a trigger so that whenever a row is deleted from *person* any linked rows would be deleted from *pa*. Then the first statement:

```
DELETE FROM person WHERE pid=1;
```

would *automatically* trigger the second:

```
DELETE FROM pa WHERE pid=1;
```

Related commands

Deleting all rows from a table can be very time consuming. Some DBMSWikipedia:Please clarify offer a TRUNCATE TABLE command that works a lot quicker, as it only alters metadata and typically does not spend time enforcing constraints or firing triggers.

DELETE only deletes the rows. For deleting a table entirely the DROP command can be used.

Join

An SQL **join** clause combines records from two or more tables in a database. It creates a set that can be saved as a table or used as it is. A `JOIN` is a means for combining fields from two tables by using values common to each. ANSI-standard SQL specifies five types of `JOIN`: `INNER`, `LEFT OUTER`, `RIGHT OUTER`, `FULL OUTER` and `CROSS`. As a special case, a table (base table, view, or joined table) can `JOIN` to itself in a *self-join*.

A programmer writes a `JOIN` statement to identify the records for joining. If the evaluated predicate is true, the combined record is then produced in the expected format, a record set or a temporary table.

Sample tables

Relational databases are often normalized to eliminate duplication of information when objects may have one-to-many relationships. For example, a Department may be associated with many different Employees. Joining two tables effectively creates another table which combines information from both tables. This is at some expense in terms of the time it takes to compute the join. While it is also possible to simply maintain a denormalized table if speed is important, duplicate information may take extra space, and add the expense and complexity of maintaining data integrity if data which is duplicated later changes.

All subsequent explanations on join types in this article make use of the following two tables. The rows in these tables serve to illustrate the effect of different types of joins and join-predicates. In the following tables the `DepartmentID` column of the `Department` table (which can be designated as `Department.DepartmentID`) is the primary key, while `Employee.DepartmentID` is a foreign key.

Employee table

LastName	DepartmentID
Rafferty	31
Jones	33
Heisenberg	33
Robinson	34
Smith	34
John	

Department table

DepartmentID	DepartmentName
31	Sales
33	Engineering
34	Clerical
35	Marketing

Note: In the Employee table above, the employee "John" has not been assigned to any department yet. Also, note that no employees are assigned to the "Marketing" department.

This is the SQL to create the aforementioned tables.

```
CREATE TABLE department
(
```

```
 DepartmentID INT,
 DepartmentName VARCHAR(20)
);

CREATE TABLE employee
(
 LastName VARCHAR(20),
 DepartmentID INT
);

INSERT INTO department(DepartmentID, DepartmentName) VALUES(31,
'Sales');
INSERT INTO department(DepartmentID, DepartmentName) VALUES(33,
'Engineering');
INSERT INTO department(DepartmentID, DepartmentName) VALUES(34,
'Clerical');
INSERT INTO department(DepartmentID, DepartmentName) VALUES(35,
'Marketing');

INSERT INTO employee(LastName, DepartmentID) VALUES('Rafferty', 31);
INSERT INTO employee(LastName, DepartmentID) VALUES('Jones', 33);
INSERT INTO employee(LastName, DepartmentID) VALUES('Heisenberg', 33);
INSERT INTO employee(LastName, DepartmentID) VALUES('Robinson', 34);
INSERT INTO employee(LastName, DepartmentID) VALUES('Smith', 34);
INSERT INTO employee(LastName, DepartmentID) VALUES('John', NULL);
```

Cross join

CROSS JOIN returns the Cartesian product of rows from tables in the join. In other words, it will produce rows which combine each row from the first table with each row from the second table.[1]

Example of an explicit cross join:

```
SELECT *
FROM employee CROSS JOIN department;
```

Example of an implicit cross join:

```
SELECT *
FROM employee, department;
```

Employee.LastName	Employee.DepartmentID	Department.DepartmentName	Department.DepartmentID
Rafferty	31	Sales	31
Jones	33	Sales	31
Heisenberg	33	Sales	31
Smith	34	Sales	31
Robinson	34	Sales	31
John		Sales	31
Rafferty	31	Engineering	33
Jones	33	Engineering	33
Heisenberg	33	Engineering	33
Smith	34	Engineering	33
Robinson	34	Engineering	33
John		Engineering	33
Rafferty	31	Clerical	34
Jones	33	Clerical	34
Heisenberg	33	Clerical	34
Smith	34	Clerical	34
Robinson	34	Clerical	34
John		Clerical	34
Rafferty	31	Marketing	35
Jones	33	Marketing	35
Heisenberg	33	Marketing	35
Smith	34	Marketing	35
Robinson	34	Marketing	35
John		Marketing	35

The cross join does not apply any predicate to filter records from the joined table. Programmers can further filter the results of a cross join by using a `WHERE` clause.

In the SQL:2011 standard, cross joins are part of the optional F401, "Extended joined table", package.

Inner join

An ***'inner join'*** is a commonly used join operation used in applications. It can only be safely used in a database that enforces referential integrity or where the join fields are guaranteed not to be NULL. Many transaction processing relational databases rely on Atomicity, Consistency, Isolation, Durability (ACID) data update standards to ensure data integrity, making inner joins an appropriate choice. Many reporting relational database and data warehouses use high volume Extract, Transform, Load (ETL) batch updates which make referential integrity difficult or impossible to enforce, resulting in potentially NULL join fields that a SQL query author cannot modify and which cause inner joins to omit data with no indication of an error. The choice to use an inner join depends on the database design and data characteristics. A left outer join can usually be substituted for an inner join when the join field in one table may contain NULL values. A commitment to an inner join assumes NULL join fields will not be introduced by future changes, including vendor updates, design changes and bulk processing outside of the application's data validation

rules such as data conversions.

Inner join creates a new result table by combining column values of two tables (A and B) based upon the join-predicate. The query compares each row of A with each row of B to find all pairs of rows which satisfy the join-predicate. When the join-predicate is satisfied, column values for each matched pair of rows of A and B are combined into a result row. The result of the join can be defined as the outcome of first taking the Cartesian product (or Cross join) of all records in the tables (combining every record in table A with every record in table B) and then returning all records which satisfy the join predicate. Actual SQL implementations normally use other approaches, such as hash joins or sort-merge joins, since computing the Cartesian product is very inefficient.

SQL specifies two different syntactical ways to express joins: "explicit join notation" and "implicit join notation".

The "explicit join notation" uses the **`JOIN`** keyword, optionally preceded by the **`INNER`** keyword, to specify the table to join, and the **`ON`** keyword to specify the predicates for the join, as in the following example:

```
SELECT *
FROM employee INNER JOIN department
  ON employee.DepartmentID = department.DepartmentID;
```

The "implicit join notation" simply lists the tables for joining, in the `FROM` clause of the `SELECT` statement, using commas to separate them. Thus it specifies a cross join, and the `WHERE` clause may apply additional filter-predicates (which function comparably to the join-predicates in the explicit notation).

The following example is equivalent to the previous one, but this time using implicit join notation:

```
SELECT *
FROM employee, department
WHERE employee.DepartmentID = department.DepartmentID;
```

The queries given in the examples above will join the Employee and Department tables using the DepartmentID column of both tables. Where the DepartmentID of these tables match (i.e. the join-predicate is satisfied), the query will combine the *LastName*, *DepartmentID* and *DepartmentName* columns from the two tables into a result row. Where the DepartmentID does not match, no result row is generated.

Thus the result of the execution of either of the two queries above will be:

Employee.LastName	Employee.DepartmentID	Department.DepartmentName	Department.DepartmentID
Robinson	34	Clerical	34
Jones	33	Engineering	33
Smith	34	Clerical	34
Heisenberg	33	Engineering	33
Rafferty	31	Sales	31

Note: Programmers should take special care when joining tables on columns that can contain NULL values, since NULL will never match any other value (not even NULL itself), unless the join condition explicitly uses the `IS NULL` or `IS NOT NULL` predicates.

Notice that the employee "John" and the department "Marketing" do not appear in the query execution results. Neither of these has any matching records in the other respective table: "John" has no associated department, and no employee has the department ID 35 ("Marketing"). Depending on the desired results, this behavior may be a subtle bug, which can be avoided with an outer join.

One can further classify inner joins as equi-joins, as natural joins, or as cross-joins.

Equi-join

An **equi-join** is a specific type of comparator-based join, that uses only equality comparisons in the join-predicate. Using other comparison operators (such as <) disqualifies a join as an equi-join. The query shown above has already provided an example of an equi-join:

```
SELECT *
FROM employee JOIN department
  ON employee.DepartmentID = department.DepartmentID;
```

We can write equi-join as below,

```
SELECT *
FROM employee, department
WHERE employee.DepartmentID = department.DepartmentID;
```

If columns in an equi-join have the same name, SQL-92 provides an optional shorthand notation for expressing equi-joins, by way of the `USING` construct:[2]

```
SELECT *
FROM employee INNER JOIN department USING (DepartmentID);
```

The `USING` construct is more than mere syntactic sugar, however, since the result set differs from the result set of the version with the explicit predicate. Specifically, any columns mentioned in the `USING` list will appear only once, with an unqualified name, rather than once for each table in the join. In the above case, there will be a single `DepartmentID` column and no `employee.DepartmentID` or `department.DepartmentID`.

The `USING` clause is not supported by MS SQL Server and Sybase.

Natural join

A natural join is a type of equi-join where the join predicate arises implicitly by comparing all columns in both tables that have the same column-names in the joined tables. The resulting joined table contains only one column for each pair of equally named columns. In the case that no columns with the same names are found, a cross join is performed.

Most experts agree that NATURAL JOINs are dangerous and therefore strongly discourage their use.[3] The danger comes from inadvertently adding a new column, named the same as another column in the other table. An existing natural join might then "naturally" use the new column for comparisons, making comparisons/matches using different criteria (from different columns) than before. Thus an existing query could produce different results, even though the data in the tables have not been changed, but only augmented. The use of column names to automatically determine table links is not an option in large databases with hundreds or thousands of tables where it would place an unrealistic constraint on naming conventions. Real world databases are commonly designed with foreign key data that is not consistently populated (NULL values are allowed), due to business rules and context. It is common practice to modify column names of similar data in different tables and this lack of rigid consistency relegates natural joins to a theoretical concept for discussion.

The above sample query for inner joins can be expressed as a natural join in the following way:

```
SELECT *
FROM employee NATURAL JOIN department;
```

As with the explicit `USING` clause, only one DepartmentID column occurs in the joined table, with no qualifier:

DepartmentID	Employee.LastName	Department.DepartmentName
34	Smith	Clerical
33	Jones	Engineering
34	Robinson	Clerical
33	Heisenberg	Engineering
31	Rafferty	Sales

PostgreSQL, MySQL and Oracle support natural joins; Microsoft T-SQL and IBM DB2 do not. The columns used in the join are implicit so the join code does not show which columns are expected, and a change in column names may change the results. In the SQL:2011 standard, natural joins are part of the optional F401, "Extended joined table", package.

In many database environments the column names are controlled by an outside vendor, not the query developer. A natural join assumes stability and consistency in column names which can change during vendor mandated version upgrades.

Outer join

An **outer join** does not require each record in the two joined tables to have a matching record. The joined table retains each record—even if no other matching record exists. Outer joins subdivide further into left outer joins, right outer joins, and full outer joins, depending on which table's rows are retained (left, right, or both).

(In this case *left* and *right* refer to the two sides of the `JOIN` keyword.)

No implicit join-notation for outer joins exists in standard SQL.

Left outer join

The result of a *left outer join* (or simply **left join**) for tables A and B always contains all records of the "left" table (A), even if the join-condition does not find any matching record in the "right" table (B). This means that if the `ON` clause matches 0 (zero) records in B (for a given record in A), the join will still return a row in the result (for that record)—but with NULL in each column from B. A **left outer join** returns all the values from an inner join plus all values in the left table that do not match to the right table.

For example, this allows us to find an employee's department, but still shows the employee(s) even when they have not been assigned to a department (contrary to the inner-join example above, where unassigned employees were excluded from the result).

Example of a left outer join (the **`OUTER`** keyword is optional), with the additional result row (compared with the inner join) italicized:

```
SELECT *
FROM employee LEFT OUTER JOIN department
  ON employee.DepartmentID = department.DepartmentID;
```

Employee.LastName	Employee.DepartmentID	Department.DepartmentName	Department.DepartmentID
Jones	33	Engineering	33
Rafferty	31	Sales	31
Robinson	34	Clerical	34
Smith	34	Clerical	34
John			
Heisenberg	33	Engineering	33

Alternative syntaxes

Oracle supports the deprecated[4] syntax:

```
SELECT *
FROM employee, department
WHERE employee.DepartmentID = department.DepartmentID(+)
```

Sybase supports the syntax:

```
SELECT *
FROM employee, department
WHERE employee.DepartmentID *= department.DepartmentID
```

IBM Informix supports the syntax:

```
SELECT *
FROM employee, OUTER department
WHERE employee.DepartmentID = department.DepartmentID
```

Right outer join

A **right outer join** (or **right join**) closely resembles a left outer join, except with the treatment of the tables reversed. Every row from the "right" table (B) will appear in the joined table at least once. If no matching row from the "left" table (A) exists, NULL will appear in columns from A for those records that have no match in B.

A right outer join returns all the values from the right table and matched values from the left table (NULL in the case of no matching join predicate). For example, this allows us to find each employee and his or her department, but still show departments that have no employees.

Below is an example of a right outer join (the **`OUTER`** keyword is optional), with the additional result row italicized:

```
SELECT *
FROM employee RIGHT OUTER JOIN department
  ON employee.DepartmentID = department.DepartmentID;
```

Employee.LastName	Employee.DepartmentID	Department.DepartmentName	Department.DepartmentID
Smith	34	Clerical	34
Jones	33	Engineering	33
Robinson	34	Clerical	34
Heisenberg	33	Engineering	33
Rafferty	31	Sales	31
		Marketing	*35*

Right and left outer joins are functionally equivalent. Neither provides any functionality that the other does not, so right and left outer joins may replace each other as long as the table order is switched.

Alternate syntaxes

Oracle supports the deprecated syntax:

```
SELECT *
FROM employee, department
WHERE employee.DepartmentID(+) = department.DepartmentID
```

Full outer join

Conceptually, a **full outer join** combines the effect of applying both left and right outer joins. Where records in the FULL OUTER JOINed tables do not match, the result set will have NULL values for every column of the table that lacks a matching row. For those records that do match, a single row will be produced in the result set (containing fields populated from both tables).

For example, this allows us to see each employee who is in a department and each department that has an employee, but also see each employee who is not part of a department and each department which doesn't have an employee.

Example of a full outer join (the **`OUTER`** keyword is optional):

```
SELECT *
FROM employee FULL OUTER JOIN department
  ON employee.DepartmentID = department.DepartmentID;
```

Employee.LastName	Employee.DepartmentID	Department.DepartmentName	Department.DepartmentID
Smith	34	Clerical	34
Jones	33	Engineering	33
Robinson	34	Clerical	34
John			
Heisenberg	33	Engineering	33
Rafferty	31	Sales	31
		Marketing	*35*

Some database systems do not support the full outer join functionality directly, but they can emulate it through the use of an inner join and UNION ALL selects of the "single table rows" from left and right tables respectively. The same example can appear as follows:

```
SELECT employee.LastName, employee.DepartmentID,
       department.DepartmentName, department.DepartmentID
```

```
FROM employee
INNER JOIN department ON employee.DepartmentID = department.DepartmentID

UNION ALL

SELECT employee.LastName, employee.DepartmentID,
       cast(NULL as varchar(20)), cast(NULL as integer)
FROM employee
WHERE NOT EXISTS (
    SELECT * FROM department
             WHERE employee.DepartmentID = department.DepartmentID)

UNION ALL

SELECT cast(NULL as varchar(20)), cast(NULL as integer),
       department.DepartmentName, department.DepartmentID
FROM department
WHERE NOT EXISTS (
    SELECT * FROM employee
             WHERE employee.DepartmentID = department.DepartmentID)
```

Self-join

A self-join is joining a table to itself.

Example

A query to find all pairings of two employees in the same country is desired. If there were two separate tables for employees and a query which requested employees in the first table having the same country as employees in the second table, a normal join operation could be used to find the answer table. However, all the employee information is contained within a single large table.[5]

Consider a modified `Employee` table such as the following:

Employee Table

EmployeeID	LastName	Country	DepartmentID
123	Rafferty	Australia	31
124	Jones	Australia	33
145	Heisenberg	Australia	33
201	Robinson	United States	34
305	Smith	Germany	34
306	John	Germany	

An example solution query could be as follows:

```
SELECT F.EmployeeID, F.LastName, S.EmployeeID, S.LastName, F.Country
FROM Employee F INNER JOIN Employee S ON F.Country = S.Country
WHERE F.EmployeeID < S.EmployeeID
```

```
ORDER BY F.EmployeeID, S.EmployeeID;
```

Which results in the following table being generated.

Employee Table after Self-join by Country

EmployeeID	LastName	EmployeeID	LastName	Country
123	Rafferty	124	Jones	Australia
123	Rafferty	145	Heisenberg	Australia
124	Jones	145	Heisenberg	Australia
305	Smith	306	John	Germany

For this example:

- `F` and `S` are aliases for the first and second copies of the employee table.
- The condition `F.Country = S.Country` excludes pairings between employees in different countries. The example question only wanted pairs of employees in the same country.
- The condition `F.EmployeeID < S.EmployeeID` excludes pairings where the `EmployeeID` of the first employee is greater than or equal to the `EmployeeID` of the second employee. In other words, the effect of this condition is to exclude duplicate pairings and self-pairings. Without it, the following less useful table would be generated (the table below displays only the "Germany" portion of the result):

EmployeeID	LastName	EmployeeID	LastName	Country
305	Smith	305	Smith	Germany
305	Smith	306	John	Germany
306	John	305	Smith	Germany
306	John	306	John	Germany

Only one of the two middle pairings is needed to satisfy the original question, and the topmost and bottommost are of no interest at all in this example.

Alternatives

The effect of an outer join can also be obtained using a UNION ALL between an INNER JOIN and a SELECT of the rows in the "main" table that do not fulfill the join condition. For example

```
SELECT employee.LastName, employee.DepartmentID,
department.DepartmentName
FROM employee
LEFT OUTER JOIN department ON employee.DepartmentID =
department.DepartmentID;
```

can also be written as

```
SELECT employee.LastName, employee.DepartmentID,
department.DepartmentName
FROM employee
INNER JOIN department ON employee.DepartmentID =
department.DepartmentID
```

```
UNION ALL

SELECT employee.LastName, employee.DepartmentID, cast(NULL as
varchar(20))
FROM employee
WHERE NOT EXISTS (
    SELECT * FROM department
             WHERE employee.DepartmentID = department.DepartmentID)
```

Implementation

Much work in database-systems has aimed at efficient implementation of joins, because relational systems commonly call for joins, yet face difficulties in optimising their efficient execution. The problem arises because inner joins operate both commutatively and associatively. In practice, this means that the user merely supplies the list of tables for joining and the join conditions to use, and the database system has the task of determining the most efficient way to perform the operation. A query optimizer determines how to execute a query containing joins. A query optimizer has two basic freedoms:

1. **Join order**: Because it joins functions commutatively and associatively, the order in which the system joins tables does not change the final result set of the query. However, join-order **could** have an enormous impact on the cost of the join operation, so choosing the best join order becomes very important.
2. **Join method**: Given two tables and a join condition, multiple algorithms can produce the result set of the join. Which algorithm runs most efficiently depends on the sizes of the input tables, the number of rows from each table that match the join condition, and the operations required by the rest of the query.

Many join-algorithms treat their inputs differently. One can refer to the inputs to a join as the "outer" and "inner" join operands, or "left" and "right", respectively. In the case of nested loops, for example, the database system will scan the entire inner relation for each row of the outer relation.

One can classify query-plans involving joins as follows:

left-deep
: using a base table (rather than another join) as the inner operand of each join in the plan

right-deep
: using a base table as the outer operand of each join in the plan

bushy
: neither left-deep nor right-deep; both inputs to a join may themselves result from joins

These names derive from the appearance of the query plan if drawn as a tree, with the outer join relation on the left and the inner relation on the right (as convention dictates).

Join algorithms

Three fundamental algorithms for performing a join operation exist: nested loop join, sort-merge join and hash join.

Join Indexes

Join indexes are database indexes that facilitate the processing of join queries in data warehouses: they are currently (2012) available in implementations by Oracle[6] and Teradata.[7]

In the Teradata implementation, specified columns, aggregate functions on columns, or components of date columns from one or more tables are specified using a syntax similar to the definition of a database view: up to 64 columns/column expressions can be specified in a single join index. Optionally, a column that defines the primary key of the composite data may also be specified: on parallel hardware, the column values are used to partition the index's contents across multiple disks. When the source tables are updated interactively by users, the contents of the join index are automatically updated. Any query whose WHERE clause specifies any combination of columns or column expressions that are an exact subset of those defined in a join index (a so-called "covering query") will cause the join index, rather than the original tables and their indexes, to be consulted during query execution.

The Oracle implementation limits itself to using bitmap indexes. A *bitmap join index* is used for low-cardinality columns (i.e., columns containing fewer than 300 distinct values, according to the Oracle documentation): it combines low-cardinality columns from multiple related tables. The example Oracle uses is that of an inventory system, where different suppliers provide different parts. The schema has three linked tables: two "master tables", Part and Supplier, and a "detail table", Inventory. The last is a many-to-many table linking Supplier to Part, and contains the most rows. Every part has a Part Type, and every supplier is based in the USA, and has a State column. There are not more than 60 states+territories in the USA, and not more than 300 Part Types. The bitmap join index is defined using a standard three-table join on the above three tables, and specifying the Part_Type and Supplier_State columns for the index. However, it is defined on the Inventory table, even though the columns Part_Type and Supplier_State are "borrowed" from Supplier and Part respectively.

As for Teradata, an Oracle bitmap join index is only utilized to answer a query when the query's WHERE clause specifies columns limited to those that are included in the join index.

Set operations

UNION operator

In SQL the **`UNION`** clause combines the results of two SQL queries into a single table of all matching rows. The two queries must result in the same number of columns and compatible data types in order to unite. Any duplicate records are automatically removed unless `UNION ALL` is used.

`UNION` can be useful in data warehouse applications where tables aren't perfectly normalized.[1] A simple example would be a database having tables `sales2005` and `sales2006` that have identical structures but are separated because of performance considerations. A `UNION` query could combine results from both tables.

Note that `UNION` does not guarantee the order of rows. Rows from the second operand may appear before, after, or mixed with rows from the first operand. In situations where a specific order is desired, `ORDER BY` must be used.

Note that `UNION ALL` may be much faster than plain `UNION`.

Examples

Given these two tables:

sales2005

person	amount
Joe	1000
Alex	2000
Bob	5000

sales2006

person	amount
Joe	2000
Alex	2000
Zach	35000

Executing this statement:

```
SELECT * FROM sales2005
UNION
SELECT * FROM sales2006;
```

yields this result set, though the order of the rows can vary because no `ORDER BY` clause was supplied:

person	amount
Joe	1000
Alex	2000
Bob	5000
Joe	2000
Zach	35000

Note that there are two rows for Joe because those rows are distinct across their columns. There is only one row for Alex because those rows are not distinct for both columns.

`UNION ALL` gives different results, because it will not eliminate duplicates. Executing this statement:

```
SELECT * FROM sales2005
UNION ALL
SELECT * FROM sales2006;
```

would give these results, again allowing variance for the lack of an `ORDER BY` statement:

person	amount
Joe	1000
Joe	2000
Alex	2000
Alex	2000
Bob	5000
Zach	35000

The discussion of full outer joins also has an example that uses `UNION`.

INTERSECT operator

The SQL `INTERSECT` operator takes the results of two queries and returns only rows that appear in both result sets. For purposes of duplicate removal the `INTERSECT` operator does not distinguish between `NULL`s. The `INTERSECT` operator removes duplicate rows from the final result set. The `INTERSECT ALL` operator does not remove duplicate rows from the final result set.

Example

The following example `INTERSECT` query returns all rows from the Orders table where Quantity is between 50 and 100.

```
SELECT *
FROM   Orders
WHERE  Quantity BETWEEN 1 AND 100

INTERSECT

SELECT *
FROM   Orders
WHERE  Quantity BETWEEN 50 AND 200;
```

EXCEPT operator

The SQL `EXCEPT` operator takes the distinct rows of one query and returns the rows that do not appear in a second result set. The `EXCEPT ALL` operator (not supported in MSSQL) does not remove duplicates. For purposes of row elimination and duplicate removal, the `EXCEPT` operator does not distinguish between `NULL`s.

Notably, the Oracle platform provides a `MINUS` operator which is functionally equivalent to the SQL standard `EXCEPT DISTINCT` operator [2].

Example

The following example `EXCEPT` query returns all rows from the Orders table where Quantity is between 1 and 49, and those with a Quantity between 76 and 100.

Worded another way; the query returns all rows where the Quantity is between 1 and 100, apart from rows where the quantity is between 50 and 75.

```
SELECT *
FROM   Orders
WHERE  Quantity BETWEEN 1 AND 100

EXCEPT

SELECT *
FROM   Orders
WHERE  Quantity BETWEEN 50 AND 75;
```

Alternatively, in implementations of the SQL language without the `EXCEPT` operator, the equivalent form of a `LEFT JOIN` where the right hand values are `NULL` can be used instead.

Example

The following example is equivalent to the above example but without using the `EXCEPT` operator.

```
SELECT o1.*
FROM (
    SELECT *
    FROM Orders
    WHERE Quantity BETWEEN 1 AND 100) o1
LEFT JOIN (
    SELECT *
    FROM Orders
    WHERE Quantity BETWEEN 50 AND 75) o2
ON o1.id = o2.id
WHERE o2.id IS NULL
```

Commit

In computer science and data management, a **commit** is the making of a set of tentative changes permanent. A popular usage is at the end of a transaction. A *commit* is an act of committing.

Data management

A `COMMIT` statement in SQL ends a transaction within a relational database management system (RDBMS) and makes all changes visible to other users. The general format is to issue a `BEGIN WORK` statement, one or more SQL statements, and then the `COMMIT` statement. Alternatively, a `ROLLBACK` statement can be issued, which undoes all the work performed since `BEGIN WORK` was issued. A `COMMIT` statement will also release any existing savepoints that may be in use.

In terms of transactions, the opposite of commit is to discard the tentative changes of a transaction, a rollback.

Revision control

Commits are also done for revision control systems for source code such as Subversion, Git or CVS. A commit in the context of these version control systems refers to submitting the latest changes of the source code to the repository, and making these changes part of the head revision of the repository. Thus, when other users do an `UPDATE` or a `checkout` from the repository, they will receive the latest committed version, unless they specify they wish to retrieve a previous version of the source code in the repository. Version control systems also have similar functionality to SQL databases in that they allow rolling back to previous versions easily. In this context, a commit with version control systems is not as dangerous as it allows easy rollback, even after the commit has been done.

Notes

Rollback

In database technologies, a **rollback** is an operation which returns the database to some previous state. Rollbacks are important for database integrity, because they mean that the database can be restored to a clean copy even after erroneous operations are performed. They are crucial for recovering from database server crashes; by rolling back any transaction which was active at the time of the crash, the database is restored to a consistent state.

The rollback feature is usually implemented with a transaction log, but can also be implemented via multiversion concurrency control.

Cascading rollback

A *cascading rollback* occurs in database systems when a transaction (T1) causes a failure and a rollback must be performed. Other transactions dependent on T1's actions must also be rollbacked due to T1's failure, thus causing a cascading effect. That is, one transaction's failure causes many to fail.

Practical database recovery techniques guarantee cascadeless rollback, therefore a cascading rollback is not a desirable result.

SQL

In SQL, `ROLLBACK` is a command that causes all data changes since the last `BEGIN WORK`, or `START TRANSACTION` to be discarded by the relational database management systems (RDBMS), so that the state of the data is "rolled back" to the way it was before those changes were made.

A `ROLLBACK` statement will also release any existing savepoints that may be in use.

In most SQL dialects, `ROLLBACK`s are connection specific. This means that if two connections are made to the same database, a `ROLLBACK` made in one connection will not affect any other connections. This is vital for proper concurrency.

Truncate

In SQL, the **`TRUNCATE TABLE`** statement is a Data Definition Language (DDL) operation that marks the extents of a table for deallocation (empty for reuse). The result of this operation quickly removes all data from a table, typically bypassing a number of integrity enforcing mechanisms. It was officially introduced in the SQL:2008 standard.

The `TRUNCATE TABLE mytable` statement is logically (though not physically) equivalent to the `DELETE FROM mytable` statement (without a `WHERE` clause). The following characteristics distinguish `TRUNCATE TABLE` from `DELETE`:

- In the Oracle Database, `TRUNCATE` is implicitly preceded and followed by a commit operation. (This may also be the case in MySQL, when using a transactional storage engine.)
- Typically, `TRUNCATE TABLE` quickly deletes all records in a table by deallocating the data pages used by the table. This reduces the resource overhead of logging the deletions, as well as the number of locks acquired. Records removed this way cannot be restored in a rollback operation. Two notable exceptions to this rule are the implementations found in PostgreSQL and Microsoft SQL Server, both of which allow `TRUNCATE TABLE` statements to be committed or rolled back transactionally.
- You cannot specify a `WHERE` clause in a `TRUNCATE TABLE` statement—it is all or nothing.
- `TRUNCATE TABLE` cannot be used when a foreign key references the table to be truncated, since `TRUNCATE TABLE` statements do not fire triggers. This could result in inconsistent data because `ON DELETE`/`ON UPDATE` triggers would not fire.
- In some database systems, `TRUNCATE TABLE` resets the count of an Identity column back to the identity's *seed*.
- In Microsoft SQL Server 2000 and beyond in full recovery mode, every change to the database is logged, so `TRUNCATE TABLE` statements can be used for tables involved in log shipping.

Views

View (database)

In database theory, a **view** is the result set of a *stored* query on the data, which the database users can query just as they would in a persistent database collection object. This pre-established query command is kept in the database dictionary. Unlike ordinary *base tables* in a relational database, a view does not form part of the physical schema: as a result set, it is a virtual table computed or collated from data in the database, dynamically when access to that view is requested. Changes applied to the data in a relevant *underlying table* are reflected in the data shown in subsequent invocations of the view. In some NoSQL databases, views are the only way to query data.

Views can provide advantages over tables:

- Views can represent a subset of the data contained in a table; consequently, a view can limit the degree of exposure of the underlying tables to the outer world: a given user may have permission to query the view, while denied access to the rest of the base table.
- Views can join and simplify multiple tables into a single virtual table
- Views can act as aggregated tables, where the database engine aggregates data (sum, average etc.) and presents the calculated results as part of the data
- Views can hide the complexity of data; for example a view could appear as Sales2000 or Sales2001, transparently partitioning the actual underlying table
- Views take very little space to store; the database contains only the definition of a view, not a copy of all the data which it presents
- Depending on the SQL engine used, views can provide extra security

Just as a function (in programming) can provide abstraction, so can a database view. In another parallel with functions, database users can manipulate nested views, thus one view can aggregate data from other views. Without the use of views, the normalization of databases above second normal form would become much more difficult. Views can make it easier to create lossless join decomposition.

Just as rows in a base table lack any defined ordering, rows available through a view do not appear with any default sorting. A view is a relational table, and the relational model defines a table as a set of rows. Since sets are not ordered - by definition - nor are the rows of a view. Therefore, an ORDER BY clause in the view definition is meaningless; the SQL standard (SQL:2003) does not allow an ORDER BY clause in the subquery of a CREATE VIEW command, just as it is refused in a CREATE TABLE statement. However, sorted data can be obtained from a view, in the same way as any other table — as part of a query statement on that view. Nevertheless, some DBMS (such as Oracle Database) do not abide by this SQL standard restriction.

Read-only vs. updatable views

Database practitioners can define views as read-only or updatable. If the database system can determine the reverse mapping from the view schema to the schema of the underlying base tables, then the view is updatable. INSERT, UPDATE, and DELETE operations can be performed on updatable views. Read-only views do not support such operations because the DBMS cannot map the changes to the underlying base tables. A view update is done by key preservation.

Some systems support the definition of INSTEAD OF triggers on views. This technique allows the definition of other logic for execution in place of an insert, update, or delete operation on the views. Thus database systems can implement data modifications based on read-only views. However, an INSTEAD OF trigger does not change the

read-only or updatable property of the view itself.

Advanced view features

Various database management systems have extended the views from read-only subsets of data.

Oracle Database introduced the concept of materialized views: pre-executed, non-virtual views commonly used in data warehousing. They give a static snapshot of the data and may include data from remote sources. The accuracy of a materialized view depends on the frequency of trigger mechanisms behind its updates. IBM DB2 provides so-called "materialized query tables" (MQTs) for the same purpose. Microsoft SQL Server introduced in its 2000 version indexed views which only store a separate index from the table, but not the entire data. PostgreSQL implemented materialized views in its 9.3 release.

Equivalence

A view is equivalent to its source query. When queries are run against views, the query is modified. For example, if there exists a view named accounts_view with the content as follows:

```
accounts_view:
--------------
SELECT name,
       money_received,
       money_sent,
       (money_received - money_sent) AS balance,
       address,
         ...
  FROM table_customers c
  JOIN accounts_table a
    ON a.customer_id = c.customer_id
```

then the application could run a simple query such as:

```
Simple query
------------
SELECT name,
       balance
  FROM accounts_view
```

The RDBMS then takes the simple query, replaces the equivalent view, then sends the following to the query optimizer:

```
Preprocessed query:
-------------------
SELECT name,
       balance
  FROM (SELECT name,
               money_received,
               money_sent,
               (money_received - money_sent) AS balance,
               address,
                      ...
          FROM table_customers c JOIN accounts_table a
```

```
                ON a.customer_id = c.customer_id        )
```

The optimizer then removes unnecessary fields and complexity (for example: it is not necessary to read the address, since the parent invocation does not make use of it) and then sends the query to the SQL engine for processing.

Materialized view

A **materialized view** is a database object that contains the results of a query. For example, it may be a local copy of data located remotely, or may be a subset of the rows and/or columns of a table or join result, or may be a summary based on aggregations of a table's data. Materialized views, which store data based on remote tables, are also known as snapshots. A snapshot can be redefined as a materialized view.

Introduction

In any database management system following the relational model, a view is a virtual table representing the result of a database query. Whenever a query or an update addresses an ordinary view's virtual table, the DBMS converts these into queries or updates against the underlying base tables. A materialized view takes a different approach in which the query result is cached as a concrete table that may be updated from the original base tables from time to time. This enables much more efficient access, at the cost of some data being potentially out-of-date. It is most useful in data warehousing scenarios, where frequent queries of the actual base tables can be extremely expensive.

In addition, because the materialized view is manifested as a real table, anything that can be done to a real table can be done to it, most importantly building indexes on any column, enabling drastic speedups in query time. In a normal view, it's typically only possible to exploit indexes on columns that come directly from (or have a mapping to) indexed columns in the base tables; often this functionality is not offered at all.

Materialized views were implemented first by the Oracle Database: the Query rewrite feature was added from version 8i.[1] They are also supported in Sybase SQL Anywhere.[2] In IBM DB2, they are called "materialized query tables"; Microsoft SQL Server has a similar feature called "indexed views".[3] MySQL doesn't support materialized views natively, but workarounds can be implemented by using triggers or stored procedures [4] or by using the open-source application Flexviews.[5] It is also possible to implement materialized views in PostgreSQL; version 9.3 natively supports materialized views.[6] In the current version 9.3 the materialized views are not auto-refreshed, and are populated only at time of creation (unless WITH NO DATA is used) and may be refreshed later manually using REFRESH MATERIALIZED VIEW command.[7]

Example syntax to create a materialized view in Oracle:

```
 CREATE MATERIALIZED VIEW MV_MY_VIEW
REFRESH FAST START WITH SYSDATE
   NEXT SYSDATE + 1
     AS SELECT * FROM <table_name>;
```

Advanced Issues

Hierarchical query

A **hierarchical query** is a type of SQL query that handles hierarchical model data. They are special case of more general recursive fixpoint queries, which compute transitive closures.

In standard SQL:1999 hierarchical queries are implemented by way of recursive *common table expressions* (CTEs). Unlike the Oracle extension described below, the recursive CTEs were designed with fixpoint semantics from the beginning. The recursive CTEs from the standard were relatively close to the existing implementation in IBM DB2 version 2. Recursive CTEs are also supported by Microsoft SQL Server, Firebird 2.1 , PostgreSQL 8.4+,[1] Oracle 11g Release 2 and CUBRID.

An alternative syntax is the non-standard `CONNECT BY` construct; it was introduced by Oracle in the 1980s. Prior to Oracle 10g, the construct was only useful for traversing acyclic graphs because it returned an error on detecting any cycles; in version 10g Oracle introduced the NOCYCLE feature (and keyword), making the traversal work in the presence of cycles as well.

CONNECT BY

`CONNECT BY` is supported by EnterpriseDB,[2] Oracle database,[3] CUBRID, and DB2 although only if it is enabled as a compatibility mode. The syntax is as follows:

```
 SELECT select_list
 FROM table_expression
 [ WHERE ... ]
 [ START WITH start_expression ]
 CONNECT BY [NOCYCLE] { PRIOR parent_expr = child_expr | child_expr =
PRIOR parent_expr }
 [ ORDER SIBLINGS BY column1 [ ASC | DESC ] [, column2 [ ASC | DESC ] ]
 ...
 [ GROUP BY ... ]
 [ HAVING ... ]
 ...
```

For example

```
 SELECT LEVEL, LPAD (' ', 2 * (LEVEL - 1)) || ename "employee", empno,
mgr "manager"
 FROM emp START WITH mgr IS NULL
 CONNECT BY PRIOR empno = mgr;
```

The output from the above query would look like:

```
 level |  employee   | empno | manager
-------+-------------+-------+---------
     1 | KING        |  7839 |
     2 |   JONES     |  7566 |    7839
     3 |     SCOTT   |  7788 |    7566
```

```
     4 |       ADAMS |  7876 |    7788
     3 |     FORD    |  7902 |    7566
     4 |       SMITH |  7369 |    7902
     2 |   BLAKE     |  7698 |    7839
     3 |     ALLEN   |  7499 |    7698
     3 |     WARD    |  7521 |    7698
     3 |     MARTIN  |  7654 |    7698
     3 |     TURNER  |  7844 |    7698
     3 |     JAMES   |  7900 |    7698
     2 |   CLARK     |  7782 |    7839
     3 |     MILLER  |  7934 |    7782
(14 rows)
```

Pseudo-columns

- `LEVEL`
- `CONNECT_BY_ISLEAF`
- `CONNECT_BY_ISCYCLE`
- `CONNECT_BY_ROOT`

Unary operators

The following example returns the last name of each employee in department 10, each manager above that employee in the hierarchy, the number of levels between manager and employee, and the path between the two:

```
   SELECT ename "Employee", CONNECT_BY_ROOT ename "Manager",
   LEVEL-1 "Pathlen", SYS_CONNECT_BY_PATH(ename, '/') "Path"
   FROM emp
   WHERE LEVEL > 1 and deptno = 10
   CONNECT BY PRIOR empno = mgr
   ORDER BY "Employee", "Manager", "Pathlen", "Path";
```

Functions

- `SYS_CONNECT_BY_PATH`

Common table expression

A Common Table Expression, or CTE, (in SQL) is a temporary named result set, derived from a simple query and defined within the execution scope of a `SELECT`, `INSERT`, `UPDATE`, or `DELETE` statement.

CTEs can be thought of as alternatives to derived tables (subquery), views, and inline user-defined functions.

Common table expressions are supported by DB2, Firebird,[4] Microsoft SQL Server, Oracle (with recursion since 11g release 2), PostgreSQL (since 8.4), SQLite (since 3.8.3), HyperSQL and H2 (experimental).[5] Oracle calls CTEs "subquery factoring". The syntax is as follows:

```
WITH [RECURSIVE] with_query [, ...]
SELECT...
```

where `with_query`'s syntax is:

```
with query_name [ (column_name [,...]) ] AS (SELECT ...)
```

Recursive CTEs (or "recursive subquery factoring" in Oracle lingo) can be used to traverse relations (as graphs or trees) although the syntax is much more involved because there are no automatic pseudo-columns created (like `LEVEL` above); if these are desired, they have to be created in the code. See MSDN documentation or IBM documentation[6][7] for tutorial examples.

The `RECURSIVE` keyword is not usually needed after WITH in systems other than PostgreSQL.

In SQL:1999 a recursive (CTE) query may appear anywhere a query is allowed. It's possible, for example, to name the result using `CREATE [RECURSIVE] VIEW`. Using a CTE inside an `INSERT INTO`, one can populate a table with data generated from a recursive query; random data generation is possible using this technique without using any procedural statements.

An example of a recursive query computing the factorial of numbers from 0 to 9 is the following:

```
WITH RECURSIVE temp (n, fact) AS
(SELECT 0, 1 -- Initial Subquery
  UNION ALL
 SELECT n+1, (n+1)*fact FROM temp -- Recursive Subquery
        WHERE n < 9)
SELECT * FROM temp;
```

Hint (SQL)

In database query operations, various **SQL** implementations use **hints** as additions to the SQL standard that instruct the database engine on how to execute the query. For example, a hint may tell the engine to use as little memory as possible (even if the query will run slowly), or to use or not to use an index (even if the query optimizer would decide otherwise).

Implementation

Different database engines use different approaches in implementing hints.

- MySQL uses its own extension to the SQL standard, where a table name may be followed by `USE INDEX`, `FORCE INDEX` or `IGNORE INDEX` keywords.[1]
- Oracle implements hints by using specially-crafted comments in the query that begin with a `+` symbol, thus not affecting SQL compatibility.[2]
- Postgres Plus® Advanced Server (a proprietary version of PostgreSQL from EnterpriseDB) offers hints compatible with those of Oracle.[3][4]

Extensions

SQL/CLI

The **SQL/CLI**, or *Call-Level Interface*, is an extension to the SQL standard is defined in SQL:1999 (based on CLI-95), but also available in later editions such as ISO/IEC 9075-3:2003. This extension defines common interfacing components (structures and procedures) that can be used to execute SQL statements from applications written in other programming languages. The SQL/CLI extension is defined in such a way that SQL statements and SQL/CLI procedure calls are treated as separate from the calling application's source code.

SQL/JRT

SQL/JRT, or *SQL Routines and Types for the Java Programming Language*, is an extension to the SQL standard first published as ISO/IEC 9075-13:2002 (part 13 of SQL:1999). SQL/JRT specifies the ability to invoke static Java methods as routines from within SQL applications, commonly referred to as "Java stored procedures". SQL/JRT also calls for the ability to use Java classes as SQL structured user-defined types. The two parts of the extension originate from the earlier ANSI SQLJ part 1 and 2 standards (not to be confused with SQLJ part 0, which defined an embedding of SQL into Java, later standardized by ISO as SQL/OLB.)

Example

SQL/JRT allows a Java function to be called from SQL code like this:

```
CREATE FUNCTION sinh(v DOUBLE) RETURNS DOUBLE
  LANGUAGE JAVA DETERMINISTIC NO SQL
  EXTERNAL NAME 'CLASSPATH:java.lang.Math.sinh'

SELECT sinh(doublecolumn) FROM mytable
```

SQL/JRT also allows Java code to dynamically generate tables using a `java.sql.ResultSet` object. The result sets returned are converted to SQL tables and can be used anywhere a table or view can be used.

Implementations

SQL/JRT stored procedures are implemented in HSQLDB.[] Java stored procedures have also been implemented in Oracle's JServer (or Aurora JVM), which was introduced in the Oracle Database version 8i in 1999;[1] it is now called Oracle JVM. IBM DB2 also supported Java stored procedures since about 1998, although using an external JVM (at that time).

SQL/MED

The **SQL/MED**, or *Management of External Data*, extension to the SQL standard is defined by ISO/IEC 9075-9:2003. SQL/MED provides extensions to SQL that define foreign-data wrappers and datalink types to allow SQL to manage external data. External data is data that is accessible to, but not managed by, an SQL-based DBMS. This standard can be used in the development of federated database systems.

Implementations

- PostgreSQL has support for some SQL/MED since version 9.1. 9.2 supports more.[1]
- LucidDB has support for SQL/MED.[2]

SQL/OLB

SQL/OLB, or *Object Language Bindings*, is a standard for embedding SQL in Java, commonly known by its prior name as SQLJ (part 0). Besides describing the syntax and semantics of SQLJ, which are typically given relative to JDBC, the standard also describes mechanisms to ensure binary portability of SQLJ applications, and specifies various Java packages and their contained classes.

SQL/OLB was informally known as "SQLJ part 0" before standardization, which first occurred under the aegis of ANSI in 1998 and then ISO in 2000. Although the latter was published after the bulk of SQL:1999, officially it was "part 10" of that standard—a convention that was maintained for subsequent ISO SQL standards, including the current one, SQL:2011.

Examples

For some (possibly outdated) examples, see the article on SQLJ.

Implementations

Both Oracle 8i and IBM DB2 introduced support around 1999. Oracle 12c claims conformance with SQL/OLB:1999, but not with the newer SQL/OLB:2008.[1]

SQL/PSM

SQL/PSM (SQL/Persistent Stored Modules) is an ISO standard mainly defining an extension of SQL with a procedural language for use in stored procedures. Initially published in 1996 as an extension of SQL-92 (ISO/IEC 9075-4:1996, a version sometimes called PSM-96 or even SQL-92/PSM), SQL/PSM was later incorporated into the multi-part SQL:1999 standard, and has been part 4 of that standard since then, most recently in SQL:2011. The SQL:1999 part 4 covered less than the original PSM-96 because the SQL statements for defining, managing, and invoking routines were actually incorporated into part 2 SQL/Foundation, leaving only the procedural language itself as SQL/PSM. The SQL/PSM facilities are still optional as far as the SQL standard is concerned; most of them are grouped in Features P001-P008.

SQL/PSM standardizes syntax and semantics for control flow, exception handling (called "condition handling" in SQL/PSM), local variables, assignment of expressions to variables and parameters, and (procedural) use of cursors. It also defines an information schema (metadata) for stored procedures. SQL/PSM is one language in which methods for the SQL:1999 structured types can be defined. (The other is Java, via SQL/JRT.)

In practice MySQL's procedural language and IBM's SQL PL (used in DB2) are closest to the SQL/PSM standard.

SQL/PSM resembles and inspired by PL/SQL, as well as PL/pgSQL, so they are similar languages. With PostgreSQL v9.X some SQL/PSM features, like overloading of SQL-invoked functions and procedures[1] are now supported. A PostgreSQL addon implements SQL/PSM[2] (alongside its own procedural language), although it is not part of the core product.[3]

SQL/Schemata

The **SQL/Schemata**, or *Information and Definition Schemas*, part to the SQL standard is defined by ISO/IEC 9075-11:2008. SQL/Schemata defines the information schema and definition schema, providing a common set of tools to make SQL databases and objects self-describing. These tools include the SQL object identifier[*clarify*], structure[*clarify*] and integrity constraints, security and authorization specifications[*clarify*], features and packages[*clarify*] of ISO/IEC 9075, support of features provided by SQL-based DBMS implementations, SQL-based DBMS implementation information and sizing items[*clarify*], and the values supported[*clarify*] by the DBMS implementations. SQL/Schemata defines a number of features, some of which are mandatory.

StreamSQL

StreamSQL is a query language that extends SQL with the ability to process real-time data streams. SQL is primarily intended for manipulating relations (also known as tables), which are finite bags of tuples (rows). StreamSQL adds the ability to manipulate streams, which are infinite sequences of tuples that are not all available at the same time. Because streams are infinite, operations over streams must be monotonic. Queries over streams are generally "continuous", executing for long periods of time and returning incremental results.

The StreamSQL language is typically used in the context of a Data Stream Management System (DSMS), for applications including algorithmic trading, market data analytics, network monitoring, surveillance, e-fraud detection and prevention, clickstream analytics and real-time compliance (anti-money laundering, RegNMS, MiFID).

Technical details

StreamSQL extends the type system of SQL to support streams in addition to tables. Several new operations are introduced to manipulate streams.

Selecting from a stream - A standard `SELECT` statement can be issued against a stream to calculate functions (using the target list) or filter out unwanted tuples (using a `WHERE` clause). The result will be a new stream.

Stream-Relation Join - A stream can be joined with a relation to produce a new stream. Each tuple on the stream is joined with the current value of the relation based on a predicate to produce 0 or more tuples.

Union and Merge - Two or more streams can be combined by unioning or merging them. Unioning combines tuples in strict FIFO order. Merging is more deterministic, combining streams according to a sort key.

Windowing and Aggregation - A stream can be windowed to create finite sets of tuples. For example, a window of size 5 minutes would contain all the tuples in a given 5 minute period. Window definitions can allow complex selections of messages, based on tuple field values. Once a finite batch of tuples is created, analytics such as count, average, max, etc., can be applied.

Windowing and Joining - A pair of streams can also be windowed and then joined together. Tuples within the join windows will combine to create resulting tuples if they fulfill the predicate.

History

StreamSQL is derived from academic research into Event Stream Processing, closely related to complex event processing. Led by Dr. Michael Stonebraker, a team of 30 professors and students on project Aurora worked collaboratively from 2001 through 2003 to develop the core principles behind StreamSQL.

The Aurora project has since been superseded by the Borealis project. Borealis is a distributed multi-processor version of Aurora.

dBase and derived languages

DBase

dBASE

Paradigm(s)	Imperative, Declarative
Appeared in	1979
Developer	C. Wayne Ratliff
Influenced	Clipper, WordTech products, Harbour. FoxBASE+, FoxPro, Visual FoxPro
Website	www.dbase.com [1]

dBASE was one of the first and in its day the most successful database management systems for microcomputers. The dBASE system includes the core database engine, a query system, a forms engine, and a programming language that ties all of these components together. dBASE's underlying file format, the `.dbf` file, is widely used in applications needing a simple format to store structured data.

dBASE was originally published by Ashton-Tate for microcomputer operating system CP/M in 1980, and later ported to Apple II and IBM PC computers running DOS. On the PC platform, in particular, dBASE became one of the best-selling software titles for a number of years. A major upgrade was released as dBASE III, and ported to a wider variety of platforms, adding UNIX, and VMS. By the mid-1980s, Ashton-Tate was one of the "big three" software publishers in the early business software market, the others being Lotus Development and WordPerfect.

Starting in the mid-1980s, several companies produced their own variations on the dBASE product and especially the dBASE programming language. These included FoxBASE+(later renamed FoxPro), Clipper, and other so-called xBase products. Many of these were technically stronger than dBASE, but could not push it aside in the market. This changed with the disastrous introduction of dBASE IV, whose design and stability were so poor many users switched to other products.[*citation needed*] At the same time, there was growing use of IBM-invented SQL (Structured Query Language) in database products. Another factor was user adoption of Microsoft Windows on desktop computers. The shift toward SQL and Windows put pressure on the makers of xBase products to invest in major redesign to provide new capabilities.

In spite of growing pressure to evolve, in the early 1990s xBase products constituted the leading database platform for implementing business applications. The size and impact of the xBase market did not go unnoticed, and within one year, the three top xBase firms were acquired by larger software companies. Borland purchased Ashton-Tate, Microsoft bought Fox Software, and Computer Associates acquired Nantucket. However, by the following decade most of the original xBase products had faded from prominence and several disappeared. Products known as dBASE still exist, owned by dBase LLC.

History

Origins

In the late 1960s, Fred Thompson at the Jet Propulsion Laboratory (JPL) was using a Tymshare product named RETRIEVE to manage a database of electronic calculators, which were at that time *very* expensive products. In 1971 Fred collaborated with Jack Hatfield, a programmer at JPL, to write an enhanced version of RETRIEVE which became the JPLDIS project. JPLDIS was written in FORTRAN on the UNIVAC 1108 mainframe, and was presented publicly in 1973. When Hatfield left JPL in 1974, Jeb Long took over his role.[2]

While working at JPL as a contractor, C. Wayne Ratliff entered the office football pool. He had no interest in the game, but felt he could win the pool by processing the post-game statistics found in newspapers. In order to do this, he turned his attention to a database system and, by chance, came across the documentation for JPLDIS. He used this as the basis for a port to PTDOS on his kit-built IMSAI 8080 microcomputer, and called the resulting system **Vulcan** (after Mr. Spock on *Star Trek*).[3]

Ashton-Tate

George Tate and Hal Lashlee had built two successful start-up companies - Discount Software was one of the first to sell PC software programs through the mail to consumers, and Software Distributors which was one of the first wholesale distributors of PC software in the world. They entered into an agreement with Ratliff to market Vulcan, and formed Ashton-Tate to do so. Ratliff ported Vulcan from PTDOS to CP/M. Hal Pawluk, who handled marketing for the nascent company, decided to change the name to the more business-like "dBASE". Pawluk devised the use of lower case "d" and all-caps "BASE" to create a distinctive name (it is an error to write it any other way). Pawluk suggested calling the new product version two ("II") to suggest it was less buggy than an initial release. **dBASE II** was the result and became a standard CP/M application along with WordStar and SuperCalc.[4]

In 1981, IBM commissioned a port of dBASE for the then-in-development PC. The resultant program was one of the initial pieces of software available when the IBM PC went on sale the fall of 1981. dBASE was one of a very few "professional" programs on the platform at that time, and became a huge success. The customer base included not only end-users, but an increasing number of "value added resellers", or VARs, who purchased dBASE, wrote applications with it, and sold the completed systems to their customers. The May 1983 release of **dBASE II RunTime** further entrenched dBASE in the VAR market by allowing the VARs to deploy their products using the lower-cost RunTime system.

The success of dBASE created many opportunities for third-parties. Soon, hundreds of companies (ranging from one-person shops to large firms) began offering dBASE-related application development, libraries of code to add functionality, applications with source code that could be customized and re-sold, consulting, training, and how-to books. A new company in San Diego (today known as **Advisor Media** http://www.Advisor.com) premiered a magazine devoted to professional use of dBASE, **Data Based Advisor**. All of these activities fueled the rapid rise of dBASE as the leading product of its type.

dBASE III

As platforms and operating systems proliferated in the early 1980s, the company found it difficult to port the assembly language-based dBASE to target systems. This led to a re-write of the platform in the C programming language, using automated code conversion tools. The resulting code worked, but was essentially undocumented and inhuman in syntax, a problem that would prove to be serious in the future.[*citation needed*]

The resulting dBASE III was released in May 1984. Although reviewers widely panned its lowered performance, the product was otherwise well reviewed. After a few rapid upgrades the system stabilized and was once again a best-seller throughout the 1980s, and formed the famous "application trio" of PC compatibles (dBASE, Lotus 123, and WordPerfect). By the fall of 1984, the company had over 500 employees and was taking in $40 million a year in sales, the vast majority from dBASE products.

Recent history

dBASE has evolved into a modern object oriented language that runs on 32 bit Windows. It can be used to build a wide variety of applications including web apps hosted on a Windows server, Windows rich client applications, and middleware applications. dBASE can access most modern database engines via ODBC drivers.

dBASE features an IDE with a Command Window and Navigator, a just in time compiler, a preprocessor, a virtual machine interpreter, a linker for creating dBASE application .exe's, a freely available runtime engine, and numerous two-way GUI design tools including a Form Designer, Report Designer, Menu Designer, Label Designer, Datamodule Designer, SQL Query Designer, and Table Designer. Two-way Tools refers to the ability to switch back and forth between using a GUI design tool and the source code editor. Other tools include a Source Code Editor, a Project Manager that simplifies building and deploying a dBASE application, and an integrated Debugger. dBASE features structured exception handling and has many built-in classes that can be subclassed via single inheritance. There are visual classes, data classes, and many other supporting classes. Visual classes include Form, SubForm, Notebook, Container, Entryfield, RadioButton, SpinBox, ComboBox, ListBox, PushButton, Image, Grid, ScrollBar, ActiveX, Report, ReportViewer, Text, TextLabel and many others. Database classes include Session, Database, Query, Rowset, Field, StoredProc and Datamodule classes. Other classes include File, String, Math, Array, Date, Exception, Object and others. dBASE objects can be dynamically subclassed by adding new properties to them at runtime.

The current version, dBASE PLUS 8, was announced on March 19, 2013. The product not only supports the existing BDE connectivity, but it also adds support for ADO and ODBC either through the new ADO approach or with the existing BDE connections. This update of dBASE PLUS 8 has been graphically enhanced, has been modernized for continued support on today's more recent operating systems including support for running applications on Microsoft's Windows 8 and Windows Server 2012 product lines. The product is fully compatible with earlier 32 bit versions of dBASE including Visual dBASE 7.x and dB2K. It is partly compatible with 16 bit Windows versions (dBASE for Windows 5.x and Visual dBASE 5.x) and with older DOS versions (dBASE II, dBASE III, dBASE IV, and dBASE 5). In May of 2012, dBase introduced a new product to allow users of the DOS based dBASE products to continue to use the product on the latest Windows OSs and hardware. The new product was called dbDOS(TM)dbdos The latest dbDOS is called dbDOS(TM) PRO 2 and continues to be enhanced.

dBASE / xBase programming language

For handling data, dBASE provided detailed procedural commands and functions to open and traverse records in data files (e.g., USE, SKIP, GO TOP, GO BOTTOM, and GO recno), manipulate field values (REPLACE and STORE), and manipulate text strings (e.g., STR() and SUBSTR()), numbers, and dates. Its ability to simultaneously open and manipulate multiple files containing related data led Ashton-Tate to label dBASE a "relational database" although it did not meet the criteria defined by Dr. Edgar F. Codd's relational model; it could more accurately be called an application development language and integrated navigational database management system that is

influenced by relational concepts.

The dBASE product used a runtime interpreter architecture, which allowed the user to execute commands by typing them in a command line "dot prompt." Upon typing a command or function and pressing the return key, the interpreter would immediately execute or evaluate it. Similarly, program scripts (text files with PRG extensions) ran in the interpreter (with the DO command), where each command and variable was evaluated at runtime. This made dBASE programs quick and easy to write and test because programmers didn't have to first compile and link them before running them. (For other languages, these steps were tedious in the days of single- and double-digit megahertz CPUs.) The interpreter also handled automatically and dynamically all memory management (i.e., no preallocating memory and no hexadecimal notation), which more than any other feature made it possible for a business person with no programming experience to develop applications.

Conversely, the ease and simplicity of dBASE presented a challenge as its users became more expert and as professional programmers were drawn to it. More complex and more critical applications demanded professional programming features for greater reliability and performance, as well as greater developer productivity.

Over time, Ashton-Tate's competitors introduced so-called clone products and compilers that had more robust programming features such as user-defined functions (UDFs) to supplement the built-in function set, scoped variables for writing routines and functions that were less likely to be affected by external processes, arrays for complex data handling, packaging features for delivering applications as executable files without external runtime interpreters, object-oriented syntax, and interfaces for accessing data in remote database management systems. Ashton-Tate also implemented many of these features with varying degrees of success. Ashton-Tate and its competitors also began to incorporate SQL, the ANSI/ISO standard language for creating, modifying, and retrieving data stored in relational database management systems.

Eventually, it became clear that the dBASE world had expanded far beyond Ashton-Tate, which was considered to be retarding innovation, growth and the impact of the technology. A "third-party" community had formed, consisting of Fox Software, Nantucket, Alpha Software, Data Based Advisor Magazine, SBT and other application development firms, and major developer groups. They sought to create a dBASE language standard, supported by IEEE committee X3J19 and initiative IEEE 1192. They began using "xBase" to generically refer to the language and database design, to distinguish it from the Ashton-Tate product.

Ashton-Tate was invited to participate, but instead it saw the rise of xBase as an illegal threat to its proprietary technology. In 1988 Ashton-Tate filed suit against Fox Software and Santa Cruz Operation (SCO) for copying dBASE's "structure and sequence" in FoxBase+ (SCO marketed XENIX and UNIX versions of the Fox products). In December 1990, U.S. District judge Terry Hatter, Jr. dismissed Ashton-Tate's lawsuit and invalidated Ashton-Tate's copyrights for not disclosing that dBASE had been based, in part, on the public domain JPLDIS. In October 1991, while the case was still under appeal, Borland International acquired Ashton-Tate, and as one of the merger's provisions the U.S. Justice Department required Borland to end the lawsuit against Fox and allow other companies to use the dBASE/xBase language without the threat of legal action.

By the end of 1992, major software companies raised the stakes by acquiring the leading xBase products. Borland acquired Ashton-Tate's dBASE products (and later WordTech's xBase products), Microsoft acquired Fox Software's FoxBASE+ and FoxPro products, and Computer Associates acquired Nantucket's Clipper products. Advisor Media built on its Data Based Advisor magazine by launching FoxPro Advisor and Clipper Advisor (and other) developer magazines and journals, and live conferences for developers. However, a planned dBASE Advisor Magazine was aborted due the market failure of dBASE IV.

By the year 2000 the xBase market had faded as developers shifted to new database systems and programming languages. Computer Associates (later known as CA) eventually dropped Clipper. Borland restructured and sold dBASE. Of the major acquirers, Microsoft stuck with xBase the longest, evolving FoxPro into Visual FoxPro, but the product is no longer offered. In 2006 Advisor Media stopped its last-surviving xBase magazine, FoxPro Advisor. The era of xBase dominance has ended, but there are still xBase products. The dBASE product line is now owned by

dBase LLC.

Programming examples

Today, implementations of the dBASE language have expanded to include many features targeted for business applications, including object-oriented programming, manipulation of remote and distributed data via SQL, Internet functionality, and interaction with modern devices.

The following example opens an employee table ("empl"), gives every manager who supervises 1 or more employees a 10-percent raise, and then prints the names and salaries.

```
USE empl
REPLACE ALL salary WITH salary * 1.1 FOR supervisors > 0
LIST ALL fname, lname, salary TO PRINT
* (comment: reserved words shown in CAPITALS for illustration purposes)
```

Note how one does not have to keep mentioning the table name. The assumed ("current") table stays the same until told otherwise. This is in contrast to SQL which almost always needs explicit tables. Because of its origins as an interpreted interactive language, dBASE used a variety of contextual techniques to reduce the amount of typing needed. This facilitated incremental, interactive development but also made larger-scale modular programming difficult. A tenet of modular programming is that the correct execution of a program module must not be affected by external factors such as the state of memory variables or tables being manipulated in other program modules. Because dBASE was not designed with this in mind, developers had to be careful about porting (borrowing) programming code that assumed a certain context and it would make writing larger-scale modular code difficult. Work-area-specific references were still possible using the arrow notation ("B->customer") so that multiple tables could be manipulated at the same time. In addition, if the developer had the foresight to name their tables appropriately, they could clearly refer to a large number of tables open at the same time by notation such as ("employee->salary") and ("vacation->start_date"). Alternatively, the alias command could be appended to the initial opening of a table statement which made referencing a table field unambiguous and simple. For example. one can open a table and assign an alias to it in this fashion, "use EMP alias Employee", and henceforth, refer to table variables as "Employee->Name".

Another notable feature is the re-use of the same clauses for different commands. For example, the FOR clause limits the scope of a given command. (It is somewhat comparable to SQL's WHERE clause). Different commands such as LIST, DELETE, REPLACE, BROWSE, etc. could all accept a FOR clause to limit (filter) the scope of their activity. This simplifies the learning of the language.

dBASE was also one of the first business-oriented languages to implement string evaluation.

```
i = 2
myMacro = "i + 10"
i = &myMacro
* comment: i now has the value 12
```

Here the "&" tells the interpreter to evaluate the string stored in "myMacro" as if it were programming code. This is an example of a feature that made dBASE programming flexible and dynamic, sometimes called "meta ability" in the profession. This could allow programming expressions to be placed inside tables, somewhat reminiscent of formulas in spreadsheet software.

However, it could also be problematic for pre-compiling and for making programming code secure from hacking. But, dBASE tended to be used for custom internal applications for small and medium companies where the lack of protection against copying, as compared to compiled software, was often less of an issue.

Interactivity

In addition to the dot-prompt, dBASE III, III+ and dBASE IV came packaged with an ASSIST application to manipulate data and queries, as well as an APPSGEN application which allowed the user to generate applications without resorting to code writing like a 4GL. The dBASE IV APPSGEN tool was based largely on portions of an early CP/M product named Personal Pearl.

Niches

Although the language has fallen out of favor as a primary business language, some find dBASE an excellent interactive ad-hoc data manipulation tool. Whereas SQL retrieves data sets from a relational database (RDBMS), with dBASE one can more easily manipulate, format, analyze and perform calculations on individual records, strings, numbers, and so on in a step-by-step imperative (procedural) way instead of trying to figure out how to use SQL's declarative operations.

Its granularity of operations is generally smaller than SQL, making it easier to split querying and table processing into easy-to-understand and easy-to-test parts. For example, one could insert a BROWSE operation between the filtering and the aggregation step to study the intermediate table or view (applied filter) before the aggregation step is applied.

As an application development platform, dBASE fills a gap between lower level languages such as C, C++, and Java and high-level proprietary 4GLs (fourth generation languages) and purely visual tools, providing relative ease-of-use for business people with less formal programming skill and high productivity for professional developers willing to trade off the low-level control.

dBASE remained a popular teaching tool even after sales slowed because the text-oriented commands were easier to present in printed training material than the mouse-oriented competitors. (Mouse-oriented commands were added to the product over time, but the command language remained a popular de facto standard while mousing commands tended to be vendor-specific.)

File formats

A major legacy of dBASE is its `.dbf` file format, which has been adopted in a number of other applications. For example, the shapefile format developed by ESRI for spatial data in its PC ArcInfo geographic information system, uses .dbf files to store feature attribute data.

Microsoft recommends saving a Microsoft Works database file in the dBASE file format so that it can be read by Microsoft Excel.[5]

dBASE's database system was one of the first to provide a header section for describing the structure of the data in the file.[*citation needed*] This meant that the program no longer required advance knowledge of the data structure, but rather could ask the data file how it was structured. There are several variations on the .dbf file structure, and not all dBASE-related products and .dbf file structures are compatible.

A second filetype is the `.dbt` file format for memo fields. While character fields are limited to 254 characters each, a memo field is a 10-byte pointer into a `.dbt` file which can include a much larger text field. dBASE was very limited in its ability to process memo fields, but some other xBase languages such as Clipper treated memo fields as strings just like character fields for all purposes except permanent storage.

dBASE uses `.ndx` files for single indexes, and `.mdx` *(multiple-index)* files for holding between 1 and 48 indexes. Some xBase languages include compatibility with `.ndx` files while others use different file formats such as `.ntx` used by Clipper and `.idx/.cdx` used by FoxPro or FlagShip. Later iterations of Clipper included drivers for `.ndx, .mdx, .idx and .cdx` indexes.

Clip (compiler)

clip

Developer(s)	ITK / Uri Hnykin
Stable release	1.2.0 / November 1, 2006
Operating system	Unix-like
License	GPL or Commercial License [1]
Website	http://www.itk.ru/ [2]

Clip compiler is a multi-platform (Linux and Windows (Cygwin)) Clipper programming language compiler with many additional features and libraries (for gtk, fivewin, netto, MySQL, ODBC, cti, tcp, gzip, Interbase, Oracle, Postgres), which is quite fast, has support for Hyper-Six and FoxPro RDD's, and can compile existing Clipper source code with very minor changes.

It has support for all the features in the original compiler, can access multiple types of databases such as Oracle, Informix, Interbase, MySQL, Postgres, all Xbase dialects (tables: Foxpro, Visual FoxPro, COMIX, indexes: NDX,NTX,CDX,)

It supports object-oriented programming, preprocessor, dynamic and static libraries, several functions for math, string management, arrays or vectors.

Clip is licensed under a "GPL type" License and uses the GNU CC compiler.

Clipper (programming language)

Clipper

Appeared in	1985
Stable release	CA Clipper 5.3b (May 20, 1997)
OS	DOS
Website	[1]

Clipper is a computer programming language that is used to create software programs that originally operated primarily under DOS. Although it is a powerful general-purpose programming language, it was primarily used to create database/business programs.

History

Clipper was originally created in 1985 as a compiler for *dBASE III*, a very popular database language at the time. Compiling dBASE code changes it from interpreted code, which must be interpreted every time each line of code is executed, to p-code, which uses a Virtual Machine to process the compiled p-code. p-code is considerably faster, but still not as fast as the machine code generated by native compilers. As a technical marketing ploy, the p-code was wrapped into object code (linkable .obj files) which gave the impression that it was compiled to native code. Clipper was created by Nantucket Corporation led by Barry ReBell (management) and Brian Russell (technical), and later sold to Computer Associates. GrafX Software licensed CA-Clipper in 2002 from CA for ongoing marketing and distribution.

As the product matured, it remained a DOS tool for many years, but added elements of the C programming language and Pascal programming language, as well as OOP, and the code-block data-type (hybridizing the concepts of dBase macros, or string-evaluation, and function pointers), to become far more powerful than the original. Nantucket's Aspen project later matured into the Windows native-code Visual Objects compiler.

The Clipper language is being actively implemented and extended by multiple organizations/vendors, like *XBase++* from Alaska Software and *FlagShip*, as well as free (GPL-licensed) projects like *Harbour* and *xHarbour*.

Many of the current implementations are portable (DOS, Windows, Linux (32- and 64-bit), Unix (32- and 64-bit), and Mac OS X), supporting many language extensions [2], and have greatly extended runtime libraries, as well as various Replaceable Database Drivers (RDD) supporting many popular database formats, like DBF, DBTNTX, DBFCDX (FoxPro, Apollo, Comix, and Advantage Database Server), MachSix (SIx Driver and Apollo), SQL, and more. These newer implementations all strive for full compatibility with the standard dBase/xBase syntax, while also offering OOP approaches and target-based syntax such as `SQLExecute()`.

The Clipper Usenet newsgroups are `comp.lang.clipper` [3] and `comp.lang.clipper.visual-objects` [4].

Programming in Clipper

A simple hello world - application:

```
? "Hello World!"
```

A simple data base input mask:

```
USE Customer SHARED NEW
clear
@  1, 0 SAY "CustNum" GET Customer->CustNum PICT "999999" VALID Customer->CustNum > 0
@  3, 0 SAY "Contact" GET Customer->Contact VALID !empty(Customer->Contact)
@  4, 0 SAY "Address" GET Customer->Address
READ
```

Version history

The various versions of Clipper were

From Nantucket Corporation; the "seasonal versions", billed as "dBase compilers"

- Nantucket Clipper Winter'84 - released May 25, 1985
- Nantucket Clipper Summer'85 - released 1985
- Nantucket Clipper Winter'85 - released January 29, 1986
- Nantucket Clipper Autumn'86 - released October 31, 1986
- Nantucket Clipper Summer'87 - released December 21, 1987

From Nantucket Corporation; Clipper 5

- Nantucket Clipper 5.00 - released 1990
- Nantucket Clipper 5.01 - released April 15, 1991
- Nantucket Clipper 5.01 Rev.129 - released March 31, 1992

and from Computer Associates; CA-Clipper 5

- CA Clipper 5.01a -
- CA Clipper 5.20 - released February 15, 1993
- CA-Clipper 5.2a - released March 15, 1993
- CA Clipper 5.2b - released June 25, 1993
- CA-Clipper 5.2c - released August 6, 1993
- CA Clipper 5.2d - released March 25, 1994
- CA-Clipper 5.2e - released February 7, 1995
- CA Clipper 5.30 - released June 26, 1995
- CA Clipper 5.3a - released May 20, 1996
- CA Clipper 5.3b - released May 20, 1997

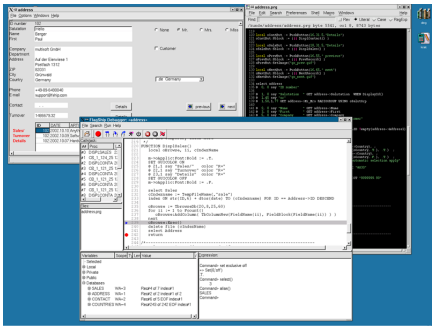
Flagship compiler

FlagShip is both object oriented and procedural programming language, based on the xBase language dialect and conventions. FlagShip is available for and is cross-compatible to different computer platforms, such as Linux, Unix and Microsoft Windows. As a true compiler, it translates the very popular database 4GL xBase source code to native 32-bit or 64-bit executables, using the same source-code and databases.

Recent history

The first FlagShip version was introduced by *multisoft Datentechnik GmbH* in 1992 to port Clipper, dBASE III+, FoxBase and FoxPro applications to different operating systems, i.e. SCO Unix, IBM AIX, Sun Solaris, HP-UX, Siemens SINIX and many other Unix systems. In 1995 also Linux ports became available. In 2002, **Visual FlagShip** *(abbreviated as VFS)* was announced for Linux, and in 2004 additionally for 32/64-bit based Microsoft Windows operating systems. The current VFS product line covers all common 32-bit and 64-bit operating systems (Windows NT, 2000, XP, Vista, 7, Server 2008).

Programming



FlagShip environment
Executing an application, including the embedded source-code debugger

FlagShip is a programming and development tool. As with other compilers, it is designed mainly for professional software developers. But because of its simple interface, it is also perfectly suitable for semi-professionals and advanced computer users, who need to create database applications with minimal programming effort. Thanks to its full Clipper compatibility, it is also best suited for porting already available DOS applications to nearly any Unix, Linux or MS-Windows systems.

There is no learning curve if you are already familiar with any xBase dialect, like dBase, FoxBase, FoxPro, Clipper, Visual Objects etc. There are millions of well trained programmers who have been using this easy but powerful 4GL syntax for years. All of them can directly switch to FlagShip. If you don't have any programming experience with xBase, but are familiar with any other language (C, C++, Java, Pascal, Delphi, Basic, Perl etc.), the learning curve is very short. With about 10 commands, you will be able to create your first application.

Visual FlagShip makes an GUI based application from your available textual xBase code automatically. Of course, because object oriented, you can modify the behavior by yourself too, using either classes or corresponding functions in procedural programming. The same source and the same application supports GUI, textual and stream mode (e.g. for Web or background). The i/o mode is either detected automatically from the current environment (heterogenal application), or can be specified at compile time or at run-time using command-line switch.

For example, these few statements, stored in text file *address.prg*

```
USE address ALIAS adr SHARED NEW
SET COLOR TO "W+/B,GR+/R,W/B,W/B,GR+/BG"
SET GUICOLOR OFF
cls
```

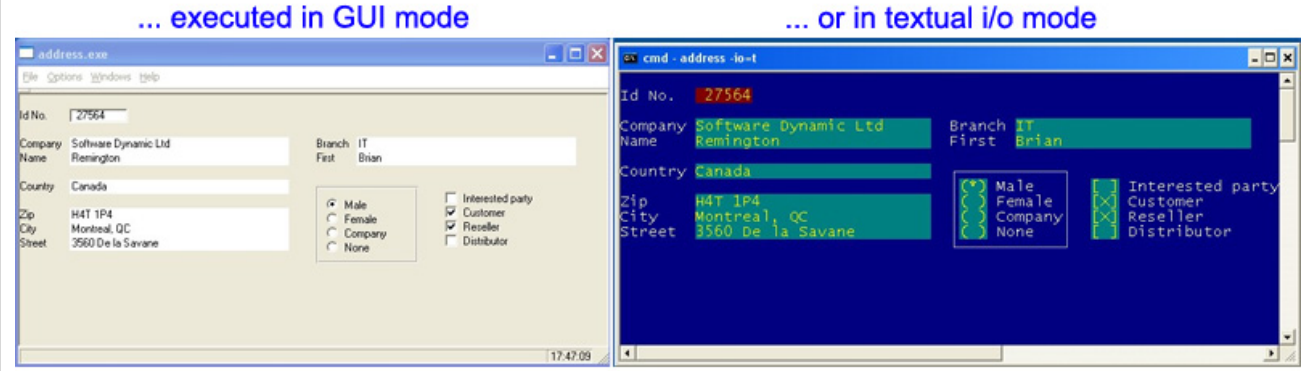
```
@  1, 0 SAY "Id No. " GET adr->IdNum   PICT "999999" VALID IdNum > 0
@  3, 0 SAY "Company" GET adr->Company
@  3,35 SAY "Branch"  GET adr->Branch  WHEN  !empty(adr->Company)
@  4, 0 SAY "Name   " GET adr->Name    VALID !empty(adr->Name)
@  4,35 SAY "First "  GET adr->First
@  6, 0 SAY "Country" GET adr->Country PICTURE "!" + repli("x",24)
@  8, 0 SAY "Zip    " GET adr->Zip     PICT "@!" VALID !empty(adr->Zip)
@  9, 0 SAY "City   " GET adr->City
@ 10, 0 SAY "Street " GET adr->Street

@  6,35,11.4,47 GET adr->Type RADIOGROUP {"Male","Female","Company","None"}
@  7,50   GET  adr->Interest  CHECKBOX  CAPTION "Interested party"
@  8,50   GET  adr->Customer  CHECKBOX  CAPTION "Customer"
@  9,50   GET  adr->Reseller  CHECKBOX  CAPTION "Reseller"
@ 10,50   GET  adr->Distrib   CHECKBOX  CAPTION "Distributor"
READ
```

... and compiled by simply

```
>FlagShip address.prg -o address
```

... creates self-containing executable (i.e. address.exe in Windows)



Additional examples and screenshots are available via the *External links* below.

FoxPro 2

FoxPro was a text-based procedurally oriented programming language and DBMS, originally published by Fox Software and later by Microsoft, for MS-DOS, Windows, Macintosh, and UNIX. The final published release of FoxPro was 2.6, after which the development has continued under Visual FoxPro.

Although FoxPro is a Database Management System (DBMS) and it does support relationships between tables, it is not considered a Relational Database Management System (RDBMS), lacking transactional processing.

Sold and supported by Microsoft, there is an active worldwide community of FoxPro users and programmers. FoxPro 2.6 for UNIX (FPU26) has even been successfully installed on Linux and FreeBSD using the Intel Binary Compatibility Standard (ibcs2) support library.

Version information

Operating system compatibility

Extant Versions by OS

Version	FP 2.0	FP 2.5	FP 2.6
MS-DOS	Yes	Yes	Yes
Windows 3.1 to XP	Yes	Yes	Yes
Macintosh	Yes	Yes	Yes
SCO UNIX	No	No	Yes
Linux & FreeBSD	No	No	Yes[1]
Windows 2000	No	No	Yes

Technical aspects

FoxPro 2 included "Rushmore" optimizing engine, which used indices to accelerate data retrieval and updating. Rushmore technology examined every data-related statement, and looked for filter expressions. If one was used, it looked for an index matching the same expression.

In addition, FoxPro2 was originally built on WatCOM C++, which had its own memory extensor - at that time state-of-the-art. FoxPro2 could access expanded and extended memory, using almost all available RAM (DOS). It used some interrupts in absence of the extended memory driver: if no HIMEM.SYS was loaded, FoxPro enabled that mechanism.

Version Timeline

Version	VERSION() returns	EXE Size	EXE Date
FPW 2.6a	FoxPro 2.6a for Windows	2,444 kb	28 September 1994
FPM 2.6a	FoxPro 2.6a for Macintosh	? kb	August 1994
FPD 2.6a	FoxPro 2.6a for DOS	1,788 kb	August 1994
FPW 2.6	FoxPro 2.6 for Windows	2.38 Mb	9 March 1994
FPM 2.6	FoxPro 2.6 for Macintosh	? kb	1993
FPD 2.6	FoxPro 2.6 for DOS	? kb	March 1994
FPU 2.6	FoxPro 2.6 for Unix	2.3 Mb	1993
FPW 2.5	FoxPro 2.5 for Windows	1.63 Mb	January 1993
FPD 2.5	FoxPro 2.5 for DOS	509,013 bytes	February 1993
FPD 2.0	FoxPro 2.0 for DOS	465.86 kb	1991
FPD 1.0	FoxPro 1.0 for DOS	?	1989

Harbour (software)

Harbour Project

Paradigm(s)	multi-paradigm: imperative, functional, object-oriented, reflective
Appeared in	1999
Designed by	Antonio Linares
Developer	Viktor Szakáts and community
Stable release	3.0.0 (17 July 2011)
Preview release	3.2.0dev [1]
Typing discipline	optionally duck, dynamic, safe, partially strong
Dialects	Clipper, Xbase++, FlagShip, FoxPro, xHarbour
Influenced by	dBase, Clipper
Influenced	xHarbour
OS	Cross-platform
License	Open source GPL Compatible
Usual filename extensions	.prg, .ch, .hb, .hbp
Website	http://harbour-project.org/

Harbour is a modern computer programming language, primarily used to create database/business programs. It is a modernized, open sourced and cross-platform version of the older and largely DOS-only Clipper system, which in turn developed from the dBase database market of the 1980s and 90s.

Harbour code using the same databases can be compiled under a wide variety of platforms, including DOS, Microsoft Windows, Linux, Unix variants, several BSD descendants, Mac OS X, MINIX 3, Windows CE, Pocket PC, Symbian, iOS, Android, QNX, VxWorks, OS/2/eComStation, BeOS/Haiku, AIX.

History

The idea of a free software Clipper compiler had been floating around for a long time and the subject has often cropped up in discussion on comp.lang.clipper. Antonio Linares founded the Harbour project and the implementation was started in March, 1999. The name "Harbour" was proposed by Linares, it is a play on a Clipper as a type of ship. Harbour is a synonym for port (where ships dock), and Harbour is a port of the Clipper language.

In 2009 Harbour was substantially redesigned, mainly by Viktor Szakáts and Przemyslaw Czerpak.

Database support

Harbour extends the Clipper Replaceable Database Drivers (RDD) approach. It offers multiple RDDs such as DBF, DBFNTX, DBFCDX, DBFDBT and DBFFPT. In Harbour multiple RDDs can be used in a single application, and new logical RDDs can be defined from combination of other RDDs. The RDD architecture allows for inheritance, so that a given RDD may extend the functionality of other existing RDD(s). Third-party RDDs, like RDDSQL, RDDSIX, RMDBFCDX, Advantage Database Server, and Mediator exemplify some of the RDD architecture features. DBFNTX implementation has almost same functionality of DBFCDX and RDDSIX. NETIO and LetoDB provide remote access over TCP protocol.

Harbour also offers ODBC support by means of an OOP syntax, and ADO support by means of OLE. MySQL, PostgreSQL, SQLite, Firebird, Oracle are examples of databases which Harbour can connect.

xBase technologies often is confused with a RDBMS software. Although this is true, xBase is more than a simple database system as the same time xBase languages using purely DBF can not provide full concept of a real RDBMS.[*citation needed*]

Programming philosophy

Unlike Java which is intended to be write once, run anywhere, Harbour aims to be **write once, compile anywhere**. As the same compiler is available for all of the above operating systems, there is no need for recoding to produce identical products for different platforms, except when operating system dependent features are used. Cross-compiling is supported with MinGW. Under Microsoft Windows, Harbour is more stable but less well-documented than Clipper, but has multi-platform capability and is more transparent, customizable and can run from a USB flash drive.

Under Linux and Windows Mobile, Clipper source code can be compiled with Harbour with very little adaptation. Most software originally written to run on Xbase++, Flagship, FoxPro, xHarbour and others dialects can be compiled with Harbor with some adaptation. As 2010 many efforts have been made to turn the transition from other xBase dialects easier.

Harbour can use the following C compilers, among others: GCC, MinGW, Clang, ICC, Microsoft Visual C++ (6.0+), Borland C++, Watcom C, Pelles C and Sun Studio.

Harbour can make use of multiple Graphic Terminal emulations, including console drivers, and Hybrid Console/GUIs, such as GTWvt, and GTWvg.

Harbour supports external GUIs, free (e.g. HBQt, HWGui, MiniGUI (latest version based on Qt) and QtContribs [2]) and commercial (e.g. FiveWin, Xailer). HBQt is a library provinding bindings to Qt. HBIDE application is a sample of HBQt potencial.

Harbour is 100% Clipper-compatible and supports many language syntax extensions including greatly extended run-time libraries such as OLE, Blat, OpenSSL, FreeImage, GD, hbtip, hbtpathy, PCRE, hbmzip (zlib), hbbz2 (bzip2), cURL, Cairo, its own implementation of CA-Tools, updated NanFor libraries and many others. Harbour has an active development community and extensive third party support.

Any xBase language provides a very productive way to build business and data intensive applications. Harbour is not an exception.

Macro Operator (runtime compiler)

One of the most powerful features of xBase languages is the Macro Operator '&'. Harbour's implementation of the Macro Operator allows for runtime compilation of any valid Harbour expression. Such a compiled expression may be used as a VALUE, i.e. the right side of an assignment (rvalue), but more interestingly, such a compiled expression may be used to resolve the left side (lvalue) of an assignment, i.e. PRIVATE, or PUBLIC variables, or a database FIELD.

Additionally, the Macro Operator may compile and execute function calls, complete assignments, or even list of arguments, and the result of the macro may be used to resolve any of the above contexts in the compiled application. In other words, any Harbour application may be extended and modified at runtime to compile and execute additional code on-demand.

Latest Macro compiler can compile any valid Harbour code including code to pre-process before compile.

Syntax:

```
&( ... )
```

The text value of the expression '...' will be compiled, and the value resulting from the execution of the compiled code is the result.

```
&SomeId
```

is the short form for &(SomeId).

```
&SomeId.postfix
```

is the short form of &(SomeId + "postfix").

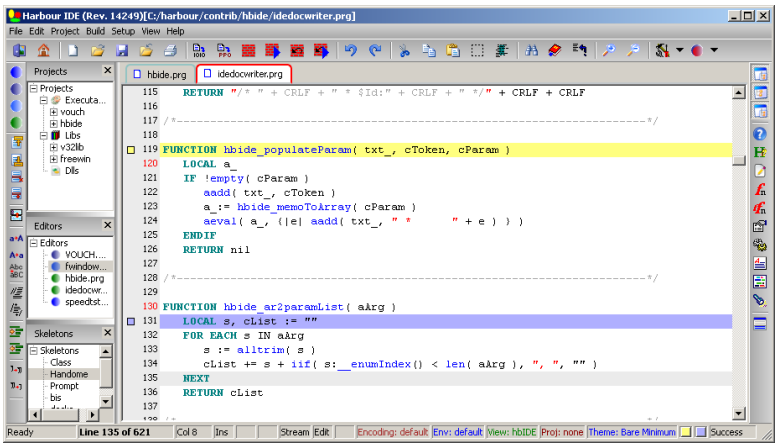
Object Oriented Programming

Programming in an OOP style is a broader issue than a specific library or a specific interface, but OOP programming is something many Clipper programmers have come to expect. CA-Clipper 5.2 and especially 5.3 added a number of base classes, and a matching OOP syntax. Libraries such as Class(y) [3], Fivewin, Clip4Win, and TopClass provide additional OOP functionality.

Harbour has OOP extensions with full support for classes including inheritance, based on Class(y) syntax. OOP syntax in Harbour is very similar to that of earlier Clipper class libraries so it should be possible to maintain legacy Clipper code with minimal changes.

Syntax and semantics

Harbour as every xBase language is case insensitive and can optionally accept keywords written just by first four characters.



Harbour code on HBIDE.

Built-in data types

Harbour has 6 scalar types : Nil, String, Date, Logical, Number, Pointer, and 4 complex types: Array, Object, CodeBlock, and Hash. A scalar holds a single value, such as a string, number, or reference to any other type. Arrays are ordered lists of scalars or complex types, indexed by number, starting at 1. Hashes, or associative arrays, are unordered collections of any type values indexed by their associated key, which may be of any scalar or complex type.

Literal (static) representation of scalar types:

- Nil: *NIL*
- String: *"hello", 'hello', [hello]*
- Date: *0d20100405*
- Logical: *.T., .F.*
- Number: *1, 1.1, –1, 0xFF*

Complex Types may also be represent as literal values:

- Array:

```
{ "String", 1, { "Nested Array" }, .T., FunctionCall(), @FunctionPointer() }
```

- CodeBlock:

```
{ |Arg1, ArgN| Arg1 := ArgN + OuterVar + FunctionCall() }
```

- Hash:

```
{ "Name" => "John", 1 => "Numeric key", { "Nested" => "Hash" } }
```

Hashes may use *any* type including other Hashes as the *Key* for any element. Hashes and Arrays may contain *any* type as the *Value* of any member, including nesting arrays, and Hashes.

Codeblocks may have references to Variables of the Procedure/Function>method in which it was defined. Such Codeblocks may be returned as a value, or by means of an argument passed BY REFERENCE, in such case the Codeblock will "outlive" the routine in which it was defined, and any variables it references, will be a *DETACHED* variable.

Detached variables will maintain their value for as long as a Codeblock referencing them still exists. Such values will be shared with any other Codeblock which may have access to those same variables. If the Codeblock did not outlive its containing routine, and will be evaluated within the lifetime of the routine in which it is defined, changes to its *Detached Variables*(s) by means of its evaluation, will be reflected back at its parent routine.

Codeblocks can be evaluated any number of times, by means of the Eval(*BlockExp*) function.

Variables

All types can be assigned to named variables. Named variable identifiers are 1 to 63 characters long, start with [A-Z|_] and further consist of the characters [A-Z|0–9|_] up to a maximum of 63 characters. Named variables are not case sensitive.

Variables have one of the following scopes:

- *LOCAL*: Visible only within the routine which declared it. Value is lost upon exit of the routine.
- *STATIC*: Visible only within the routine which declared it. Value is preserved for subsequent invocations of the routine. If a STATIC variable is declared before any Procedure/Function/Method is defined, it has a MODULE scope, and is visible within any routine defined within that same source file, it will maintain its life for the duration of the application lifetime.
- *PRIVATE*: Visible within the routine which declared it, and all routines *called* by that routine.
- *PUBLIC*: Visible by *all* routines in the same application.

LOCAL and *STATIC* are resolved at compile time, and thus are much faster than *PRIVATE* and *PUBLIC* variables which are dynamic entities accessed by means of a runtime Symbol table. For this same reason, *LOCAL* and *STATIC* variables are *not* exposed to the Macro compiler, and any macro code which attempts to reference them will generate a runtime error.

Due to the dynamic nature of *PRIVATE* and *PUBLIC* variables, they can be created and destroyed at runtime, can be accessed and modified by means of runtime macros, and can be accessed and modified by Codeblocks created on the fly.

Control structures

The basic control structures include all of the standard dBase, and Clipper control structures as well as additional ones inspired by the C or Java programming languages:

Loops

```
[DO] WHILE ConditionExp
   ...
   [LOOP]
   [EXIT]
END[DO]
```

```
FOR Var := InitExp TO EndExp [STEP StepExp]
   ...
   [LOOP]
   [EXIT]
NEXT
```

```
FOR EACH Var IN CollectionExp
   ...
   [Var:__enumIndex()]
   [LOOP]
   [EXIT]
NEXT
```

- The ... is a sequence of one of more Harbour statements, and square bracketes `[]` denote optional syntax.
- The *Var*:__enumIndex() may be optionally used to retrieve the current iteration index (1 based).
- The *LOOP* statement restarts the current iteration of the enclosing loop structure, and if the enclosing loop is a *FOR* or *FOR EACH* loop, it increases the iterator, moving to the next iteration of the loop.
- The *EXIT* statement immediately terminates execution of the enclosing loop structure.
- The *NEXT* statement closes the control structure and moves to the next iteration of loop structure.

In the *FOR* statement, the *assignment* expression is evaluated prior to the first loop iteration. The *TO* expression is evaluated and compared against the value of the control variable, prior to each iteration, and the loop is terminated if it evaluates to a numeric value greater than the numeric value of the control variable. The optional *STEP* expression is evaluated after each iteration, prior to deciding whether to perform the next iteration.

In *FOR EACH*, the *Var* variable will have the value (scalar, or complex) of the respective element in the collection value. The collection expression, may be an Array (of any type or combinations of types), an Hash Table, or an Object type.

IF statements

```
IF CondExp
   ...
[ELSEIF] CondExp
   ...
[ELSE]
   ...
END[IF]
```

... represents 0 or more *statement(s)*.

The condition expression(s) has to evaluate to a *LOGICAL* value.

SWITCH statements

Harbour supports a SWITCH construct inspired by the C implementation of switch().

```
SWITCH SwitchExp
CASE LiteralExp
   ...
   [EXIT]
[CASE LiteralExp]
   ...
   [EXIT]
[OTHERWISE]
   ...
END[SWITCH]
```

- The *LiteralExp* must be a compiled time resolvable numeric expression, and may involve operators, as long as such operators involve compile time static value.
- The *EXIT* optional statement is the equivalent of the C statement *break*, and if present, execution of the SWITCH structure will end when the EXIT statement is reached, otherwise it will continue with the first statement below the next CASE statement (fall through).

BEGIN SEQUENCE statements

```
BEGIN SEQUENCE
   ...
   [BREAK]
   [Break( [Exp] )]
RECOVER [USING Var]
   ...
END[SEQUENCE]
```

or:

```
BEGIN SEQUENCE
   ...
   [BREAK]
   [Break()]
END[SEQUENCE]
```

The BEGIN SEQUENCE structure allows for a well behaved abortion of any sequence, even when crossing nested procedures/functions. This means that a called procedure/function, may issue a BREAK statement, or a Break() expression, to force unfolding of any nested procedure/functions, all the way back to the first outer BEGIN SEQUENCE structure, either after its respective END statement, or a RECOVER clause if present. The Break statement may optionally pass any type of expression, which may be accepted by the RECOVER statement to allow further recovery handing.

Additionally the Harbour *Error Object* supports *canDefault*, *canRetry* and *canSubstitute* properties, which allows error handlers to perform some preparations, and then request a *Retry Operation*, a *Resume*, or return a Value to replace the expression triggering the error condition.

Alternatively TRY [CATCH] [FINALLY] statements are available on *xhb* library working like the SEQUENCE construct.

Procedures/Functions

```
[STATIC] PROCEDURE SomeProcedureName
[STATIC] PROCEDURE SomeProcedureName()
[STATIC] PROCEDURE SomeProcedureName( Param1 [, ParamsN] )
```

```
INIT PROCEDURE SomeProcedureName
EXIT PROCEDURE SomeProcedureName
```

```
[STATIC] FUNCTION SomeProcedureName
[STATIC] FUNCTION SomeProcedureName()
[STATIC] FUNCTION SomeProcedureName( Param1 [, ParamsN] )
```

Procedures/Functions in Harbour can be specified with the keywords `PROCEDURE`, or `FUNCTION`. Naming rules are same as those for *Variables* (up to 63 characters non case sensitive). Both Procedures and Functions may be qualified by the scope qualifier *STATIC* to restrict their usage to the scope of the module where defined.

The *INIT* or *EXIT* optional qualifiers, will flag the procedure to be automatically invoked just before calling the application startup procedure, or just after quitting the application, respectively. Parameters passed to a procedure/function appear in the subroutine as local variables, and may accept any type, including references.

Changes to argument variables are not reflected in respective variables passed by the calling procedure/function/method unless explicitly passed BY REFERENCE using the @ prefix.

PROCEDURE have no return value, and if used in an Expression context will produce a *NIL* value.

FUNCTION may return any type by means of the RETURN statement, anywhere in the body of its definition.

An example procedure definition and a function call follows:

```
x := Cube( 2 )

FUNCTION Cube( n )
   RETURN n ** 3
```

Sample code

The typical "hello world" program would be:

```
  ? "Hello, world!"
```

Or:

```
  QOut( "Hello, world!" )
```

Or:

```
  Alert( "Hello, world!" )
```

Or, enclosed in an explicit procedure:

```
PROCEDURE Main()

   ? "Hello, world!"
```

```
    RETURN
```

OOP examples

```
#include "hbclass.ch"

PROCEDURE Main()

   LOCAL oPerson

   CLS

   oPerson := Person():New( "Dave" )

   oPerson:Eyes := "Invalid"

   oPerson:Eyes := "Blue"

   Alert( oPerson:Describe() )

   RETURN

CREATE CLASS Person

   VAR Name INIT ""

   METHOD New( cName )
   METHOD Describe()

   ACCESS Eyes INLINE ::pvtEyes
   ASSIGN Eyes( x ) INLINE iif( HB_ISSTRING( x ) .AND. x $ "Blue,Brown,Green", ::pvtEyes := x, Alert( "Invalid value" ) )

   PROTECTED:

   VAR pvtEyes

END CLASS

// Sample of normal Method definition
METHOD New( cName ) CLASS Person

   ::Name := cName

   RETURN Self

METHOD Describe() CLASS Person

   LOCAL cDescription
```

```
IF Empty( ::Name )
   cDescription := "I have no name yet."
ELSE
   cDescription := "My name is: " + ::Name + ";"
ENDIF

IF ! Empty( ::Eyes )
   cDescription += "my eyes' color is: " + ::Eyes
ENDIF

RETURN cDescription
```

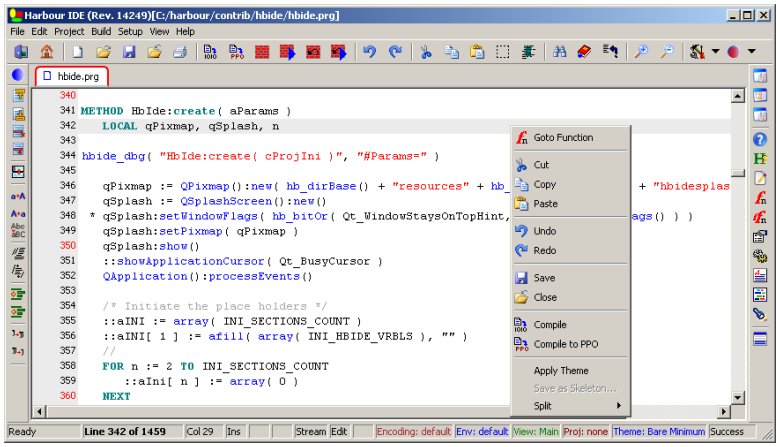
Tools

- hbmk2 – Powerful build tool like make
- hbrun – Shell interpreter for Harbour. Macro compiling allows to run any valid Harbour code as it's being compiled
- hbformat – Formats source code written on Harbour or another dialect according defined rules
- hbpp – Pre-processor, a powerful tool which avoids typical problems found on C language pre-processor
- hbi18n – Tools to localizing text on applications
- hbdoc – Creates documentation for Harbour

All tools are multiplatform.

Development

Today Habour development is leading by Viktor Szakáts with huge collaborations and leading many components of core and contribs by Przemysław Czerpak. HBIDE and some components, specially HBQt, are developed by Pritpal Bedi. Others members send minor changes to the GitHub source repository. As of 2010 Harbour development is keeping vibrant activity.



HBIDE look.

Popularity

Although there is no way to measure popularity of Harbour or xBase, the *TIOBE Programming Community Index* As of June 2006[4] ranked Microsoft Visual FoxPro, a high profile dialect of xBase, on 12th position on programming languages popularity ranking. FoxPro/xBase ranked on 25th position As of August 2010[4]. As of September 2010[4], the Clipper Usenet newsgroups `comp.lang.clipper` [3] is still active. As of August 2010[4] Harbour figured on 16th position on weekly downloads in compiler category and 132nd position on global rank.

xHarbour comparison

xHarbour is a fork of the earlier Harbour project. xHarbour takes a more aggressive approach to implementing new features in the language, while Harbour is more conservative in its approach, aiming first of all for an exact replication of Clipper behaviour and then implementing new features and extensions as a secondary consideration. It should also be noted that Harbour is supported on a wide variety of operating systems while xHarbour only really supports MS Windows and Linux 32-bit.

The Harbour developers have attempted to document all hidden behaviour in the Clipper language and test Harbour-compiled code alongside the same code compiled with Clipper to maintain compatibility.

The Harbour developers explicitly reject extensions to the language where those extensions would break Clipper compatibility. These rejections were soften recently since the new Harbour architecture allow extensions out of the core compiler.

A detailed comparison between extensions implemented in Harbour and xHarbour can be found in source repository of the project on GitHub.

As of 2009–2010, Harbour has seen a huge increase in its adoption while xHarbour decline as can be seen on its mailing list.

GUI libraries and tools

- **hbide** – Integrated Development Environment to help Harbour development and various xBase dialects
- **HwGui** [5] – Open Source cross-platform GUI library for Harbour
- **HMG** [6] – Free / Open Source xBase Win32 / GUI Development System for Harbour
- **MiniGUI** [7] – Free / Open Source xBase Win32 / GUI Development System (a Fork (software development) of both HMG and Harbour)
- **ooHG** [8] – Object Oriented Harbour GUI - a fork "class based and oop programming" of HMG

Visual FoxPro

Visual FoxPro

Visual FoxPro v9 running on Windows XP	
Developer(s)	Microsoft
Final release	v9.0 SP2 / October 16, 2007
Development status	Discontinued
Operating system	Windows 2000, Windows XP and Windows Server 2003
Platform	IA-32
Available in	**IDE:** English, German, Spanish **Runtime:** Above plus French, Chinese, Russian, Czech, Korean
Type	Integrated development environment, programming language
License	Commercial proprietary software
Website	msdn.microsoft.com/vfoxpro [1]

Visual FoxPro is a data-centric object-oriented procedural programming language produced by Microsoft. It is derived from FoxPro (originally known as **FoxBASE**) which was developed by Fox Software beginning in 1984. Fox Technologies merged with Microsoft in 1992, after which the software acquired further features and the prefix "Visual". The last version of FoxPro (2.6) worked under Mac OS, DOS, Windows, and Unix: Visual FoxPro 3.0, the first "Visual" version, reduced platform support to only Mac and Windows, and later versions were Windows-only. The current version of Visual FoxPro is COM-based and Microsoft has stated that they do not intend to create a Microsoft .NET version.

Version 9.0, released in 2004 and updated in 2007, is the final version of the product.

History

FoxPro originated as a member of the class of languages commonly referred to as "xBase" languages, which have syntax based on the dBase programming language. Other members of the xBase language family include Clipper and Recital. (A history of the early years of xBase can be found in the dBase article.)

Visual FoxPro, commonly abbreviated as VFP, is tightly integrated with its own relational database engine, which extends FoxPro's xBase capabilities to support SQL query and data manipulation. Unlike most database management systems, Visual FoxPro is a full-featured, dynamic programming language that does not require the use of an additional general-purpose programming environment. It can be used to write not just traditional "fat client" applications, but also middleware and web applications.

In late 2002, it was demonstrated that Visual FoxPro can run on Linux under the Wine Windows compatibility suite. In 2003, this led to complaints by Microsoft: it was claimed that the deployment of runtime FoxPro code on non-Windows machines violates the End User License Agreement.[2]

Visual FoxPro had a rapid rise and fall in popularity as measured by the TIOBE Programming Community Index.[3] In December 2005, VFP broke into the top 20 for the first time. In June 2006 it peaked at position 12, making it (at the time) a "B" language. By September 2010, FoxPro and its variants had fallen out of the top 50, where it has remained ever since.

In March 2007, Microsoft announced that there will be no VFP 10,[4] thus making VFP9 (released to manufacturing on December 17, 2004) the last commercial VFP release from Microsoft. The support of Version 9 is ongoing with

service packs that were released December 8, 2005 and October 11, 2007.

At the time of the end of life announcement, work on the next release codenamed Sedna (named after a recently discovered dwarf planet) which was built on top of the VFP9 codebase had already begun. "Sedna" is a set of add-ons to VFP 9.0 of xBase components to support a number of interoperability scenarios with various Microsoft technologies including SQL Server 2005, .NET Framework, Windows Vista, Office 2007, Windows Search and Team Foundation Server (TFS). Microsoft released Sedna under the Shared source license on the CodePlex site. Microsoft has clarified that the VFP core will still remain closed source. Sedna was released on January 25, 2008.[5] As of March 2008, all xBase components of the VFP 9 SP2 (including Sedna) were available for community-development on CodePlex.

In late March 2007 a grassroots campaign was started by the Spanish-speaking FoxPro community at MasFoxPro[6] ("MoreFoxPro" in English) to sign a petition to Microsoft to continue updating Visual FoxPro or release it to the community as Open Source. On April 3, 2007 the movement was noted by the technical press[7]

Also on April 3, 2007 Microsoft responded to the petitioner's requests with this statement from Alan Griver:

```
   "We're very aware of the FoxPro community and that played a large
part in what we announced on March 13th. It's never an easy decision to
 announce that we're not going to release another version of a product
and it's one that we consider very carefully.
```

```
   "We're not announcing the end of FoxPro: Obviously, FoxPro
applications will continue to work.  By some of our internal estimates,
 there are more applications running in FoxPro 2.6 than there are in
VFP and FoxPro 2.6 hasn't been supported in many years.  Visual FoxPro
9 will be supported by Microsoft through 2015.
```

```
   "For Microsoft to continue to evolve the FoxPro base, we would need
to look at creating a 64-bit development environment and that would
involve an almost complete rewrite of the core product.  We've also
invested in creating a scalable database with SQL Server, including the
 freely available SQL Server Express Edition. As far as forming a
partnership with a third-party is concerned, we've heard from a number
of large FoxPro customers that this would make it impossible for them
to continue to use FoxPro since it would no longer be from an approved
vendor. We felt that putting the environment into open source on
CodePlex, which balances the needs of both the community and the large
customers, was the best path forward."
```

Code samples

The FoxPro language contains commands quite similar to other programming languages such as Basic. Loops include do, if, while, for, else commands in a usage easily understood by anyone familiar with other programming languages. Commands take the form of "command" and "endcommand"

Some basic syntax samples:

```
FOR i = 1 to 10
   x = x + 6.5
ENDFOR

IF i = 25
```

```
   i = i + 1
ELSE
   i = i + 3
ENDIF

x = 1
DO WHILE x < 50
   x =  x + 1
ENDDO

x = 1
DO WHILE .T.
  x = x + 1
  IF x < 50
   LOOP
  ELSE
   EXIT
  ENDIF
ENDDO

nMonth = MONTH(DATE())
DO CASE
      CASE nMonth <= 3
               MESSAGEBOX("Q1")

      CASE nMonth <= 6
               MESSAGEBOX("Q2")

      CASE nMonth <= 9
               MESSAGEBOX("Q3")

      OTHERWISE
               MESSAGEBOX("Q4")
ENDCASE

FOR EACH oControl IN THISFORM.Controls
  MESSAGEBOX(oControl.Name)
ENDFOR

f = Factorial(10)

FUNCTION Factorial(n)
 LOCAL i,r
 r = 1
 FOR i = n TO 1 STEP -1
  r = r * n
 ENDFOR
```

```
 RETURN r
ENDFUNC
```

Hello World example:

```
MESSAGEBOX("Hello World")
```

Object

```
loForm = CREATEOBJECT("HiForm")
loForm.Show(1)

DEFINE CLASS HiForm AS Form
  AutoCenter = .T.
  Caption = "Hello, World"

  ADD OBJECT lblHi as Label WITH ;
    Caption = "Hello, World!"
ENDDEFINE
```

```
loMine = CREATEOBJECT("MyClass")
? loMine.cProp1   && This will work. (Double-ampersand marks an end-of-line comment)
? loMine.cProp2   && Program Error: Property CPROP2 is not found.

? loMine.MyMethod1()  && This will work.
? loMine.MyMethod2()  && Program Error: Property MYMETHOD2 is not found.

DEFINE CLASS MyClass AS Custom
  cProp1 = "My Property"    && This is a public property
  HIDDEN cProp2     && This is a private (hidden) property
  dProp3 = {}     && Another public property

  PROCEDURE Init()    && Class constructor
    This.cProp2 = "This is a hidden property."
  ENDPROC

  PROCEDURE dProp3_Access    && Property Getter
   RETURN DATE()
  ENDPROC
  PROCEDURE dProp3_Assign(vNewVal)   && Property Setter
    IF VARTYPE(vNewVal) = "D"
     THIS.dProp3 = vNewVal
    ENDIF
  ENDPROC

  PROCEDURE MyMethod1()
    * This is a public method, calling a hidden method that returns
    * the value of a hidden property.
    RETURN This.MyMethod2()
```

```
  ENDPROC

  HIDDEN PROCEDURE MyMethod2()  && This is a private (hidden) method
    RETURN This.cProp2
  ENDPROC
ENDDEFINE
```

Data handling

The language also has extensive database manipulation and indexing commands. The "help" index of commands in VFP 9 has several hundred commands and functions described. The examples below show how to code the creation and indexing of tables, however VFP has table and database builder screens which create the tables and indexes without making you write code.

```
&& Create a table
CREATE TABLE randData (iData I)

&& Populate with random data using xBase and SQL DML commands
FOR i = 1 TO 50
    APPEND BLANK
    REPLACE iData WITH (RAND() * 100)

    INSERT INTO randData (iData) VALUES (RAND() * 100)
ENDFOR

&& Place a structural index on the data
INDEX ON iData TAG iData
CLOSE ALL

&& Display ordered data using xBase-style commands
USE randData
SET ORDER TO iData
GO TOP
LIST NEXT 10  && First 10
GO BOTTOM
SKIP -10
LIST REST     && Last 10
CLOSE ALL

&& Browse ordered data using SQL DML commands
SELECT * ;
  FROM randData ;
  ORDER BY iData DESCENDING
```

ODBC access using SQL passthrough

```
&& Connect to an ODBC data source
LOCAL nHnd
nHnd = SQLCONNECT ("ODBCDSN", "user", "pwd")

&& Execute a SQL command
LOCAL nResult
nResult = SQLEXEC (nHnd, "USE master")
IF nResult < 0
  MESSAGEBOX ("MASTER database does not exist!")
  RETURN
ENDIF

&& Retrieve data from the remote server and stores it in
&& a local data cursor
nResult = SQLEXEC (nHnd, "SELECT * FROM authors", "QAUTHORS")

&& Update a record in a remote table using parameters
PRIVATE cAuthorID, cAuthorName
cAuthorID = "1001"
cAuthorName = "New name"
nResult = SQLEXEC (nHnd, "UPDATE authors SET auth_name = ?cAuthorName WHERE auth_id = ?cAuthorID")

&& Close the connection
SQLDISCONNECT(nHnd)
```

Visual Objects

Visual Objects is an object-oriented computer programming language that is used to create software programs that operate primarily under Windows. Although it can be used as a general-purpose programming tool, it is almost exclusively used to create database programs.

The original Visual Objects project (code-named **Aspen**) was started as part of Nantucket's attempts to bring the Clipper language to Windows, and move from the procedural to the object-oriented style. It also converted Clipper from a p-code system to being a true native compiler and introduced more elements of the C language (such as typed variables), while including Windows extensions (such as COM, ODBC, and later ADO). With its symbol datatype, it offers the ability to form name-based linkages, which may be used to connect menu events to object methods or form direct linkages between server columns and controls.

The Windows version was finally brought to market by Computer Associates. Unfortunately it was released before it was market-ready and in almost head-to-head competition with the first release of Borland's Delphi product. The language is still in use however the last release by GrafX Software was in 2007. The next incarnation of the Visual Objects language is Vulcan.NET, written by GrafX from scratch to be both Visual Objects compatible and be a true CLS compliant .NET language, taking full advantage of the .NET framework.

XBase

xBase is the generic term for all programming languages that derive from the original dBASE (Ashton-Tate) programming language and database formats. These are sometimes informally known as dBASE "clones". While there was a non-commercial predecessor to the Ashton-Tate product (Vulcan written by Wayne Ratliff), most clones are based on Ashton-Tate's 1986 dBASE III+ release — scripts written in the dBASE III+ dialect are most likely to run on all the clones.

History of the X

Ashton-Tate always maintained that everything relating to dBASE was proprietary, and as a result, filed lawsuits against several of the "clone" software vendors. One effect of this action was to cause the clone vendors to avoid using the term "dBASE": a trademark term held by Ashton-Tate. This gave rise to the creation of the generic term "xBase" meaning "dBASE or dBASE-like." A suggested name that narrowly failed was "*base" (pronounced "star base" and an homage to Vulcan and Star Trek), and some wanted it spelled "X-base" to further differentiate it from the trademark.

Standards effort

By 1987 there were an increasing number of "clone" software products that mimicked dBASE. Each of these products had its own unique set of supported language features and syntax. As such, it was often very difficult to move code developed with one dBASE-like product to run in another one. (This was in contrast to older programming languages such as C or COBOL where due to published official standards, carefully developed code could possibly be run in a wide range of software environments.) While there were many cries for a standard for the dBASE programming language syntax, nothing would happen as long as Ashton-Tate asserted ownership of all-things dBASE.

Once Borland acquired Ashton-Tate in mid-1991 (and was apparently required to drop the lawsuits as an anti-trust related condition of the merger), such standardization efforts were given new life. An ANSI committee (ANSI/X3J19) was officially formed, and began regular meetings in 1992. Marc Schnapp was the first chairman, and the first meeting was held at the Jet Propulsion Laboratory in Pasadena, California which was essentially the birthplace of Vulcan and dBASE II. The group met on a regular basis in a variety of locations over the next few years, and representatives from most major vendors participated. But despite lip service from all the vendors on the need for a standard, no one seemed willing to change their product syntax to match that of a competitor.

Influences over time

In 1989, Microtrend Books published the first "Xbase" cross-reference book (before the term was coined), *The dBASE Language Handbook*, by David M. Kalman, which covered Quicksilver, Clipper, dbxl, dBASE III, dBASE III Plus, dBASE IV, and FoxBase+. At more than 1,000 pages, it compared the execution of commands and functions to enable developers to build and maintain portable applications.

In 1993, Sybex, Inc. (computer books) published the *Xbase Cross Reference Handbook*, by Sheldon M. Dunn, another cross reference of the most commonly used xBase languages at that time—dBASE III+, dBASE IV, FoxPro for DOS, FoxPro for Windows, FoxPro for Macintosh and Clipper 5.1. At 1352 pages and 5.1 pounds shipping weight, the Cross Reference was hardly a handbook, but it provided the xBase community with an up-to-date, all-in-one reference manual, and addressed one of the major documentation problems that the community was facing. The software companies had decided to break their manuals into sections, separating commands from functions, etc., and splitting the (previous) manual into two or three different manuals, and the community was left trying to figure what-was-what and which manual to keep close at hand. 1993 was pivotal for the xBase community

because, as previously noted, Ashton-Tate had earlier sold dBASE as well as the rest of their product line to Borland and Microsoft had purchased FoxPro from Fox Software. Borland had also purchased QuickSilver to get a foot up the development ladder for a dBASE version for Windows (then 3.1). In 1994, Borland launched dBase V for Windows and dBASE V for DOS before selling the dBASE name and product line to dBASE Inc. [1]

In recent years there seems to be a renewed interest in xBase, mostly because of a number of open source, portable, xBase implementations (listed below), and the scripting applicability of the language. While newer desk-top database tools are optimized for mouse usage, xBase has always been "keyboard friendly", which helps make scripting and meta-programming (automating the automation) easier. Meta-programming generally does not work as well with mouse-oriented techniques because automating mouse movements can require calculating and processing of screen coordinates, something most developers find tedious and difficult to debug. xBase is one of the few table-oriented scripting languages still available.

xBase products

As of 2010, xBase is available and still expanding in terms of platform support (operating system), HTML clients, ASP Servers, Windows Scripting Host, and self-contained interpreters. Its current usage tends to be wider in Europe and Asia than in the United States.

The commercially available products:

- Apollo database engine [1] for managing CA-Clipper and FoxPro from Vista Software
- Clipper, Visual Objects (Windows 32) and Vulcan.NET [3] from GrafX Software
- dBase from dBASE Inc.
- DBFView, DBF editor/viewer/converter from Apycom Software
- FlagShip from multisoft GmbH
- Recital from Recital Corp.
- Visual FoxPro is available from Microsoft
- XBase++ from Alaska Software
- xHarbour Builder from xHarbour.com Inc.
- DBF Viewer 2000 from HiBase Group
- DBF Database management tools [2] from Astersoft Co. Ltd.
- DBF Commander Professional [3]
- Visual DBU [4] visual administration of any database/table from DS-Datasoft

Some free versions are also available, including:

- ActiveVFP – Free and open source project for creating web applications with Foxpro
- CLIP – GNU, object oriented, CA-Clipper compatible compiler
- Harbour Project – from active community
- xHarbour – Open Source alternative
- FlagShip free test version
- DBF Commander (free version) [5]
- DBFree [15] – script interpreter for developing xBase applications for the web

Defunct products:

- Vulcan (dBase predecessor)
- DBIII Compiler
- QuickSilver
- dbXL
- Dialog
- Joinner (from Brazilian company Tuxon)

- VP-Info
- Force
- dbFast
- CodeBase
- Multibase
- FoxBase
- Cule.Net from Software Perspectives

Interpreted versus compiled

xBase products generally split into an interpreted camp and the compiler camp. The original product was interpreted, but the "clones", led by Clipper, began creating compiler versions of the product. Compiling improved overall run-time speed and source-code security, but at the expense of an interpreted mode for interactive development or ad-hoc projects.

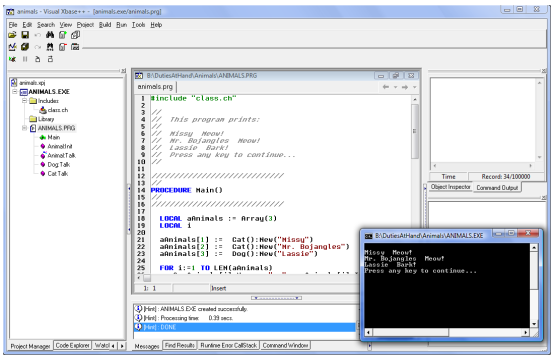
XBase++

Xbase++ is an object oriented programming language which has multiple inheritance and polymorphism. It is based on the XBase language dialect and conventions. It is 100% Clipper compatible language supporting multiple inheritance, polymorphism, object oriented programming. It supports the xBase data types, including Codeblocks. With Xbase++ it is possible to generate applications for Windows NT, 95, 98, Me, 2000, XP, VISTA and Windows 7.



Visual Xbase++ with sample *Animals*

Clipper Support

XBase++ supports the old commands @SAY/GET to define data entry forms as well as a graphic editor to create data entry forms similar to Visual FoxPro. It also has a visual development environment [1], support for OEM files (DOS format) and ANSI (Windows), an integrated debugger and a resource compiler to add icons and graphics to the application. It can generate EXE or DLL files.

RDD

Xbase++ supports the Replaceable Database Drivers (RDD, which provide access to multiple database formats) of Clipper through the DatabaseEngines (DBEs). The basic package includes support for DBF, FOX, NTX, CDX, SDF and DEL(delimited). It also supports CORBA 2.0, Visual FoxPro 3.0 to 5.0 database formats, and access to SQL servers.

Birth

XBase++ was born after the decision of Computer Associates to abandon Clipper to develop Visual Objects. The failure of Visual Objects as Clipper substitute empowered the creation of third party libraries and the creation of Clipper syntax compilers.

Source Code samples

```
#include "class.ch"

//
//  This program prints:
//
//  Missy  Meow!
//  Mr. Bojangles  Meow!
//  Lassie  Bark!
//  Press any key to continue...
//

////////////////////////////
//
PROCEDURE Main()
//
```

```
////////////////////////////

  LOCAL aAnimals := Array(3)
  LOCAL i

  aAnimals[1] :=  Cat():New("Missy")
  aAnimals[2] :=  Cat():New("Mr. Bojangles")
  aAnimals[3] :=  Dog():New("Lassie")

  FOR i:=1 TO LEN(aAnimals)
     ? aAnimals[i]:Name + "  " + aAnimals[i]:Talk()
  NEXT i

  WAIT

RETURN

////////////////////////////
//
CLASS Animal
//
////////////////////////////

XHarbour

xHarbour is a free multi-platform extended Clipper compiler, offering multiple graphic terminals (GTs), including console drivers, GUIs, and hybrid console/GUIs. xHarbour is backward-compatible with Clipper and supports many language syntax extensions, greatly extended run-time libraries, and extensive third party support.

Like most dynamic languages, xHarbour is also available as a scripting language (standalone application, linkable library, MS ActiveScript engine [Windows Script Host, HTML, ASP]) utilizing an interpreter written in the xHarbour language.

The xHarbour Usenet newsgroup `[news:comp.lang.xharbour comp.lang.xharbour]` is an active community for discussing xHarbour related questions.

Built-in data types

xHarbour has 6 scalar types : Nil, String, Date, Logical, Number, Pointer, and 4 complex types: Array, Object, CodeBlock, and Hash. A scalar holds a single value, such as a string, number, or reference to any other type. Arrays are ordered lists of scalars or complex types, indexed by number, starting at 1. Hashes, or associative arrays, are unordered collections of any type values indexed by their associated key, which may be of any scalar or complex type.

Literal (static) representation of scalar types:

- Nil: *NIL*
- String: *"hello", 'hello', [hello], or E"hello\n"*
- Date: *ctod("2005-03-17")*
- Logical: *.T., .F.*
- Number: *1, 1.1, -1, 0xFF*

Complex Types may also be represent as literal values:

- Array:

```
{ "String", 1, { "Nested Array" }, .T., FunctionCall(), @FunctionPointer() }
```

- CodeBlock:

```
{ |Arg1, ArgN| Arg1 := ArgN + OuterVar + FunctionCall() }
```

- Hash:

```
{ "Name" => "John", 1 => "Numeric key", { "Nested" => "Hash" } }
```

Hashes may use *any* type including other Hashes as the *Key* for any element. Hashes and Arrays may contain *any* type as the *Value* of any member, including nesting arrays, and Hashes.

Codeblocks may have references to Variables of the Procedure/Function>method in which it was defined. Such Codeblocks may be returned as a value, or by means of an argument passed BY REFERENCE, in such case the Codeblock will "outlive" the routine in which it was defined, and any variables it references, will be a *DETACHED* variable.

Detached variables will maintain their value for as long as a Codeblock referencing them still exists. Such values will be shared with any other Codeblock which may have access to those same variables. If the Codeblock did not outlive its containing routine, and will be evaluated within the lifetime of the routine in which it is defined, changes to its *Detached Variables*(s) by means of its evaluation, will be reflected back at its parent routine.

Codeblocks can be evaluated any number of times, by means of the Eval(*BlockExp*) function.

Variables

All types can be assigned to named variables. Named variable identifiers are 1 to 63 characters long, start with [A-Z|_] and further consist of the characters [A-Z|0-9|_] up to a maximum of 63 characters. Named variables are not case sensitive.

Variables have one of the following scopes:

- *LOCAL*: Visible only within the routine which declared it. Value is lost upon exit of the routine.
- *STATIC*: Visible only within the routine which declared it. Value is preserved for subsequent invocations of the routine. If a STATIC variable is declared before any Procedure/Function/Method is defined, it has a MODULE scope, and is visible within any routine defined within that same source file, it will maintain its life for the duration of the application lifetime.
- *GLOBAL* Visible within any routine defined in the same source module where the GLOBAL variable is declared, as well as any routine of any other source module, which explicitly declares it, by means of the *GLOBAL EXTERNAL* declaration. Both GLOBAL and GLOBAL EXTERNAL declarations must be declared before any Procedure/Function/Method is defined.
- *PRIVATE*: Visible within the routine which declared it, and all routines *called* by that routine.
- *PUBLIC*: Visible by *all* routines in the same application.

LOCAL, *STATIC*, and *GLOBAL* are resolved at compile time, and thus are much faster than *PRIVATE* and *PUBLIC* variables which are dynamic entities accessed by means of a runtime Symbol table. For this same reason, *LOCAL*, *STATIC* and *GLOBAL* variables are *not* exposed to the Macro compiler, and any macro code which attempts to reference them will generate a runtime error.

Due to the dynamic nature of *PRIVATE* and *PUBLIC* variables, they can be created and destroyed at runtime, can be accessed and modified by means of runtime macros, and can be accessed and modified by Codeblocks created on the fly.

Control structures

The basic control structures include all of the standard dBase, and Clipper control structures as well as additional ones inspired by the C or Java programming languages:

Loops

```
[DO] WHILE ConditionExp
   ...
   [LOOP]
   [EXIT]
END[DO]
```

```
FOR Var := InitExp TO EndExp [STEP StepExp]
   ...
   [LOOP]
   [EXIT]
NEXT
```

```
FOR EACH Var IN CollectionExp
   ...
   [HB_EnumIndex()]
   [LOOP]
```

```
   [EXIT]
NEXT
```

- The ... is a sequence of one of more xHarbour statements, and square bracketes `[]` denote optional syntax.
- The *HB_EnumIndex()* may be optionally used to retrieve the current iteration index (1 based).
- The *LOOP* statement restarts the current iteration of the enclosing loop structure, and if the enclosing loop is a *FOR* or *FOR EACH* loop, it increases the iterator, moving to the next iteration of the loop.
- The *EXIT* statement immediately terminates execution of the enclosing loop structure.
- The *NEXT* statement closes the control structure and moves to the next iteration of loop structure.

In the *FOR* statement, the *assignment* expression is evaluated prior to the first loop iteration. The *TO* expression is evaluated and compared against the value of the control variable, prior to each iteration, and the loop is terminated if it evaluates to a numeric value greater than the numeric value of the control variable. The optional *STEP* expression is evaluated after each iteration, prior to deciding whether to perform the next iteration.

In *FOR EACH*, the *Var* variable will have the value (scalar, or complex) of the respective element in the collection value. The collection expression, may be an Array (of any type or combinations of types), an Hash Table, or an Object type.

IF statements

```
IF CondExp
   ...
[ELSEIF] CondExp
   ...
[ELSE]
   ...
END[IF]
```

... represents 0 or more *statement(s)*.

The condition expression(s) has to evaluate to a *LOGICAL* value.

DO CASE statements

```
DO CASE
   CASE CondExp
      ...
   [CASE CondExp]
      ...
   [OTHERWISE]
      ...
END[CASE ]
```

Above construct is logically equivalent to:

```
IF CondExp
   ...
ELSEIF CondExp
   ...
[ELSEIF CondExp]
   ...
[ELSE]
```

```
   ...
END[IF]
```

SWITCH statements

xHarbour supports a SWITCH construct inspired by the C implementation of switch().

```
SWITCH SwitchExp
   CASE LiteralExp
      ...
      [EXIT]
```

```
   [CASE LiteralExp]
      ...
      [EXIT]

   [DEFAULT]
      ...
END
```

- The *LiteralExp* must be a compiled time resolvable numeric expression, and may involve operators, as long as such operators involve compile time static value.
- The *EXIT* optional statement is the equivalent of the C statement *break*, and if present, execution of the SWITCH structure will end when the EXIT statement is reached, otherwise it will continue with the first statement below the next CASE statement (fall through).

BEGIN SEQUENCE statements

```
BEGIN SEQUENCE
   ...
   [BREAK]
   [Break([Exp])]
RECOVER [USING Var]
   ...
END[SEQUENCE]
```

or:

```
BEGIN SEQUENCE
   ...
   [BREAK]
   [Break()]
END[SEQUENCE]
```

The BEGIN SEQUENCE structure allows for a well behaved abortion of any sequence, even when crossing nested procedures/functions. This means that a called procedure/function, may issue a BREAK statement, or a Break() expression, to force unfolding of any nested procedure/functions, all the way back to the first outer BEGIN SEQUENCE structure, either after its respective END statement, or a RECOVER clause if present. The Break statement may optionally pass any type of expression, which may be accepted by the RECOVER statement to allow further recovery handing.

Additionally the xHarbour Error Object supports canDefault, canRetry and canSubstitute properties, which allows error handlers to perform some preparations, and then request a Retry Operation, a Resume, or return a Value to replace the expression triggering the error condition.

TRY [CATCH] [FINALLY] statements

```
TRY
   ...
   [BREAK]
   [Break([Exp])]
   [Throw([Exp])]
CATCH [Var]
   ...
END
```

```
TRY
   ...
   [BREAK]
   [Break([Exp])]
   [Throw([Exp])]
CATCH [Var]
   ...
FINALLY
   ...
END
```

or:

```
TRY
   ...
   [BREAK]
   [Break([Exp])]
   [Throw([Exp])]
FINALLY
   ...
END
```

The TRY construct is very similar to the BEGIN SEQUENCE construct, except it automatically integrates error handling, so that any error will be intercepted, and recovered by means of the CATCH statement or forwarded to an outer CATCH handler otherwise. The FINALLY section is guaranteed to be executed before the TRY or CATCH sections forward flow control by means of RETURN, BREAK, or THROW.

Procedures/Functions

```
[STATIC] PROCEDURE SomeProcedureName
[STATIC] PROCEDURE SomeProcedureName()
[STATIC] PROCEDURE SomeProcedureName( Param1' [, ParamsN] )
```

```
INIT PROCEDURE SomeProcedureName
EXIT PROCEDURE SomeProcedureName
```

```
[STATIC] FUNCTION SomeProcedureName
[STATIC] FUNCTION SomeProcedureName()
[STATIC] FUNCTION SomeProcedureName( Param1' [, ParamsN] )
```

Procedures/Functions in xHarbour can be specified with the keywords `PROCEDURE`, or `FUNCTION`. Naming rules are same as those for *Variables* (up to 63 characters non case sensitive). Both Procedures and Functions may be qualified by the scope qualifier *STATIC* to restrict their usage to the scope of the module where defined.

The *INIT* or *EXIT* optional qualifiers, will flag the procedure to be automatically invoked just before calling the application startup procedure, or just after quitting the application, respectively. Parameters passed to a procedure/function appear in the subroutine as local variables, and may accept any type, including references.

Changes to argument variables are not reflected in respective variables passed by the calling procedure/function/method unless explicitly passed BY REFERENCE using the @ prefix.

PROCEDURE have no return value, and if used in an Expression context will produce a *NIL* value.

FUNCTION may return any type by means of the RETURN statement, anywhere in the body of its definition.

An example procedure definition and a function call follows:

```
x := Cube( 2 )

FUNCTION Cube( n )
RETURN n ** 3
```

Database support

xHarbour extends the Clipper Replaceable Database Drivers (RDD) approach. It offers multiple RDDs such as DBF, DBFNTX, DBFCDX, DBFDBT, and DBFFPT. In xHarbour multiple RDDs can be used in a single application, and new logical RDDs can be defined from combination of other RDD. The RDD architecture allows for inheritance, so that a given RDD may extend the functionality of other existing RDD(s). 3rd party RDDs, like RDDSQL, RDDSIX, RMDBFCDX, *Advantage Database Server*, and *Mediator* exemplify some of the RDD architecture features.

xHarbour also offers ODBC support by means of an OOP syntax, and ADO support by means of OLE.

Macro Operator (runtime compiler)

One of the most powerful features of the xBase languages is the MACRO Operator '&'. xHarbour's implementation of the Macro Operator allows for runtime compilation of any valid xHarbour expression. Such compiled expression may be used as a VALUE, i.e. the right side of an Assignment, but more interestingly, such compiled expression may be used to resolve the LEFT side of an assignment, i.e. PRIVATE, or PUBLIC variables, or Database FIELD.

Additionally the Macro Operator may compile and execute function calls, complete assignments, or even list of arguments, and the result of the macro may be used to resolve any of the above contexts in the compiled application. IOW, any xHarbour application may be extended, and/or modified in runtime, to compile and execute additional code on demand.

The xHarbour implementation of this feature is so complete that the xHarbour interpreter, xbScript, uses it heavily, to compile xHarbour scripts.

Syntax:

```
&( ... )
```

The text value of the expression '...' will be compiled, and the value resulting from the execution of the compiled code is the result.

```
&SomeId
```

is the short form for &(SomeId).

```
&SomeId.postfix
```

is the short form of &(SomeId + "postfix").

Sample code

The typical "hello world" program would be:

```
? "Hello, world!"
```

Or:

```
QOut( "Hello, world!" )
```

Or:

```
Alert( "Hello, world!" )
```

Or, enclosed in an explicit procedure:

```
PROCEDURE Main()

   ? "Hello, world!"

RETURN
```

OOP examples

```
#include "hbclass.ch"

PROCEDURE Main()

   LOCAl oPerson := Person( "Dave" )

   oPerson:Eyes := "Invalid"

   oPerson:Eyes := "Blue"

   Alert( oPerson:Describe() )
RETURN

CLASS Person
   DATA Name INIT ""

   METHOD New() CONSTRUCTOR

   ACCESS Eyes INLINE ::pvtEyes
   ASSIGN Eyes( x ) INLINE IIF( ValType( x ) == 'C' .AND. x IN "Blue,Brown,Green", ::pvtEyes := x, Alert( "Invalid value" ) )

   // Sample of IN-LINE Method definition
   INLINE METHOD Describe()
      LOCAL cDescription

      IF Empty( ::Name )
         cDescription := "I have no name yet."
      ELSE
         cDescription := "My name is: " + ::Name + ";"
      ENDIF

      IF ! Empty( ::Eyes )
         cDescription += "my eyes' color is: " + ::Eyes
      ENDIF
   ENDMETHOD

   PRIVATE:
      DATA pvtEyes
ENDCLASS

// Sample of normal Method definition.
METHOD New( cName ) CLASS Person

  ::Name := cName

RETURN Self
```

Scripting

xHarbour is also available as an interpreted language in few flavors of scripting engines.

- *Stand alone Interpreter*: Portable, self-contained, interpreter xBaseScript.
- *ActiveScript*: Microsoft ActiveScript compliant OLE DLL, which supports xHarbour scripting in:
  - Windows Script Host (WSH).
  - Internet Explorer, HTML client side scripting.
  - IIS, and any other ASP compliant server.

Other Query Languages

QUEL query languages

QUEL is a relational database query language, based on tuple relational calculus, with some similarities to SQL. It was created as a part of the Ingres DBMS effort at University of California, Berkeley, based on Codd's earlier suggested but not implemented *Data Sub-Language ALPHA*. QUEL was used for a short time in most products based on the freely available Ingres source code, most notably PostgreSQL. As Oracle and DB2 gained market share in the early 1980s, most companies then supporting QUEL moved to SQL instead. QUEL continues to be available as a part of the Ingres DBMS, although no QUEL-specific language enhancements have been added for many yearsWikipedia:Manual of Style/Dates and numbers#Chronological items.

Usage

QUEL statements are always defined by *tuple variables*, which can be used to limit queries or return result sets. Consider this example, taken from one of the first original Ingres papers:

> *Example* 1.1. Compute salary divided by age-18 for employee Jones.
>
> range of E is EMPLOYEE
>
> retrieve into W
>
> (COMP = E.Salary / (E.Age - 18))
>
> where E.Name = "Jones"
>
> Here E is a tuple variable which ranges over the EMPLOYEE relation, and all tuples in that relation are found which satisfy the qualification E.Name = “Jones.” The result of the query is a new relation W, which has a single domain COMP that has been calculated for each qualifying tuple.

An equivalent SQL statement is:

```
select (e.salary / (e.age - 18)) as comp
from employee as e
where e.name = "Jones"
```

QUEL is generally more "normalized" than SQL.[*citation needed*] Whereas every major SQL command has a format that is at least somewhat different from the others, in QUEL a single syntax is used for all commands.[*citation needed*]

For instance, here is a sample of a simple session that creates a table, inserts a row into it, and then retrieves and modifies the data inside it and finally deletes the row that was added (assuming that name is a unique field).

```
create student(name = c10, age = i4, sex = c1, state = c2)
range of s is student
append to s (name = "philip", age = 17, sex = "m", state = "FL")
retrieve (s.all) where s.state = "FL"
replace s (age=s.age+1)
retrieve (s.all)
delete s where s.name="philip"
```

Here is a similar set of SQL statements:

```
 create table student(name char(10), age int, sex char(1), state
char(2))
 insert into student (name, age, sex, state) values ("philip", 17, "m",
 "FL")
 select * from student where state = "FL"
 update student set age=age+1
 select * from student
 delete from student where name="philip"
```

Note that syntax varies significantly between commands, and that even similar commands like `insert` and `update` use different styles.

Another feature of QUEL was a built-in system for moving records en-masse into and out of the system. Consider this command:

```
copy student(name=c0, comma=d1, age=c0, comma=d1, sex=c0, comma=d1, address=c0, nl=d1)
 into "/student.txt"
```

which creates a comma-delimited file of all the records in the student table. The d1 indicates a delimiter, as opposed to a data type. Changing the `into` to a `from` reverses the process. Similar commands are available in many SQL systems, but usually as external tools, as opposed to being internal to the SQL language. This makes them unavailable to stored procedures.

QUEL has an extremely powerful aggregation capability. Aggregates can be nested, and different aggregates can have independent by-lists and/or restriction clauses. For example:

```
 retrieve (a=count(y.i by y.d where y.str = "ii*" or y.str = "foo"),b=max(count(y.i by y.d)))
```

This example illustrates one of the arguably less desirable quirks of QUEL, namely that all string comparisons are potentially pattern matches. `y.str = "ii*"` matches all y.str values starting with ii.

Further reading

- C. J. Date: A Critique of the SQL Database Language (https://www.cs.duke.edu/courses/spring03/cps216/papers/date-1983.pdf). SIGMOD Record 14(3): 8-54, 1984.

Query by Example

Query by Example (**QBE**) is a database query language for relational databases. It was devised by Moshé M. Zloof at IBM Research during the mid-1970s, in parallel to the development of SQL. It is the first graphical query language, using visual tables where the user would enter commands, example elements and conditions. Many graphical front-ends for databases use the ideas from QBE today. Originally limited only for the purpose of retrieving data, QBE was later extended to allow other operations, such as inserts, deletes and updates, as well as creation of temporary tables.

The motivation behind QBE is that a parser can convert the user's actions into statements expressed in a database manipulation language, such as SQL. Behind the scenes, it is this statement that is actually executed. A suitably comprehensive front-end can minimize the burden on the user to remember the finer details of SQL, and it is easier and more productive for end-users (and even programmers) to select tables and columns by selecting them rather than typing in their names,

In the context of information retrieval, QBE has a somewhat different meaning. The user can submit a document, or several documents, and ask for "similar" documents to be retrieved from a document database. Similarity search is based comparing document vectors (see Vector Space Model).

QBE is a seminal work in end-user development, frequently cited in research papers as an early example of this topic.

Currently, QBE is supported in several relational database front ends, notably Microsoft Access, which implements "Visual Query by Example", as well as Microsoft SQL Server Enterprise Manager. It is also implemented in several object-oriented databases (e.g. in db4o).

QBE is based on the logical formalism called tableau query, although QBE adds some extensions to that, much like SQL is based on the relational algebra.

Example

A simple example using the Suppliers and Parts database is given here to illustrate how QBE works.

S	S#	SNAME	OWNER	SCITY
	P.SX		J. DOE	ROME

Simple QBE Example

As a general technique

The term also refers to a general technique influenced by Zloof's work whereby only items with search values are used to "filter" the results. It provides a way for a software user to perform queries without having to know a query language (such as SQL). The software can automatically generate the queries for the user (usually behind the scenes). Here are some examples:

Example Form **B**:

```
.....Name: Bob
..Address:
.....City:
....State: TX
..Zipcode:
```

Resulting SQL:

```
SELECT * FROM Contacts WHERE Name='Bob' AND State='TX'
```

Note how blank items do not generate SQL terms. Since "Address" is blank, there is no clause generated for it.

Example Form **C**:

```
.....Name:
..Address:
.....City: Sampleton
....State:
..Zipcode: 12345
```

Resulting SQL:

```
SELECT * FROM Contacts WHERE City='Sampleton' AND Zipcode='12345'
```

More advanced versions of QBE have other comparison operator options, often via a pull-down menu, such as "Contains", "Starts With", "Greater-Than", and so forth.

SQR

SQR (Hyperion SQR Production Reporting, Part of OBIEE) is a programming language designed for generating reports from database management systems. The name is an acronym of **S**tructured **Q**uery **R**eporter, which suggests its relationship to SQL (Structured Query Language). Any SQL statement can be embedded in an SQR program.

History

SQ Software created SQR in the mid 1980s. It had a marketing agreement with D & N Systems, which changed its name to SQL Solutions and was later acquired by Sybase Inc. Sybase purchased SQ Software in the early 1990s. To avoid competing directly with Oracle Corporation, Sybase had a marketing and development agreement with MITI for the Oracle database versions of SQR. MITI acquired the full rights to SQR in the mid 1990s. MITI changed its name to SQRiBE Technologies in 1997. Brio Technology acquired SQRiBE in August, 1999. Brio Technology later changed its name to Brio Software. Brio licensed the compiler source code to PeopleSoft Inc. sometime around 2000. Hyperion Solutions Corporation acquired Brio Software in October, 2003. Oracle Corporation acquired PeopleSoft in December, 2004. And as of March 2007 Oracle Corporation has acquired Hyperion Solutions.

SQR-Related Products

- ORACLE: Hyperion SQR Production Reporting - System 9 (Release 9.3.1, 2008);
- ORACLE: PeopleSoft Enterprise Tools & Technology (PeopleTools, Release 8.52, 2011)

General Components

1. SQR Server
2. SQR Viewer
3. SQR Print
4. SQR Execute
5. SQR Workbench for Windows; SQR Developer

Features

SQR is notable for its powerful database and printing functions. It can embed any SQL statement almost anywhere in a program. There is a version of SQR that can use multidimensional databases like Essbase. It can combine database reads with print instructions. It flexibly formats data breaks and page breaks. It prints variable fonts, sizes, and colors. It has a graph generation command that offers dozens of parameters for adjusting content and appearance.

Syntax

SQR has four scalar data types. The first three are numeric (variables begin with “#”), character string (variables begin with “$”), and date (variables begin with “$”, same as with character string variables.). Date variables must be declared, to be distinguished from character string variables. There is the option to declare numeric variables to specify them more precisely (integer, floating point, etc.). The last data type is a database column (variables begin with “&”). The values of database columns are set only by a SQL “select” statement; no other command can change their values.

SQR has arrays like those of the C programming language or COBOL. An array has one or more fields, each field either a numeric, string, or date variable. Each field may have multiple occurrences, giving SQR the equivalent of two-dimensional arrays. SQR has special commands that manipulate multiple items within a single array. There are also many commands that cannot use an array element in place of a scalar variable.

SQR has four control structures. The first three are if-else-end, while-end, and evaluate (like case or switch). The fourth is the embedded SQL “select” statement, which allows SQR statements to be executed for each row of data in a loop.

SQR has commands to open, read, write, append, and close computer files. File input and output is sequential and record-oriented only; random access is not supported.

.QL

.QL

Paradigm(s)	multi-paradigm, logic-paradigm, object-oriented-paradigm
Appeared in	2007
Developer	Semmle
Typing discipline	static, strong
Major implementations	SemmleCode
Influenced by	Datalog

.QL (pronounced "dot-cue-el") is an object-oriented query language used to retrieve data from relational database management systems. It is reminiscent of the standard query language SQL and the object-oriented programming language Java. .QL is an object-oriented variant of a logical query language called Datalog. Hierarchical data can therefore be naturally queried in .QL in a recursive manner.

Queries written in .QL are optimised, compiled into SQL and can then be executed on any major relational database management system. .QL query language is being used in SemmleCode to query a relational representation of Java programs.

.QL is developed at Semmle Limited and is based on the company's proprietary technology.

Language Features

.QL has several language features to make queries concise, intuitive and reusable:

- Extensible type hierarchy
- Methods and predicates
- Definition before use

Example query

The sample query below illustrates use of .QL to query a Java program. This is how one would select all classes that contain more than ten public methods:

```
from Class c, int numofm
where numofm = count(Method m| m.getDeclaringType()=c
                     and m.hasModifier("public"))
      and numofm > 10
select c.getPackage(), c, numofm
```

In fact, this query selects not only all classes with more than ten public methods, but also their corresponding packages and the number of methods each class has.

Yahoo! query language

Yahoo! Query Language (**YQL**) is an SQL-like query language created by Yahoo! as part of their Developer Network. YQL is designed to retrieve and manipulate data from APIs through a single Web interface, thus allowing mashups that enable developers to create their own applications.

Initially launched in October 2008 with access to Yahoo APIs, February 2009 saw the addition of open data tables from third parties such as Google Reader, the *Guardian*, and *The New York Times*. Some of these APIs still require an API key to access them. On April 29th of 2009, Yahoo introduced the capability to execute the tables of data built through YQL using JavaScript run on the company's servers for free.

YANG

In Network management systems, it is necessary to get/set parameters that reflect the state of the equipment being managed. So there is a need to represent data and there is a need to retrieve/set the data. So, any network management protocol would configure and get status/notifications from the equipment.

There are various protocols to get/set the data. Ex: SNMP, NetConf, TL1 etc. Each protocol also creates its own data format, which the protocol needs to understand/interpret. Building network management systems also becomes cumbersome, since there is an inevitable need for integration across various NMS systems into OSS systems. Companies earmark good budget for building the NMS systems - reasonable chunk of time of which goes into defining the data format. YANG, a data modeling language, cuts across all of these protocols and creates a well-defined standard that could be used by any protocol.

'YANG' [1] is a data modeling language for the NETCONF network configuration protocol. The YANG data modeling language was developed by the NETMOD working group in the IETF and was published as RFC 6020 in October 2010. The data modeling language can be used to model both configuration data as well as state data of network elements. Furthermore, YANG can be used to define the format of event notifications emitted by network elements and it allows data modelers to define the signature of remote procedure calls that can be invoked on network elements via the NETCONF protocol.

YANG is a modular language representing data structures in an XML tree format. The data modeling language comes with a number of builtin data types. Additional application specific data types can be derived from the builtin data types. More complex reusable data structures can be represented as groupings. YANG data models can use XPATH expressions to define constraints on the elements of a YANG data model.

WQL

Windows Management Instrumentation Query Language (**WQL**) is Microsoft's implementation of the CIM Query Language (CQL), a query language for the Common Information Model (CIM) standard from the Distributed Management Task Force (DMTF). It is a subset of the standard ANSI SQL with minor semantic changes.[1] A basic WQL query remains fairly understandable for people with basic SQL knowledge.

WQL is dedicated to WMI and is designed to perform queries against the CIM repository to retrieve information or get event notifications.

Example

As an example, the following WQL query selects all the drives on a computer that have less than 2 MB of free space:[2]

```
SELECT * FROM Win32_LogicalDisk WHERE FreeSpace < 2097152
```

Versa (query language)

Versa is an RDF query language, that is, a query language for databases, able to retrieve and manipulate data stored in Resource Description Framework (RDF) format. Versa differs from most other RDF query languages, which are typically based on SQL or specialized XML vocabularies. Although the design of Versa was inspired by XPath, its compact, functional syntax also somewhat resembles Lisp. As of 2006[1], the only Versa implementation is in the Python-language, open source 4Suite XML framework.

History and status

Versa's origins can be traced to 2000, when professional XML consultancy Fourthought, Inc. began developing RIL, an open, XML-based RDF Inference Language. RIL was implemented briefly in Fourthought's 4Suite Server product, which allowed for persistent storage and querying of an RDF model and associated XML document store.

In October 2001, the query portion of RIL was spun off into a separate project named Versa, with the intent that after Versa stabilized, development would resume to establish RIL as a formal language for working Versa query results. RIL development never resumed, however; inference abilities in 4Suite were easily handled by XSLT extensions and did not need a separate language.

Versa initially had limits that required the language to be redesigned. The overhaul was performed in late 2001 and early 2002 by software engineers from Sun Microsystems and Fourthought, to facilitate internal knowledge management applications at Sun and to drive applications that were in development for Fourthought's other clients. 4Suite's Versa library was used as the reference implementation, and a draft specification was published.

Versa development slowed in 2002, although Sun and Fourthought continued to work together to develop Versa based applications through 2004. In mid-2005, Chimezie Ogbuji and Daniel Krech began planning to fold the abilities of 4Suite's outdated RDF libraries (4RDF), including Versa support, into RDFLib, which offers complementary features and would allow Versa to be used independently of 4Suite. This coincided with renewed interest in refining the Versa draft specification and publishing a "1.0" version.

As of 2006, the development of Versa is being coordinated primarily by Chimezie and Uche Ogbuji of Fourthought.

Syntax examples

Get the URIs of all known resources:

SPARQL

SPARQL

Paradigm(s)	Query language
Appeared in	2008
Developer	W3C
Stable release	1.1 (2013-03-21)
Major implementations	C#, Java, C
Website	[1]

SPARQL (pronounced "sparkle", a recursive acronym for ***S**PARQL **P**rotocol **a**nd **R**DF **Q**uery **L**anguage*) is an RDF query language, that is, a query language for databases, able to retrieve and manipulate data stored in Resource Description Framework format. It was made a standard by the *RDF Data Access Working Group* (DAWG) of the World Wide Web Consortium, and is recognized as one of the key technologies of the semantic web. On 15 January 2008, SPARQL 1.0 became an official W3C Recommendation, and SPARQL 1.1 in March, 2013.

SPARQL allows for a query to consist of triple patterns, conjunctions, disjunctions, and optional patterns.

Implementations for multiple programming languages exist. "SPARQL will make a huge difference" making the web machine-readable according to Sir Tim Berners-Lee in a May 2006 interview.

There exist tools that allow one to connect and semi-automatically construct a SPARQL query for a SPARQL endpoint, for example ViziQuer. In addition, there exist tools that translate SPARQL queries to other query languages, for example to SQL and to XQuery. SPARQL City's SPARQLverse also allows queries directly against non-SPARQL databases such as MongoDB and Cassandra, representing their data as though it is RDF.

Advantages

SPARQL allows users to write queries against data that can loosely be called "key-value" data, more specifically it is data that follows the RDF specification of the W3C. The entire database is thus a set of "subject-predicate-object" triples. This is analogous to some NoSQL database's usage of the term "document-key-value", such as MongoDB.

RDF data can also be considered in SQL relational database terms as a table with three columns - the subject column, the predicate column and the object column. Unlike relational databases, the object column is heterogeneous, the per-cell data type is usually implied (or specified in the ontology) by the predicate value. Alternately, again comparing to SQL relational, all of the triples for a given subject could be represented as a row, with the subject being the primary key and each possible predicate being a column and the object is the value in the cell. However, SPARQL/RDF becomes easier and more powerful for columns that could contain multiple values (like "children"), and where the column itself could be a joinable variable in the query, rather than directly specified.

SPARQL thus provides a full set of analytic query operations such as JOIN, SORT, AGGREGATE for data whose schema is intrinsically part of the data rather than requiring a separate schema definition. Schema information (the ontology) is often provided externally, though, to allow different datasets to be joined in an unambiguous manner. In addition, SPARQL provides specific graph traversal syntax for data that can be thought of as a graph. Some implementations, such as SPARQLverse [2] also allow additional triple attributes such as timestamp and allow additional analytic functionality such as windowed aggregates.

The example below demonstrates a simple query that leverages the ontology definition "foaf", often called the "friend-of-a-friend" ontology.

Specifically, the following query returns names and emails of every person in the dataset:

```
PREFIX foaf: <http://xmlns.com/foaf/0.1/>
SELECT ?name ?email
WHERE {
  ?person a foaf:Person.
  ?person foaf:name ?name.
  ?person foaf:mbox ?email.
}
```

This query joins together all of the triples with a matching subject, where the type predicate, "a", is a person (foaf:Person) and the person has one or more names (foaf:name) and mailboxes (foaf:mbox).

The author of this query chose to reference the subject using the variable name "?person" for readable clarity. Since the first element of the triple is always the subject, the author could have just as easily used any variable name, such as "?subj" or "?x". Whatever name is chosen, it must be that same on each line of the query to signify that the query engine is to join triples with the same subject.

The result of the join is a set of rows - ?person, ?name, ?email. This query is returning the the ?name and ?email because ?person is often a complex URI rather than a human-friendly string. Note that in some of the ?people may have multiple mailboxes, so in the returned set, a ?name row may appear multiple times, once for each mailbox.

This query can be distributed to multiple SPARQL endpoints (services that accept SPARQL queries and return results), computed, and results gathered, a procedure known as federated query.

Whether in a federated manner or locally, additional triple definitions in the query could allow joins to different subject types, such as automobiles, to allow simple queries, for example, to return a list of names and emails for people who drive automobiles with a high MPG rating.

Query forms

In the case of queries that read data from the database, the SPARQL language specifies four different query variations for different purposes.

SELECT query

: Used to extract raw values from a SPARQL endpoint, the results are returned in a table format.

CONSTRUCT query

: Used to extract information from the SPARQL endpoint and transform the results into valid RDF.

ASK query

: Used to provide a simple True/False result for a query on a SPARQL endpoint.

DESCRIBE query

: Used to extract an RDF graph from the SPARQL endpoint, the contents of which is left to the endpoint to decide based on what the maintainer deems as useful information.

Each of these query forms takes a WHERE block to restrict the query although in the case of the DESCRIBE query the WHERE is optional.

SPARQL 1.1 specifies a language for updating the database with several new query forms.

Example

Another SPARQL query example that models the question "What are all the country capitals in Africa?":

```
PREFIX abc: <http://example.com/exampleOntology#>
SELECT ?capital ?country
WHERE {
  ?x abc:cityname ?capital ;
     abc:isCapitalOf ?y .
  ?y abc:countryname ?country ;
     abc:isInContinent abc:Africa .
}
```

Variables are indicated by a "?" or "$" prefix. Bindings for ?capital and the ?country will be returned.

The SPARQL query processor will search for sets of triples that match these four triple patterns, binding the variables in the query to the corresponding parts of each triple. Important to note here is the "property orientation" (class matches can be conducted solely through class-attributes or properties - see Duck typing)

To make queries concise, SPARQL allows the definition of prefixes and base URIs in a fashion similar to Turtle. In this query, the prefix "abc" stands for “http://example.com/exampleOntology#”.

Extensions

GeoSPARQL defines filter functions for geographic information system (GIS) queries using well-understood OGC standards (GML, WKT, etc.).

RDF query language

An **RDF query language** is a computer language, specifically a query language for databases, able to retrieve and manipulate data stored in Resource Description Framework format.

SPARQL is emerging as the de facto RDF query language, and is a W3C recommendation. Released as a Candidate Recommendation in April 2006, it returned to Working Draft status in October 2006, due to open issues. It returned to Candidate Recommendation status in June 2007. On 12 November 2007 the status of SPARQL changed into Proposed Recommendation. On 15 January 2008, SPARQL was standardized.

Other RDF query languages

- DQL, XML-based, queries and results expressed in DAML+OIL
- N3QL, based on Notation 3
- R-DEVICE
- RDFQ, XML-based
- RDQ, SQL-like
- RDQL, SQL-like
- RQL/RVL, SQL-like
- SeRQL, SQL-like, similar to RQL/RVL
- Versa (query language), compact syntax (non−SQL-like), solely implemented in 4Suite (Python)
- XUL has a template [1] element in which to declare rules for matching data in RDF. XUL uses RDF extensively for databinding.
- Adenine (programming language written in RDF).

Access query language

Access, the successor to ENGLISH, is an English-like query language used in the Pick operating system.

The original name ENGLISH is something of a misnomer, as PICK's flexible dictionary structure meant that file and attribute names could be given aliases in any natural language. For instance the command SORT could be given the alias TRIEZ, the file CUSTOMER the alias CLIENT, the attribute BALANCE the alias BILAN and the particle BY the alias PAR. This would allow the database to be interrogated using the French-language command string "TRIEZ CLIENT PAR BILAN", resulting in a list of customers by balance.

Nonprocedural language

NPL (for **NonProcedural Language**) was a relational database language developed by T.D. Truitt et al.[1][2] in 1980 for Apple II and MS-DOS. In general, a non-procedural language (also called a declarative language) requires the programmer to specify *what* the program should do, rather than (as with a procedural language) providing the sequential steps indicating *how* the program should perform its task(s).

Notes and references

Facebook Query Language

Facebook Query Language

Appeared in	February 2007
Influenced by	SQL
Platform	Facebook Platform
Website	[1]

Facebook Query Language (**FQL**) is a query language that allows querying Facebook user data by using a SQL-style interface, avoiding the need to use the Facebook Platform Graph API. Data returned from an FQL query is in JSON format by default.

History

FQL was first made publicly available in February 2007.

Example

In the following query, four different types of data are retrieved from a single table (status) and for a single user ("me"):

```
SELECT status_id,message,time,source FROM `status` WHERE uid = me()
```

This query can run by querying the Facebook graph endpoint */fql* with the parameters set to *q=[FQL]*

Databases Programming

Active database

An **active database** is a database that includes an event-driven architecture (often in the form of ECA rules) which can respond to conditions both inside and outside the database. Possible uses include security monitoring, alerting, statistics gathering and authorization.

Most modern relational databases include active database features in the form of database triggers.

References

Database trigger

A **database trigger** is procedural code that is automatically executed in response to certain events on a particular table or view in a database. The trigger is mostly used for maintaining the integrity of the information on the database. For example, when a new record (representing a new worker) is added to the employees table, new records should also be created in the tables of the taxes, vacations and salaries.

The need and the usage

Triggers are commonly used to:

- audit changes (e.g. keep a log of the users and roles involved in changes)
- enhance changes (e.g. ensure that every change to a record is time-stamped by the server's clock)
- enforce business rules (e.g. require that every invoice have at least one line item)
- execute business rules (e.g. notify a manager every time an employee's bank account number changes)
- replicate data (e.g. store a record of every change, to be shipped to another database later)
- enhance performance (e.g. update the account balance after every detail transaction, for faster queries)

The examples above are called Data Manipulation Language (DML) triggers because the triggers are defined as part of the Data Manipulation Language and are executed at the time the data is manipulated. Some systems, for example Microsoft SQL Server, also support non-data triggers, which fire in response to Data Definition Language (DDL) events such as creating tables, or runtime events such as logon, commit and rollback. Such DDL triggers can be used for database auditing purposes.

The following are major features of database triggers and their effects:

- triggers do not accept parameters or arguments (but may store affected-data in temporary tables)
- triggers cannot perform commit or rollback operations because they are part of the triggering SQL statement (only through autonomous transactions)

Triggers in DBMS

Below follows a series of descriptions of how some popular DBMS support triggers.

Oracle

In addition to triggers that fire when data is modified, Oracle 9i supports triggers that fire when schema level objects (that is, tables) are modified and when user logon or logoff events occur. These trigger types are referred to as "Schema-level triggers".

Schema-level triggers

- After Creation
- Before Alter
- After Alter
- Before Drop
- After Drop
- Before Logoff
- After Logon

The four main types of triggers are:

1. Row Level Trigger: This gets executed before or after *any column value of a row* changes
2. Column Level Trigger: This gets executed before or after the *specified column* changes
3. For Each Row Type: This trigger gets executed once for each row of the result set caused by insert/update/delete
4. For Each Statement Type: This trigger gets executed only once for the entire result set, but fires each time the statement is executed.

Mutating tables

When a single SQL statement modifies several rows of a table at once, the order of the operations is not well-defined; there is no "order by" clause on "update" statements, for example. Row-level triggers are executed as each row is modified, so the order in which trigger code is run is also not well-defined. Oracle protects the programmer from this uncertainty by preventing row-level triggers from modifying other rows in the same table – this is the "mutating table" in the error message. Side-effects on other tables are allowed, however.

One solution is to have row-level triggers place information into a temporary table indicating what further changes need to be made, and then have a statement-level trigger fire just once, at the end, to perform the requested changes and clean up the temporary table.

Because a foreign key's referential actions are implemented via implied triggers, they are similarly restricted. This may become a problem when defining a self-referential foreign key, or a cyclical set of such constraints, or some other combination of triggers and CASCADE rules, e.g. user deletes a record from table A, CASCADE rule on table A deletes a record from table B, trigger on table B attempts to SELECT from table A, error occurs.

Microsoft SQL Server

Microsoft SQL Server supports triggers either before, after, or instead of an insert, update or delete operation. They can be set on tables and views with the constraint that a view can be referenced only by an INSTEAD OF trigger.

Microsoft SQL Server 2005 introduced support for Data Definition Language (DDL) triggers, which can fire in reaction to a very wide range of events, including:

- Drop table
- Create table
- Alter table
- Login events

A full list [1] is available on MSDN.

Performing conditional actions in triggers (or testing data following modification) is done through accessing the temporary *Inserted* and *Deleted* tables.

PostgreSQL

PostgreSQL introduced support for triggers in 1997. The following functionality in SQL:2003 was previously not implemented in PostgreSQL:

- SQL allows triggers to fire on updates to specific columns; As of version 9.0 of PostgreSQL this feature is also implemented in PostgreSQL.
- The standard allows the execution of a number of SQL statements other than SELECT, INSERT, UPDATE, such as CREATE TABLE as the triggered action. This can be done through creating a stored procedure or function to call CREATE TABLE.[2]

Synopsis:

```
CREATE TRIGGER name { BEFORE | AFTER } { event [ OR ... ] }
    ON TABLE [ FOR [ EACH ] { ROW | STATEMENT } ]
    EXECUTE PROCEDURE funcname ( arguments )
```

Firebird

Firebird supports multiple row-level, BEFORE or AFTER, INSERT, UPDATE, DELETE (or any combination thereof) triggers per table, where they are always "in addition to" the default table changes, and the order of the triggers relative to each other can be specified where it would otherwise be ambiguous (POSITION clause.) Triggers may also exist on views, where they are always "instead of" triggers, replacing the default updatable view logic. (Before version 2.1, triggers on views deemed updatable would run in addition to the default logic.)

Firebird does not raise mutating table exceptions (like Oracle), and triggers will by default both nest and recurse as required (SQL Server allows nesting but not recursion, by default.) Firebird's triggers use NEW and OLD context variables (not Inserted and Deleted tables,) and provide UPDATING, INSERTING, and DELETING flags to indicate the current usage of the trigger.

```
{CREATE | RECREATE | CREATE OR ALTER} TRIGGER name FOR {table name |
view name}
 [ACTIVE | INACTIVE]
 {BEFORE | AFTER}
 {INSERT [OR UPDATE] [OR DELETE] | UPDATE [OR INSERT] [OR DELETE] |
DELETE [OR UPDATE] [OR INSERT] }
 [POSITION n] AS
BEGIN
```

```
 .....
END
```

As of version 2.1, Firebird additionally supports the following database-level triggers:

- CONNECT (exceptions raised here prevent the connection from completing)
- DISCONNECT
- TRANSACTION START
- TRANSACTION COMMIT (exceptions raised here prevent the transaction from committing, or preparing if a two-phase commit is involved)
- TRANSACTION ROLLBACK

Database-level triggers can help enforce multi-table constraints, or emulate materialized views. If an exception is raised in a TRANSACTION COMMIT trigger, the changes made by the trigger so far are rolled back and the client application is notified, but the transaction remains active as if COMMIT had never been requested; the client application can continue to make changes and re-request COMMIT.

Syntax for database triggers:

```
{CREATE | RECREATE | CREATE OR ALTER} TRIGGER name
 [ACTIVE | INACTIVE] ON
 {CONNECT | DISCONNECT | TRANSACTION START | TRANSACTION COMMIT |
TRANSACTION ROLLBACK}
 [POSITION n] AS
BEGIN
 .....
END
```

MySQL

MySQL 5.0.2 introduced support for triggers. MySQL supports these trigger types:

- Insert Trigger
- Update Trigger
- Delete Trigger

Note: MySQL allows only one trigger of each type on each table (i.e. one before insert, one after insert, one before update, one after update, one before delete and one after delete).

Note: MySQL does NOT fire triggers outside of a statement (i.e. API's, foreign key cascades)

The SQL:2003 standard mandates that triggers give programmers access to record variables by means of a syntax such as `REFERENCING NEW AS n`. For example, if a trigger is monitoring for changes to a salary column one could write a trigger like the following:

```
CREATE TRIGGER salary_trigger
    BEFORE UPDATE ON employee_table
    REFERENCING NEW ROW AS n, OLD ROW AS o
    FOR EACH ROW
    IF n.salary <> o.salary THEN

    END IF;
;
```

Sample Mytrigger as follows:

```
-- First of all, drop any other trigger with the same name
DROP TRIGGER IF EXISTS `Mytrigger`;
-- Create New Trigger
DELIMITER $$

CREATE
    /*[DEFINER = { user | CURRENT_USER }]*/
    TRIGGER `DB`.`mytriggers` BEFORE/AFTER INSERT/UPDATE/DELETE
    ON `DB`.`<Table Name>`
    FOR EACH ROW BEGIN

    END$$

DELIMITER ;

-- Example:
DROP TRIGGER IF EXISTS `Mytrigger`;

DELIMITER $$
CREATE TRIGGER `Mytrigger`
AFTER INSERT ON Table_Current
FOR EACH ROW
BEGIN

    UPDATE Table_Record

    SET `Value` = NEW.`Value`
    WHERE `Name` = NEW.`Name`
    AND `Value` < NEW.`Value`;

END $$
DELIMITER;
```

IBM DB2 LUW

IBM DB2 for distributed systems known as DB2 for LUW (LUW means Linux Unix Windows) supports three trigger types: Before trigger, After trigger and Instead of trigger. Both statement level and row level triggers are supported. If there are more triggers for same operation on table then firing order is determined by trigger creation data. Since version 9.7 IBM DB2 supports autonomous transactions [3].

Before trigger is for checking data and deciding if operation should be permitted. If exception is thrown from before trigger then operation is aborted and no data are changed. In DB2 before triggers are read only — you can't modify data in before triggers. After triggers are designed for post processing after requested change was performed. After triggers can write data into tables and unlike someWikipedia:Avoid weasel words other databases you can write into any table including table on which trigger operates. Instead of triggers are for making views writeable.

Triggers are usually programmed in SQL PL language.

SQLite

```
CREATE [TEMP | TEMPORARY] TRIGGER [IF NOT EXISTS] [database_name .]
trigger_name
[BEFORE | AFTER | INSTEAD OF] {DELETE | INSERT | UPDATE [OF column_name
 [, column_name]...]}
ON {table_name | view_name}
   [FOR EACH ROW] [WHEN condition]
BEGIN
   ...
END
```

SQLite only supports row-level triggers, not statement-level triggers.

Updateable views, which are not supported in SQLite, can be emulated with INSTEAD OF triggers.

XML databases

An example of implementation of triggers in non-relational database can be Sedna, that provides support for triggers based on XQuery. Triggers in Sedna were designed to be analogous to SQL:2003 triggers, but natively base on XML query and update languages (XPath, XQuery and XML update language).

A trigger in Sedna is set on any nodes of an XML document stored in database. When these nodes are updated, the trigger automatically executes XQuery queries and updates specified in its body. For example, the following trigger cancels person node deletion if there are any open auctions referenced by this person:

```
CREATE TRIGGER "trigger3"
    BEFORE DELETE
    ON doc("auction")/site//person
    FOR EACH NODE
    DO
    {
       if(exists($WHERE//open_auction/bidder/personref/@person=$OLD/@id))
       then ( )
       else $OLD;
    }
```

Stored procedure

A **stored procedure** is a subroutine available to applications that access a relational database system. A stored procedure (sometimes called a **proc**, **sproc**, **StoPro**, **StoredProc**, **sp** or **SP**) is actually stored in the database data dictionary.

Typical use for stored procedures include data validation (integrated into the database) or access control mechanisms. Furthermore, stored procedures can consolidate and centralize logic that was originally implemented in applications. Extensive or complex processing that requires execution of several SQL statements is moved into stored procedures, and all applications call the procedures. One can use nested stored procedures by executing one stored procedure from within another.

Stored procedures are similar to user-defined functions (UDFs). The major difference is that UDFs can be used like any other expression within SQL statements, whereas stored procedures must be invoked using the `CALL` statement.[1]

```
CALL procedure(...)
```

or

```
EXECUTE procedure(...)
```

Stored procedures may return result sets, *i.e.* the results of a `SELECT` statement. Such result sets can be processed using cursors, by other stored procedures, by associating a result set locator, or by applications. Stored procedures may also contain declared variables for processing data and cursors that allow it to loop through multiple rows in a table. Stored procedure flow control statements typically include `IF`, `WHILE`, `LOOP`, `REPEAT`, and `CASE` statements, and more. Stored procedures can receive variables, return results or modify variables and return them, depending on how and where the variable is declared.

Implementation

The exact and correct implementation of stored procedures varies from one database system to another. Most major database vendors support them in some form. Depending on the database system, stored procedures can be implemented in a variety of programming languages, for example SQL, Java, C, or C++. Stored procedures written in non-SQL programming languages may or may not execute SQL statements themselves.

The increasing adoption of stored procedures led to the introduction of procedural elements to the SQL language in the SQL:1999 and SQL:2003 standards in the part SQL/PSM. That made SQL an imperative programming language. Most database systems offer proprietary and vendor-specific extensions, exceeding SQL/PSM. A standard specification for Java stored procedures exists as well as SQL/JRT.

Database system	Implementation language
CUBRID	Java
DB2	SQL PL (close to the SQL/PSM standard) or Java
Firebird	PSQL (Fyracle also supports portions of Oracle's PL/SQL)
Informix	SPL or Java
Microsoft SQL Server	Transact-SQL and various .NET Framework languages
MySQL	own stored procedures, closely adhering to SQL/PSM standard.
Oracle	PL/SQL or Java
PostgreSQL	PL/pgSQL, can also use own function languages such as pl/perl or pl/php
Sybase ASE	Transact-SQL

Comparison with dynamic SQL

Overhead

Because stored procedure statements are stored directly in the database, they *may* remove all or part of the compilation overhead that is typically required in situations where software applications send inline (dynamic) SQL queries to a database. (However, most database systems implement "statement caches" and other mechanisms to avoid repetitive compilation of dynamic SQL statements.) In addition, while they avoid some overhead, pre-compiled SQL statements add to the complexity of creating an optimal execution plan because not all arguments of the SQL statement are supplied at compile time. Depending on the specific database implementation and configuration, mixed performance results will be seen from stored procedures versus generic queries or user defined functions.

Avoidance of network traffic

A major advantage with stored procedures is that they can run directly within the database engine. In a production system, this typically means that the procedures run entirely on a specialized database server, which has direct access to the data being accessed. The benefit here is that network communication costs can be avoided completely. This becomes particularly important for complex series of SQL statements.

Encapsulation of business logic

Stored procedures allow programmers to embed business logic as an API in the database, which can simplify data management and reduce the need to encode the logic elsewhere in client programs. This can result in a lesser likelihood of data corruption by faulty client programs. The database system can ensure data integrity and consistency with the help of stored procedures.

Delegation of access-rights

In many systems, stored procedures can be granted access rights to the database that users who execute those procedures do not directly have.

Some protection from SQL injection attacks

Stored procedures can be used to protect against injection attacks. Stored procedure parameters will be treated as data even if an attacker inserts SQL commands. Also, some DBMSs will check the parameter's type. A stored procedure that in turn generates dynamic SQL using the input is however still vulnerable to SQL injections unless proper precautions are taken.

Other uses

In some systems, stored procedures can be used to control transaction management; in others, stored procedures run inside a transaction such that transactions are effectively transparent to them. Stored procedures can also be invoked from a database trigger or a condition handler. For example, a stored procedure may be triggered by an insert on a specific table, or update of a specific field in a table, and the code inside the stored procedure would be executed. Writing stored procedures as condition handlers also allows database administrators to track errors in the system with greater detail by using stored procedures to catch the errors and record some audit information in the database or an external resource like a file.

Comparison with functions

- A function is a subprogram written to perform certain computations
- A scalar function returns only a single value (or NULL), whereas a table function returns a (relational) table comprising zero or more rows, each row with one or more columns.
- Functions must return a value (using the `RETURN` keyword), but for stored procedures this is not compulsory.
- Stored procedures can use `RETURN` keyword but without any value being passed.
- Functions could be used in `SELECT` statements, provided they don't do any data manipulation. However, procedures cannot be included in `SELECT` statements.
- A stored procedure can return multiple values using the `OUT` parameter or return no value at all.
- A stored procedure saves the query compilation time.

Comparison with prepared statements

Prepared statements take an ordinary statement or query and parameterize it so that different literal values can be used at a later time. Like stored procedures, they are stored on the server for efficiency and provide some protection from SQL injection attacks. Although simpler and more declarative, prepared statements are not ordinarily written to use procedural logic and cannot operate on variables. Because of their simple interface and client-side implementations, prepared statements are more widely reusable between DBMSs.

Disadvantages

- Stored procedure languages are quite often **vendor-specific**. Switching to another vendor's database most likely requires rewriting any existing stored procedures.
- Stored procedure languages from different vendors have different levels of sophistication.
  - For example, Oracle's PL/SQL has more language features and built-in features (via packages such as DBMS_ and UTL_ and others) than Microsoft's T-SQL.[*citation needed*]
- Tool support for writing and debugging stored procedures is often not as good as for other programming languages, but this differs between vendors and languages.
  - For example, both PL/SQL and T-SQL have dedicated IDEs and debuggers. PL/PgSQL can be debugged from various IDEs.

PL/SQL

PL/SQL (**Procedural Language/Structured Query Language**) is Oracle Corporation's procedural language extension for SQL and the Oracle relational database. PL/SQL is available in Oracle Database (since version 7), TimesTen in-memory database (since version 11.2.1), and IBM DB2 (since version 9.7). Oracle Corporation usually extends PL/SQL functionality with each successive release of the Oracle Database.

PL/SQL includes procedural language elements such as conditions and loops. You can declare constants and variables, procedures and functions, types and variables of those types, and triggers. You can handle exceptions (runtime errors). Arrays are supported involving the use of PL/SQL collections. Implementations from version 8 of Oracle Database onwards have included features associated with object-orientation. You can create PL/SQL units—procedures, functions, packages, types, and triggers —that are stored in the database for reuse by applications that use any of the Oracle Database programmatic interfaces.

Similar languages

PL/SQL functions analogously to the embedded procedural languages associated with other relational databases. Sybase ASE and Microsoft SQL Server have Transact-SQL, PostgreSQL has PL/pgSQL (which tries to emulate PL/SQL to an extent), and IBM DB2 includes SQL Procedural Language, which conforms to the ISO SQL's SQL/PSM standard.

The designers of PL/SQL modelled its syntax on that of Ada. Both Ada and PL/SQL have Pascal as a common ancestor, and so PL/SQL also resembles Pascal in numerous aspects. The structure of a PL/SQL package closely resembles the basic Pascal program structure or a Borland Delphi unit. Programmers can define global data-types, constants and static variables, public and private, in a PL/SQL package.

PL/SQL also allows for the definition of classes and instantiating these as objects in PL/SQL code. This resembles usages in object-oriented programming languages like Object Pascal, C++ and Java. PL/SQL refers to a class as an "Abstract Data Type" (ADT) or "User Defined Type" (UDT), and defines it as an Oracle SQL data-type as opposed to a PL/SQL user-defined type, allowing its use in both the Oracle SQL Engine and the Oracle PL/SQL engine. The constructor and methods of an Abstract Data Type are written in PL/SQL. The resulting Abstract Data Type can operate as an object class in PL/SQL. Such objects can also persist as column values in Oracle database tables.

PL/SQL is fundamentally distinct from Transact-SQL, despite superficial similarities. Porting code from one to the other usually involves non-trivial work, not only due to the differences in the feature sets of the two languages, but also due to the very significant differences in the way Oracle and SQL Server deal with concurrency and locking.

The Fyracle project aims to enable the execution of PL/SQL code in the open-source Firebird database.

The StepSqlite product is a PL/SQL compiler for the popular small database SQLite.

PL/SQL Program Unit

A PL/SQL program unit is one of the following: PL/SQL Anonymous Block, Procedure, Function, Package Specification, Package Body, Trigger, Type Specification, Type Body, Library. Program units are the PL/SQL source code that is compiled, developed and ultimately executed on the database.

PL/SQL Anonymous Block

The basic unit of a PL/SQL source program is the block, which groups related declarations and statements. A PL/SQL block is defined by the keywords DECLARE, BEGIN, EXCEPTION, and END. These keywords divide the block into a declarative part, an executable part, and an exception-handling part. The declaration section is optional and may be used to define and initialize constants and variables. If a variable is not initialized then it defaults to NULL value. The optional exception-handling part is used to handle run time errors. Only the executable part is required. A block can have a label.

For example:

```
<<label>>   -- this is optional
declare
-- this section is optional
  number1 number(2);
  number2 number1%type    := 17;             -- value default
  text1   varchar4(12) := 'Hello world';
  text2   date         := SYSDATE;        -- current date and time
begin
-- this section is mandatory, must contain at least one executable statement
  SELECT street_number
    INTO number1
    FROM address
   WHERE name = 'INU';
exception
-- this section is optional
   WHEN OTHERS THEN
     DBMS_OUTPUT.PUT_LINE('Error Code is ' || to_char(sqlcode )  );
     DBMS_OUTPUT.PUT_LINE('Error Message is ' || sqlerrm   );
end;
```

The symbol := functions as an assignment operator to store a value in a variable.

Blocks can be nested: Because a block is an executable statement, it can appear in another block wherever an executable statement is allowed. You can submit a block to an interactive tool (such as SQL*Plus) or embed it in an Oracle Precompiler or OCI program. The interactive tool or program runs the block one time. The block is not stored in the database, and for that reason, it is called an anonymous block (even if it has a label).

Function

The purpose of a PL/SQL function is generally to compute and return a single value. This returned value may be a single scalar value (such as a number, date or character string) or a single collection (such as a nested table or varray). User-defined functions supplement the built-in functions provided by Oracle Corporation.

The PL/SQL function has the form:

```
CREATE OR REPLACE FUNCTION <function_name> [(input/output variable declarations)] RETURN return_type
[AUTHID <CURRENT_USER | DEFINER>] <IS|AS>   -- heading part
amount number;-- declaration block]
BEGIN  -- exectutable part
      <PL/SQL block with return statement>
        RETURN <return_value>;
[Exception
      none]
        RETURN <return_value>;
END;
```

A pipelined table functions return collections and take the form:

```
CREATE OR REPLACE FUNCTION <function_name> [(input/output variable declarations)] RETURN return_type
[AUTHID <CURRENT_USER | DEFINER>] [<AGGREGATE | PIPELINED>] <IS|USING>
      [declaration block]
BEGIN
      <PL/SQL block with return statement>
        PIPE ROW <return type>;
        RETURN;
[Exception
      exception block]
        PIPE ROW <return type>;
        RETURN;
END;
```

A function should only use the default IN type of parameter. The only out value from the function should be the value it returns.

Procedure

Procedures are similar to Functions, in that they are named program units that can be invoked repeatedly. The primary difference is that **functions can be used in a SQL statement whereas procedures cannot**. Another difference is that the procedure can return multiple values whereas a function should only return a single value.

The procedure begins with a mandatory heading part to hold the procedure name and optionally the procedure parameter list. Next are the declarative, executable and exception-handling parts, as in the PL/SQL Anonymous Block. Here is an example of a simple procedure.

```
CREATE PROCEDURE create_email_address ( -- Procedure heading part begins
name1 VARCHAR2,
name2 VARCHAR2,
company VARCHAR2
) -- Procedure heading part ends
AS
```

```
-- Declarative part begins (optional)
error_message VARCHAR2(30) := 'Email address is too long.';
BEGIN -- Executable part begins (mandatory)
email := name1 || '.' || name2 || '@' || company;
EXCEPTION -- Exception-handling part begins (optional)
WHEN VALUE_ERROR THEN
DBMS_OUTPUT.PUT_LINE(error_message);
END create_email_address;
```

The example above shows a Standalone Procedure - this type of procedure is created and stored in a database schema using the CREATE PROCEDURE statement. A procedure may also be created in a PL/SQL package - this is called a Package Procedure. A procedure created in a PL/SQL anonymous block is called a Nested Procedure. The Standalone or Package procedures are stored in the database and so are referred to as Stored Procedures.

There are three types of parameter: IN, OUT and IN OUT.

1. An IN parameter is used as input only. An IN parameter is passed by reference though it can be changed by the inactive program.
2. An OUT parameter is initially NULL. The program assigns the parameter a value and that value is returned to the calling program.
3. An IN OUT parameter may or may not have an initial value. That initial value may or may not be modified by the called program. Any changes made to the parameter are returned to the calling program by default by copying but - with the NOCOPY hint - may be passed by reference.

Package

Packages are groups of conceptually linked functions, procedures, variables, PL/SQL table and record TYPE statements, constants, cursors etc. The use of packages promotes re-use of code. Packages are composed of the package specification and an optional package body. The specification is the interface to the application; it declares the types, variables, constants, exceptions, cursors, and subprograms available. The body fully defines cursors and subprograms, and so implements the spec. Two advantages of packages include:

1. Modular approach, encapsulation/hiding of business logic, security, performance improvement, re-usability. They support Object-oriented programming features like function overloading and encapsulation.
2. Using package variables one can declare session level (scoped) variables, since variables declared in the package specification have a session scope.

Trigger

A trigger is like a stored procedure that Oracle Database invokes automatically whenever a specified event occurs. It is a named PL/SQL unit that is stored in the database and can be invoked repeatedly. Unlike a stored procedure, you can enable and disable a trigger, but you cannot explicitly invoke it. While a trigger is enabled, the database automatically invokes it—that is, the trigger fires—whenever its triggering event occurs. While a trigger is disabled, it does not fire.

You create a trigger with the CREATE TRIGGER statement. You specify the triggering event in terms of triggering statements and the item on which they act. The trigger is said to be created on or defined on the item, which is either a table, a view, a schema, or the database. You also specify the timing point, which determines whether the trigger fires before or after the triggering statement runs and whether it fires for each row that the triggering statement affects.

If the trigger is created on a table or view, then the triggering event is composed of DML statements, and the trigger is called a DML trigger. If the trigger is created on a schema or the database, then the triggering event is composed

of either DDL or database operation statements, and the trigger is called a system trigger.

An INSTEAD OF trigger is either: A DML trigger created on a view or a system trigger defined on a CREATE statement. The database fires the INSTEAD OF trigger instead of running the triggering statement.

Benefits of Triggers

Triggers can be written for the following purposes:

Generating some derived column values automatically

Enforcing referential integrity

Event logging and storing information on table access

Auditing

Synchronous replication of tables

Imposing security authorizations

Preventing invalid transactions

Data Types

The major datatypes in PL/SQL include NUMBER, INTEGER, CHAR, VARCHAR2, DATE and TIMESTAMP.

Numeric variables

```
variable_name number(P[,S]) := 0;
```

To define a numeric variable, the programmer appends the variable type **NUMBER** to the name definition. To specify the (optional) precision (P) and the (optional) scale (S), one can further append these in round brackets, separated by a comma. ("Precision" in this context refers to the number of digits which the variable can hold, "scale" refers to the number of digits which can follow the decimal point.)

A selection of other datatypes for numeric variables would include: binary_float, binary_double, dec, decimal, double precision, float, integer, int, numeric, real, smallint, binary_integer.

Character variables

```
variable_name varchar2(10) := 'Text';
```

To define a character variable, the programmer normally appends the variable type VARCHAR2 to the name definition. There follows in brackets the maximum number of characters which the variable can store.

Other datatypes for character variables include: varchar, char, long, raw, long raw, nchar, nchar2, clob, blob, bfile

Date variables

```
variable_name date := to_date('01-01-2005 14:20:23','DD-MM-YYYY hh24:mi:ss');
```

Date variables can contain date and time. The time may be left out, but there is no way to define a variable that only contains the time. There is no DATETIME type. And there is no TIME type. But there is a TIMESTAMP type that can contain fine grained timestamp up to millisecond or nanosecond. Oracle Datatypes [1]

The `TO_DATE` function can be used to convert strings to date values. The function converts the first quoted string into a date, using as a definition the second quoted string, for example:

```
 to_date('31-12-2004','dd-mm-yyyy')
```

or

```
 to_date ('31-Dec-2004','dd-mon-yyyy', 'NLS_DATE_LANGUAGE = American')
```

To convert the dates to strings one uses the function `TO_CHAR (date_string, format_string).`

PL/SQL also supports the use of ANSI date and interval literals. The following clause gives an 18-month range:

```
WHERE dateField BETWEEN DATE '2004-12-30' - INTERVAL '1-6' YEAR TO MONTH
    AND DATE '2004-12-30'
```

Exceptions

Exceptions, errors which arise during the execution of the code, have one of two types:

User-defined exceptions are always raised explicitly by the programmers, using the `RAISE` or `RAISE_APPLICATION_ERROR` commands, in any situation where they have determined that it is impossible for normal execution to continue. The `RAISE` command has the syntax:

```
RAISE <exception name>;
```

Oracle Corporation has predefined several exceptions like `NO_DATA_FOUND`, `TOO_MANY_ROWS`, *etc.* Each exception has an SQL Error Number and SQL Error Message associated with it. Programmers can access these by using the `SQLCODE` and `SQLERRM` functions.

Datatypes for specific columns

Variable_name Table_name.Column_name%type;

This syntax defines a variable of the type of the referenced column on the referenced tables.

Programmers specify user-defined datatypes with the syntax:

```
type data_type is record (field_1 type_1 :=xyz, field_2 type_2 :=xyz, ..., field_n type_n :=xyz);
```

For example:

```
declare
    type t_address is  record (
        name address.name%type,
        street address.street%type,
        street_number address.street_number%type,
        postcode address.postcode%type);
    v_address t_address;
begin
    select name, street, street_number, postcode into v_address from address where rownum = 1;
end;
```

This sample program defines its own datatype, called *t_address*, which contains the fields *name, street, street_number* and *postcode*.

So according to the example, we are able to copy the data from the database to the fields in the program.

Using this datatype the programmer has defined a variable called *v_address* and loaded it with data from the ADDRESS table.

Programmers can address individual attributes in such a structure by means of the dot-notation, thus: *"v_address.street := 'High Street';"*

Conditional statements

The following code segment shows the IF-THEN-ELSIF construct. The ELSIF and ELSE parts are optional so it is possible to create simpler IF-THEN or, IF-THEN-ELSE constructs.

```
IF x = 1 THEN
   sequence_of_statements_1;
ELSIF x = 2 THEN
   sequence_of_statements_2;
ELSIF x = 3 THEN
   sequence_of_statements_3;
ELSIF x = 4 THEN
   sequence_of_statements_4;
ELSIF x = 5 THEN
   sequence_of_statements_5;
ELSE
   sequence_of_statements_N;
END IF;
```

The CASE statement simplifies some large IF-THEN-ELSE structures.

```
CASE
   WHEN x = 1 THEN sequence_of_statements_1;
   WHEN x = 2 THEN sequence_of_statements_2;
   WHEN x = 3 THEN sequence_of_statements_3;
   WHEN x = 4 THEN sequence_of_statements_4;
   WHEN x = 5 THEN sequence_of_statements_5;
   ELSE sequence_of_statements_N;
END CASE;
```

CASE statement can be used with predefined selector:

```
CASE x
   WHEN 1 THEN sequence_of_statements_1;
   WHEN 2 THEN sequence_of_statements_2;
   WHEN 3 THEN sequence_of_statements_3;
   WHEN 4 THEN sequence_of_statements_4;
   WHEN 5 THEN sequence_of_statements_5;
   ELSE sequence_of_statements_N;
END CASE;
```

Array handling

PL/SQL refers to arrays as "collections". The language offers three types of collections:

1. Associative arrays (Index-by tables)
2. Nested tables
3. Varrays (variable-size arrays)

Programmers must specify an upper limit for varrays, but need not for index-by tables or for nested tables. The language includes several collection methods used to manipulate collection elements: for example FIRST, LAST, NEXT, PRIOR, EXTEND, TRIM, DELETE, etc. Index-by tables can be used to simulate associative arrays, as in this example of a memo function for Ackermann's function in PL/SQL.

Associative arrays (Index-by tables)

With index-by tables, the array can be indexed by numbers or strings. It parallels a Java *map*, which comprises key-value pairs. There is only one dimension and it is unbounded.

Nested tables

With nested tables the programmer needs to understand what is nested. Here, a new type is created that may be composed of a number of components. That type can then be used to make a column in a table, and nested within that column will be those components.

Varrays (variable-size arrays)

With Varrays you need to understand that the word "variable" in the phrase "variable-size arrays" doesn't apply to the size of the array in the way you might think that it would. The size the array is declared with is in fact fixed. The number of elements in the array is variable up to the declared size. Arguably then, variable-sized arrays aren't that variable in size.

Looping

As a procedural language by definition, PL/SQL provides several iteration constructs, including basic LOOP statements, WHILE loops, FOR loops, and Cursor FOR loops.

LOOP statements

Syntax [2]

```
<<parent_loop>>
LOOP
      statements

      <<child_loop>>
      loop
            statements
            exit parent_loop when <condition>; -- Terminates both loops
            exit when <condition>; -- Returns control to parent_loop
      end loop child_loop;
        if <condition> then
           continue; -- continue to next iteration
        end if;
```

```
      exit when <condition>;
END LOOP parent_loop;
```

Loops can be terminated by using the `EXIT` keyword, or by raising an exception.

FOR loops

```
 declare
     var number;
 begin
     /*N.B. for loop variables in pl/sql are new declarations, with scope only inside the loop */
for var in 0 .. 10 loop
          dbms_output.put_line(var);
     end loop;

     if (var is null) then
          dbms_output.put_line('var is null');
     else
          dbms_output.put_line('var is not null');
     end if;
 end;
```

This is the output
Output:

```
 0
 1
 2
 3
 4
 5
 6
 7
 8
 9
 10
 var is null
```

Cursor FOR loops

```
FOR RecordIndex IN (SELECT person_code FROM people_table)
LOOP
  DBMS_OUTPUT.PUT_LINE(RecordIndex.person_code);
END LOOP;
```

Cursor-for loops automatically open a cursor, read in their data and close the cursor again.

As an alternative, the PL/SQL programmer can pre-define the cursor's SELECT-statement in advance in order (for example) to allow re-use or to make the code more understandable (especially useful in the case of long or complex queries).

```
DECLARE
  CURSOR cursor_person IS
    SELECT person_code FROM people_table;
BEGIN
  FOR RecordIndex IN cursor_person
  LOOP
    DBMS_OUTPUT.PUT_LINE(recordIndex.person_code);
  END LOOP;
END;
```

The concept of the person_code within the FOR-loop gets expressed with dot-notation (".")::

```
RecordIndex.person_code
```

Dynamic SQL

While programmers can readily embed Data Manipulation Language (DML) statements directly into their PL/SQL code using straightforward SQL statements, Data Definition Language (DDL) requires more complex "Dynamic SQL" statements to be written in the PL/SQL code. However, DML statements underpin the majority of PL/SQL code in typical software applications.

In the case of PL/SQL dynamic SQL, early versions of the Oracle Database required the use of a complicated Oracle `DBMS_SQL` package library. More recent versions have however introduced a simpler "Native Dynamic SQL", along with an associated `EXECUTE IMMEDIATE` syntax.

SQL PL

SQL PL stands for Structured Query Language Procedural Language and was developed by IBM as a set of commands that extend the use of SQL in the IBM DB2 (DB2 UDB Version 7) database system.[1] It provides procedural programmability in addition to the querying commands of SQL. It is a subset of the SQL Persistent Stored Modules (SQL/PSM) language standard.

As of DB2 version 9, SQL PL stored procedures can run natively inside the DB2 process (inside the DBM1 address space, more precisely) instead of being fenced in an external process. In DB2 version 9.7 IBM also added a PL/SQL front-end to this infrastructure (called "SQL Unified Runtime Engine"), meaning that procedural SQL using either the ISO standard or Oracle's syntax compile to bytecode running on the same engine in DB2.

SQL programming tool

In the field of software, **SQL programming tools** provide platforms for database administrators (DBAs) and application developers to perform daily tasks efficiently and accurately.

Database administrators and application developers often face constantly changing environments which they rarely completely control. Many changes result from new development projects or from modifications to existing code, which, when deployed to production, do not always produce the expected result.

For organizations to better manage development projects and the teams that develop code, suppliers of SQL programming tools normally provide more than facility to the database administrator or application developer to aid in database management and in quality code-deployment practices.

Features

SQL programming tools may include the following features:

SQL editing

SQL editors allow users to edit and execute SQL statements. They may support the following features:

- cut, copy, paste, undo, redo, find (and replace), bookmarks
- block indent, print, save file, uppercase/lowercase
- keyword highlighting
- auto-completion
- access to frequently used files
- output of query result
- editing query-results
- committing and rolling-back transactions
- inside cut paper

Object browsing

Tools may display information about database objects relevant to developers or to database administrators. Users may:

- view object descriptions
- view object definitions (DDL)
- create database objects
- enable and disable triggers and constraints
- recompile valid or invalid objects
- query or edit tables and views

Some tools also provide features to display dependencies among objects, and allow users to expand these dependent objects recursively (for example: packages may reference views, views generally reference tables, super/subtypes, and so on).

Session browsing

Database administrators and application developers can use session browsing tools to view the current activities of each user in the database. They can check the resource-usage of individual users, statistics information, locked objects and the current running SQL of each individual session.

User-security management

DBAs can create, edit, delete, disable or enable user-accounts in the database using security-management tools. DBAs can also assign roles, system privileges, object privileges, and storage-quotas to users.

Debugging

Some tools offer features for the debugging of stored procedures: Step In, Step Over, Step Out, Run Until Exception, Breakpoints, View & Set Variables, View Call Stack, and so on. Users can debug any program-unit without making any modification to it, including triggers and object types.

Performance monitoring

Monitoring tools may show the database resources — usage summary, service time summary, recent activities, top sessions, session history or top SQL — in easy-to-read graphs. Database administrators can easily monitor the health of various components in the monitoring instance. Application developers may also make use of such tools to diagnose and correct application-performance problems as well as improve SQL server performance.

User-defined function

A **User-Defined Function (UDF)** is a function provided by the user of a program or environment, in a context where the usual assumption is that functions are built into the program or environment.

BASIC language

In some old implementations of the BASIC programming language, user-defined functions are defined using the "DEF FN" syntax. More modern dialects of BASIC are influenced by the structured programming paradigm, where most or all of the code is written as user-defined functions or procedures, and the concept becomes practically redundant.

Databases

In SQL databases, a user-defined function provides a mechanism for extending the functionality of the database server by adding a function that can be evaluated in SQL statements. The SQL standard distinguishes between scalar and table functions. A scalar function returns only a single value (or NULL), whereas a table function returns a (relational) table comprising zero or more rows, each row with one or more columns.

User-defined functions in SQL are declared using the `CREATE FUNCTION` statement. For example, a function that converts Celsius to Fahrenheit might be declared like this:

```
CREATE FUNCTION dbo.CtoF(Celsius FLOAT)
  RETURNS FLOAT
  RETURN (Celsius * 1.8) + 32
```

Once created, a user-defined function may be used in expressions in SQL statements. For example, it can be invoked where most other intrinsic functions are allowed. This also includes SELECT statements, where the function can be used against data stored in tables in the database. Conceptually, the function is evaluated once per row in such usage. For example, assume a table named ELEMENTS, with a row for each known chemical element. The table has a column named BoilingPoint for the boiling point of that element, in Celsius. The query

```
SELECT Name, CtoF(BoilingPoint)
  FROM Elements
```

would retrieve the name and the boiling point from each row. It invokes the CtoF user-defined function as declared above in order to convert the value in the column to a value in Fahrenheit.

Each user-defined function carries certain properties or characteristics. The SQL standard defines the following properties:

- Language - defines the programming language in which the user-defined function is implemented; examples are SQL, C, or Java.
- Parameter style - defines the conventions that are used to pass the function parameters and results between the implementation of the function and the database system (only applicable if language is not SQL).
- Specific name - a name for the function that is unique within the database. Note that the function name does not have to be unique, considering overloaded functions. Some SQL implementations require that function names are unique within a database, and overloaded functions are not allowed.
- Determinism - specifies whether the function is deterministic or not. The determinism characteristic has an influence on the query optimizer when compiling a SQL statement.
- SQL-data access - tells the database management system whether the function contains no SQL statements (NO SQL), contains SQL statements but does not access any tables or views (CONTAINS SQL), reads data from

tables or views (READS SQL DATA), or actually modifies data in the database (MODIFIES SQL DATA).

User-defined functions should not be confused with stored procedures. Stored procedures allow the user to group a set of SQL commands. A procedure can accept parameters and execute its SQL statements depending on those parameters. A procedure is not an expression and, thus, cannot be used like user-defined functions.

Some database management systems allow the creation of user defined functions in languages other than SQL. Microsoft SQL Server, for example, allows the user to use .NET languages including C# for this purpose. DB2 and Oracle support user-defined functions written in C or Java programming languages.

SQL Server 2000

There are three types of UDF in Microsoft SQL Server 2000:

- Scalar functions.
- Inline table-valued functions.
- Multistatementtable-valued functions.

Scalar functions return a single data value (not a table) with RETURNS clause. Scalar functions can use all scalar data types, with exception of timestamp and user-defined data types. Inline table-valued functions return the result set of a single SELECT statement. Multistatement table-valued functions return a table, which was built with many TRANSACT-SQL statements.

User-defined functions can be invoked from a query like built-in functions such as OBJECT_ID, LEN, DATEDIFF, or can be executed through an EXECUTE statement like stored procedures.

Performance Notes: 1. On Microsoft SQL Server 2000 a table-valued function which "wraps" a View may be much faster than the View itself. The following MyFunction is an example of a "function-wrapper" which runs faster than the underlying view MyView:

```
CREATE FUNCTION MyFunction()
    RETURNS @Tbl TABLE
    (
        StudentID              VARCHAR(255),
        SAS_StudentInstancesID INT,
        Label                  VARCHAR(255),
        Value                  MONEY,
        CMN_PersonsID          INT
    )
AS
BEGIN
    INSERT @Tbl
    (
        StudentID,
        SAS_StudentInstancesID,
        Label,
        Value,
        CMN_PersonsID
    )
    SELECT
        StudentID,
        SAS_StudentInstancesID,
        Label,
```

```
        Value,
        CMN_PersonsID
    FROM MyView -- where MyView selects (with joins) the same columns from large table(s)

    RETURN
END
```

2. On Microsoft SQL Server 2005 the result of the same code execution is the opposite: view is executed faster than the "function-wrapper".

User-defined functions are subroutines made of one or more Transact-SQL statements that can be used to encapsulate code for reuse. It takes zero or more arguments and evaluates a return value. Has both control-flow and DML statements in its body similar to stored procedures. Does not allow changes to any Global Session State, like modifications to database or external resource, such as a file or network. Does not support output parameter. DEFAULT keyword must be specified to pass the default value of parameter. Errors in UDF cause UDF to abort which, in turn, aborts the statement that invoked the UDF.

```
CREATE FUNCTION CubicVolume
-- Input dimensions in centimeters
(
    @CubeLength decimal(4,1),
    @CubeWidth  decimal(4,1),
    @CubeHeight decimal(4,1)
)
    RETURNS decimal(12,3)
AS
BEGIN
  RETURN(@CubeLength * @CubeWidth * @CubeHeight)
END
```

Data type supported in Microsoft SQL Server 2000 Like a temporary table used to store results Mostly used to define temporary variable of type (table) and the return value of a UDF The scope is limited to function, stored procedure, or batch in which it is defined Assignment operation is not allowed between (Table) variables May be used in SELECT, INSERT, UPDATE, and DELETE CREATE FUNCTION to create UDF ALTER FUNCTION to change the characteristics of UDF DROP FUNCTION to remove UDF

Cursor (databases)

In computer science, a database **cursor** is a control structure that enables traversal over the records in a database. Cursors facilitate subsequent processing in conjunction with the traversal, such as retrieval, addition and removal of database records. The database cursor characteristic of traversal makes cursors akin to the programming language concept of iterator.

Cursors are used by database programmers to process individual rows returned by database system queries. Cursors enable manipulation of whole result sets at once. In this scenario, a cursor enables the rows in a result set to be processed sequentially.

In SQL procedures, a cursor makes it possible to define a result set (a set of data rows) and perform complex logic on a row by row basis. By using the same mechanics, a SQL procedure can also define a result set and return it directly to the caller of the SQL procedure or to a client application.

A cursor can be viewed as a pointer to one row in a set of rows. The cursor can only reference one row at a time, but can move to other rows of the result set as needed.

Usage

To use cursors in SQL procedures, you need to do the following:

1. Declare a cursor that defines a result set.
2. Open the cursor to establish the result set.
3. Fetch the data into local variables as needed from the cursor, one row at a time.
4. Close the cursor when done.

To work with cursors you must use the following SQL statements

This section introduces the ways the SQL:2003 standard defines how to use cursors in applications in embedded SQL. Not all application bindings for relational database systems adhere to that standard, and some (such as CLI or JDBC) use a different interface.

A programmer makes a cursor known to the DBMS by using a `DECLARE ... CURSOR` statement and assigning the cursor a (compulsory) name:

```
DECLARE cursor_name CURSOR FOR SELECT ... FROM ...
```

Before code can access the data, it must open the cursor with the `OPEN` statement. Directly following a successful opening, the cursor is positioned *before* the first row in the result set.

```
OPEN cursor_name
```

Programs position cursors on a specific row in the result set with the `FETCH` statement. A fetch operation transfers the data of the row into the application.

```
FETCH cursor_name INTO ...
```

Once an application has processed all available rows or the fetch operation is to be positioned on a non-existing row (compare scrollable cursors below), the DBMS returns a SQLSTATE '02000' (usually accompanied by an SQLCODE +100) to indicate the end of the result set.

The final step involves closing the cursor using the `CLOSE` statement:

```
CLOSE cursor_name
```

After closing a cursor, a program can open it again, which implies that the DBMS re-evaluates the same query or a different query and builds a new result set.

Scrollable cursors

Programmers may declare cursors as scrollable or not scrollable. The scrollability indicates the direction in which a cursor can move.

With a **non-scrollable** (or **forward-only**) cursor, you can `FETCH` each row at most once, and the cursor automatically moves to the next row. After you fetch the last row, if you fetch again, you will put the cursor after the last row and get the following code: SQLSTATE 02000 (SQLCODE +100).

A program may position a **scrollable** cursor anywhere in the result set using the `FETCH` SQL statement. The keyword SCROLL must be specified when declaring the cursor. The default is `NO SCROLL`, although different language bindings like JDBC may apply a different default.

```
DECLARE cursor_name sensitivity SCROLL CURSOR FOR SELECT ... FROM ...
```

The target position for a scrollable cursor can be specified relatively (from the current cursor position) or absolutely (from the beginning of the result set).

```
FETCH [ NEXT | PRIOR | FIRST | LAST ] FROM cursor_name
```

```
FETCH ABSOLUTE n FROM cursor_name
```

```
FETCH RELATIVE n FROM cursor_name
```

Scrollable cursors can potentially access the same row in the result set multiple times. Thus, data modifications (insert, update, delete operations) from other transactions could have an impact on the result set. A cursor can be SENSITIVE or INSENSITIVE to such data modifications. A sensitive cursor picks up data modifications impacting the result set of the cursor, and an insensitive cursor does not. Additionally, a cursor may be ASENSITIVE, in which case the DBMS tries to apply sensitivity as much as possible.

"WITH HOLD"

Cursors are usually closed automatically at the end of a transaction, i.e. when a COMMIT or ROLLBACK (or an implicit termination of the transaction) occurs. That behavior can be changed if the cursor is declared using the WITH HOLD clause. (The default is WITHOUT HOLD.) A holdable cursor is kept open over COMMIT and closed upon ROLLBACK. (Some DBMS deviate from this standard behavior and also keep holdable cursors open over ROLLBACK.)

```
DECLARE cursor_name CURSOR WITH HOLD FOR SELECT ... FROM ...
```

When a COMMIT occurs, a holdable cursor is positioned *before* the next row. Thus, a positioned UPDATE or positioned DELETE statement will only succeed after a FETCH operation occurred first in the transaction.

Note that JDBC defines cursors as holdable per default. This is done because JDBC also activates auto-commit per default. Due to the usual overhead associated with auto-commit and holdable cursors, both features should be explicitly deactivated at the connection level.

Positioned update/delete statements

Cursors can not only be used to fetch data from the DBMS into an application but also to identify a row in a table to be updated or deleted. The SQL:2003 standard defines positioned update and positioned delete SQL statements for that purpose. Such statements do not use a regular WHERE clause with predicates. Instead, a cursor identifies the row. The cursor must be opened and already positioned on a row by means of `FETCH` statement.

```
UPDATE table_name
SET    ...
WHERE  CURRENT OF cursor_name
```

```
DELETE
FROM   table_name
WHERE  CURRENT OF cursor_name
```

The cursor must operate on an updatable result set in order to successfully execute a positioned update or delete statement. Otherwise, the DBMS would not know how to apply the data changes to the underlying tables referred to in the cursor.

Cursors in distributed transactions

Using cursors in distributed transactions (X/Open XA Environments), which are controlled using a transaction monitor, is no different from cursors in non-distributed transactions.

One has to pay attention when using holdable cursors, however. Connections can be used by different applications. Thus, once a transaction has been ended and committed, a subsequent transaction (running in a different application) could inherit existing holdable cursors. Therefore, an application developer has to be aware of that situation.

Cursors in XQuery

The XQuery language allows cursors to be created using the **subsequence()** function.

The format is:

```
let $displayed-sequence := subsequence($result, $start, $item-count)
```

Where $**result** is the result of the initial XQuery, **$start** is the item number to start and **$item-count** is the number of items to return.

Equivalently this can also be done using a predicate:

```
let $displayed-sequence := $result[$start to $end]
```

Where $end is the end sequence.

For complete examples see the XQuery Wikibook [1].

Disadvantages of cursors

The following information may vary depending on the specific database system.

Fetching a row from the cursor may result in a network round trip each time. This uses much more network bandwidth than would ordinarily be needed for the execution of a single SQL statement like DELETE. Repeated network round trips can severely impact the speed of the operation using the cursor. Some DBMSs try to reduce this impact by using block fetch. Block fetch implies that multiple rows are sent together from the server to the client. The client stores a whole block of rows in a local buffer and retrieves the rows from there until that buffer is exhausted.

Cursors allocate resources on the server, such as locks, packages, processes, and temporary storage. For example, Microsoft SQL Server implements cursors by creating a temporary table and populating it with the query's result set. If a cursor is not properly closed (*deallocated*), the resources will not be freed until the SQL session (connection) itself is closed. This wasting of resources on the server can lead to performance degradations and failures.

Example

```
EMPLOYEES TABLE
SQL> desc EMPLOYEES_DETAILS;
 Name                                      Null?    Type
 ----------------------------------------- -------- --------------------

 EMPLOYEE_ID                               NOT NULL NUMBER(6)
 FIRST_NAME                                         VARCHAR2(20)
 LAST_NAME                                 NOT NULL VARCHAR2(25)
 EMAIL                                     NOT NULL VARCHAR2(30)
 PHONE_NUMBER                                       VARCHAR2(20)
 HIRE_DATE                                 NOT NULL DATE
 JOB_ID                                    NOT NULL VARCHAR2(10)
 SALARY                                             NUMBER(8,2)
 COMMISSION_PCT                                     NUMBER(2,2)
 MANAGER_ID                                         NUMBER(6)
 DEPARTMENT_ID                                      NUMBER(4)

SAMPLE CURSOR KNOWN AS EE

CREATE OR REPLACE
PROCEDURE EE AS
BEGIN
      DECLARE
v_employeeID EMPLOYEES_DETAILS.EMPLOYEE_ID%TYPE;
v_FirstName EMPLOYEES_DETAILS.FIRST_NAME%TYPE;
v_LASTName EMPLOYEES_DETAILS.LAST_NAME%TYPE;

v_JOB_ID EMPLOYEES_DETAILS.JOB_ID%TYPE:= 'IT_PROG';

Cursor c_EMPLOYEES_DETAILS IS
SELECT EMPLOYEE_ID, FIRST_NAME, LAST_NAME
FROM EMPLOYEES_DETAILS
```

```
WHERE JOB_ID ='v_JOB_ID';
BEGIN
OPEN c_EMPLOYEES_DETAILS;

LOOP

FETCH c_EMPLOYEES_DETAILS INTO v_employeeID,v_FirstName,v_LASTName;

DBMS_OUTPUT.put_line( v_employeeID);
DBMS_OUTPUT.put_line( v_FirstName);
DBMS_OUTPUT.put_line( v_LASTName);

EXIT WHEN c_EMPLOYEES_DETAILS%NOTFOUND;
END LOOP;

CLOSE c_EMPLOYEES_DETAILS;
END;

END;
```

SQL Problems Requiring Cursors

A cursor is a construct available in most implementations of SQL that allows the programmer to handle data in a row-by-row manner rather than as a group. Parallelizing row-by-row processing is much more complex than serial processing, which is another reason to make use of non-procedural SQL wherever possible. Database vendors typically handle parallel processing without requiring special handling by application developers.

Parallel processing can be orders of magnitude faster than serial processing.

Constraints

In this article, the following constraints apply:

- **The term "cursor" includes all cursor-like behavior.** For example, using a loop in a shell script that loops across single-row SQL queries or the output of multi-row SQL queries is cursor-like behavior and does not achieve the goal of true set-based processing within the database.
- **All set-based SQL must be ANSI SQL.** A number of vendors provide some extremely powerful proprietary extensions. The goal is to avoid such extensions in favor of ANSI SQL.
- **The solution must be generalizable.** In one or more examples below, specific values may be used for demonstration purposes, but any solution must scale to any number feasible within the power of the database software and machine resources.

Example: Insert rows based on a count in the table itself

The table below represents types of marbles. The four text columns represent four marble characteristics. Each characteristic has two values for a total of 16 types of marbles.

The "quantity" column represents how many marbles of that type we have. The task is to create a second table holding one row for each marble of that type. Thus, the target table would have the four text columns, and a total of 40 + 20 + 20 + 10 + ... + 10 + 5 = 270 rows.

Source table:

```
  QUANTITY TEXTURE    APPEARANCE SHAPE      COLOR
---------- ---------- ---------- ---------- -----
        40 smooth     shiny      round      blue
        20 smooth     shiny      warped     blue
```

```
        20 smooth     dull       round      blue
        10 smooth     dull       warped     blue
        20 rough      shiny      round      blue
        10 rough      shiny      warped     blue
        10 rough      dull       round      blue
         5 rough      dull       warped     blue
        40 rough      dull       warped     red
        20 rough      dull       round      red
        20 rough      shiny      warped     red
        10 rough      shiny      round      red
        20 smooth     dull       warped     red
        10 smooth     dull       round      red
        10 smooth     shiny      warped     red
         5 smooth     shiny      round      red
```

Table to generate:

```
TEXTURE    APPEARANCE SHAPE      COLOR
---------- ---------- ---------- -----
smooth     shiny      round      blue   -- 1
smooth     shiny      round      blue   -- 2
...                                     -- and so on
smooth     shiny      round      blue   -- 40
smooth     shiny      warped     blue   -- 1
smooth     shiny      warped     blue   -- 2
...                                     -- and so on
smooth     shiny      warped     blue   -- 20
...                                     -- and so on
smooth     shiny      round      red    -- 1
smooth     shiny      round      red    -- 2
smooth     shiny      round      red    -- 3
smooth     shiny      round      red    -- 4
smooth     shiny      round      red    -- 5
```

Solution in cursor form

Generating the target table with a cursor is fairly simple.

```
declare
  cursor c is select * from marbles_seed;

begin
  for r in c loop
    for i in 1..r.quantity loop
      insert into marbles values (
        r.texture,
        r.appearance,
        r.shape,
        r.color_actual
      );
```

```
    end loop;
  end loop;
end;
```

Solution in SQL

Solving the problem with SQL is a bit more code and requires a bit more creative thought than the nested loop approach of cursors.

Number table

The solution requires an intermediate table. The table has one column of type NUMBER that has the values 0 to whatever number of rows is needed. For this discussion, we'll limit it to one million rows. The code is as follows: Setup:

```
create table numbers_seed ( n number(1) );
create table numbers ( n number(7));
insert into numbers_seed values ( 0 );
insert into numbers_seed values ( 1 );
insert into numbers_seed values ( 2 );
insert into numbers_seed values ( 3 );
insert into numbers_seed values ( 4 );
insert into numbers_seed values ( 5 );
insert into numbers_seed values ( 6 );
insert into numbers_seed values ( 7 );
insert into numbers_seed values ( 8 );
insert into numbers_seed values ( 9 );
insert into numbers
select n6.n * 100000 +
       n5.n * 10000 +
       n4.n * 1000 +
       n3.n * 100 +
       n2.n * 10 +
       n1.n * 1 n
from numbers_seed n1,
       numbers_seed n2,
       numbers_seed n3,
       numbers_seed n4,
       numbers_seed n5,
       numbers_seed n6
```

The numbers table can be created in parallel.

Solution core

Assume the marble type table above is named marbles_seed and the target table is named marbles. The code that generates the needed 270 rows is:

```
insert into marbles
(m.texture, m.appearance, m.shape, m.color_actual)

select m.texture,
       m.appearance,
       m.shape,
       m.color_actual
  from marbles_seed m,
       numbers n
 where m.quantity > n.n
```

The database can process this insert in parallel without the programmer's involvement.

WxSQLite3

wxSQLite3

Developer(s)	Ulrich Telle
Stable release	3.0.0 / January 2012
Development status	Active
Written in	C++
Operating system	Cross-platform
Type	Development Library
License	wxWindows Library Licence [1]
Website	wxSQLite3 [2]

wxSQLite3 is a C++ wrapper around the public domain SQLite 3.x database and is specifically designed for use in programs based on the wxWidgets library.

wxSQLite3 does not try to hide the underlying database, in contrary almost all special features of the current SQLite version 3.7.10 are supported, like for example the creation of user defined scalar or aggregate functions. Since SQLite stores strings in UTF-8 encoding, the wxSQLite3 methods provide automatic conversion between wxStrings and UTF-8 strings. This works best for the Unicode builds of wxWidgets. In ANSI builds the current locale conversion object (wxConvCurrent) is used for conversion to/from UTF-8. Special care has to be taken if external administration tools are used to modify the database contents, since not all of these tools operate in Unicode resp. UTF-8 mode.

Since version 1.7.0 optional support for key based database encryption (128 bit AES) is also included. Starting with version 1.9.6 of wxSQLite3 the encryption extension is compatible with the SQLite amalgamation source and includes the extension functions module. Support for 256 bit AES encryption has been added in version 1.9.8.

Database connectivity

Application programming interface

An **application programming interface** (**API**) specifies how some software components should interact with each other.

In addition to accessing databases or computer hardware, such as hard disk drives or video cards, an API can be used to ease the work of programming graphical user interface components. In practice, many times an API comes in the form of a library that includes specifications for routines, data structures, object classes, and variables. In some other cases, notably for SOAP and REST services, an API comes as just a specification of remote calls exposed to the API consumers.

An API specification can take many forms, including an International Standard such as POSIX, vendor documentation such as the Microsoft Windows API, the libraries of a programming language, e.g., Standard Template Library in C++ or Java API. Web APIs are also a vital component of today's web fabric. An API differs from an application binary interface (ABI) in that an API is source code based while an ABI is a binary interface. For instance POSIX is an API, while the Linux Standard Base is an ABI.

Detailed explanation

API in procedural languages

In most procedural languages, an API specifies a set of functions or routines that accomplish a specific task or are allowed to interact with a specific software component. This specification is presented in a human readable format in paper books, or in electronic formats like ebooks or as man pages. For example, the math API on Unix systems is a specification on how to use the mathematical functions included in the math library. Among these functions there is a function, named `sqrt()`, that can be used to compute the square root of a given number.

The Unix command `man 3 sqrt` presents the signature of the function `sqrt` in the form:

```
SYNOPSIS
            #include <math.h>
            double sqrt(double X);
            float  sqrtf(float X);
DESCRIPTION
       sqrt computes the positive square root of the argument. ...
RETURNS
       On success, the square root is returned. If X is real and
positive...
```

This description means that `sqrt()` function returns the square root of a positive floating point number (`single` or `double` precision), as another floating point number.

Hence the API in this case can be interpreted as the collection of the include files used by a program, written in the C language, to reference that library function, and its human readable description provided by the man pages.

Similarly, other languages have procedural libraries; for example, Perl has dedicated APIs for the same mathematical task with built-in documentation available, which is accessible using the perldoc utility:

```
$ perldoc -f sqrt
       sqrt EXPR
       sqrt    #Return the square root of EXPR.  If EXPR is omitted, returns
               #square root of $_.  Only works on non-negative operands, unless
               #you've loaded the standard Math::Complex module.
```

API in object-oriented languages

In its simplest form, an object API is a prescription of how *objects work* in a given object-oriented language – usually it is expressed as a set of classes with an associated list of class methods.

For example, in the Java language, if the class `Scanner` is to be used (a class that reads input from the user in text-based programs), it is required to import the `java.util.Scanner` library, so objects of type `Scanner` can be used by invoking some of the class' methods:

```
import java.util.Scanner;

public class Test {
   public static void main(String[] args) {
        System.out.println("Enter your name: ");
        Scanner inputScanner = new Scanner(System.in);
        String name = inputScanner.nextLine();
        System.out.println("Your name is " + name + ".");
        inputScanner.close();
  }
}
```

In the example above, methods `nextLine()` and `close()` are part of the API for the `Scanner` class, and hence are described in the documentation for that API.

More generally, in object-oriented languages, an API usually includes a description of a set of class definitions, with a set of behaviors associated with those classes. This abstract concept is associated with the real functionality exposed, or made available, by the classes that are implemented in terms of class methods (or more generally by all its public components hence all public methods, but also possibly including any internal entity made public, like fields, constants, nested objects, enums, etc.).

The API in this case can be conceived of as the totality of all the methods publicly exposed by the classes (usually called the class *interface*). This means that the API prescribes the methods by which one interacts with/handles the objects derived from the class definitions.

More generally, one can see the API as the collection of all the *kinds* of objects one can derive from the class definitions, and their associated possible behaviors. Again: the use is mediated by the public methods, but in this interpretation, the methods are seen as a *technical detail* of how the behavior is implemented.

For instance: a class representing a `Stack` can simply expose publicly two methods `push()` (to add a new item to the stack), and `pop()` (to extract the last item, ideally placed on top of the stack).

In this case the API can be interpreted as the two methods `pop()` and `push()`, or, more generally, as the *idea* that one can use an item of type `Stack` that implements the behavior of a stack: a pile *exposing* its top to add/remove elements. The second interpretation appears more appropriate in the spirit of object orientation.

This concept can be carried to the point where a class interface in an API has no methods at all, but only behaviors associated with it. For instance, the Java and Lisp language APIs include the interface named `Serializable`, which is a marker interface that requires each class implementing it to behave in a serialized fashion. This does not require implementation of a public method, but rather requires any class which implements this interface to be based

on a representation that can be *saved* (serialized) at any time.[1]

Similarly the behavior of an object in a concurrent (multi-threaded) environment is not necessarily determined by specific methods, belonging to the interface implemented, but still belongs to the API for that Class of objects, and should be described in the documentation.

In this sense, in object-oriented languages, the API defines a set of object behaviors, possibly mediated by a set of class methods.

In such languages, the API is still distributed as a library. For example, the Java language libraries include a set of APIs that are provided in the form of the JDK used by the developers to build new Java programs. The JDK includes the documentation of the API in JavaDoc notation.

The quality of the documentation associated with an API is often a factor determining its success in terms of ease of use.

API libraries and frameworks

An API is usually related to a software library: the API describes and prescribes the *expected behavior* while the library is an *actual implementation* of this set of rules. A single API can have multiple implementations (or none, being abstract) in the form of different libraries that share the same programming interface.

An API can also be related to a software framework: a framework can be based on several libraries implementing several APIs, but unlike the normal use of an API, the *access* to the behavior *built into the framework* is mediated by extending its content with new classes plugged into the framework itself. Moreover the overall program flow of control can be out of the control of the caller, and in the hands of the framework via inversion of control or a similar mechanism.

API and protocols

An API can also be an implementation of a protocol.

When an API implements a protocol it can be based on proxy methods for remote invocations that underneath rely on the communication protocol. The role of the API can be exactly to hide the detail of the transport protocol. E.g.: RMI is an API that implements the JRMP protocol or the IIOP as RMI-IIOP.

Protocols are usually shared between different technologies (system based on given computer programming languages in a given operating system) and usually allow the different technologies to exchange information, acting as an abstraction/mediation level between the two different environments. APIs are usually specific to a given technology: hence the APIs of a given language cannot be used in other languages, unless the function calls are wrapped with specific adaptation libraries.

To enable the exchange of information among systems that use different technologies, when an API implements a protocol, it can prescribe a *language-neutral* message format: e.g. SOAP uses XML as a general container for the messages to be exchanged.

Object exchange API and protocols

An object API can prescribe a specific (local) object exchange format, an object exchange protocol can define a way to transfer the same kind of information in a message sent to a remote system.

When a message is exchanged via a protocol between two different platforms using objects on both sides, the object in a programming language can be transformed (marshalled and unmarshalled) in an object in a remote and different language: so, e.g., a program written in Java invokes a service via SOAP or IIOP written in C# both programs use APIs for remote invocation (each locally to the machine where they are working) to (remotely) exchange information that they both convert from/to an object in local memory.

Instead when a similar object is exchanged via an API local to a single machine the object is effectively exchanged (or a reference to it) in memory: e.g. via memory allocated by a single process, or among multiple processes using shared memory, an application server, or other sharing technologies like tuple spaces.

Object remoting API and protocols

An object remoting API is based on a remoting protocol, such as CORBA, that allows remote object method invocation. A method call, executed locally on a proxy object, invokes the corresponding method on the remote object, using the remoting protocol, and acquires the result to be used locally as return value.

When remoting is in place, a modification on the proxy object corresponds to a modification on the remote object. When only an object transfer takes place, the modification to the local copy of the object is not reflected on the original object, unless the object is sent back to the sending system.

API sharing and reuse via virtual machine

Some languages like those running in a virtual machine (e.g. .NET CLI compliant languages in the Common Language Runtime (CLR), and JVM compliant languages in the Java Virtual Machine) can share an API. In this case, a virtual machine enables language interoperability, by abstracting a programming language using an intermediate bytecode and its language bindings. In these languages, the compiler performs just-in-time compilation or ahead-of-time compilation transforming the source code, possibly written in multiple languages, into its language-independent bytecode representation.

For instance, through the bytecode representation, a program written in Groovy or Scala language can use any standard Java class and hence any Java API. This is possible thanks to the fact both Groovy and Scala have an object model that is a superset of that of the Java language; thus, any API exposed via a Java object is accessible via Groovy or Scala by an equivalent object invocation translated in bytecode.

On the other side, Groovy and Scala introduce first-class *entities* that are not present in Java, like closures. These entities cannot be natively represented in Java language (Java 8 will include a concept of closure); thus, in order to enable interoperation a closure is encapsualted in a *standard* object. In this case the *closure invocation* is mediated by a method named `call()` which is always present in an closure object as seen by Java.

Web APIs

When used in the context of web development, an API is typically defined as a set of Hypertext Transfer Protocol (HTTP) request messages, along with a definition of the structure of response messages, which is usually in an Extensible Markup Language (XML) or JavaScript Object Notation (JSON) format. While "web API" historically has been virtually synonymous for web service, the recent trend (so-called Web 2.0) has been moving away from Simple Object Access Protocol (SOAP) based web services and service-oriented architecture (SOA) towards more direct representational state transfer (REST) style web resources and resource-oriented architecture (ROA). Part of this trend is related to the Semantic Web movement toward Resource Description Framework (RDF), a concept to promote web-based ontology engineering technologies. Web APIs allow the combination of multiple APIs into new applications known as mashups.

Web use to share content

The practice of publishing APIs has allowed web communities to create an open architecture for sharing content and data between communities and applications. In this way, content that is created in one place can be dynamically posted and updated in multiple locations on the web:

- Photos can be shared from sites like Flickr and Photobucket to social network sites like Facebook and MySpace.
- Content can be embedded, e.g. embedding a presentation from SlideShare on a LinkedIn profile.
- Content can be dynamically posted. Sharing live comments made on Twitter with a Facebook account, for example, is enabled by their APIs.
- Video content can be embedded on sites served by another host.
- User information can be shared from web communities to outside applications, delivering new functionality to the web community that shares its user data via an open API. One of the best examples of this is the Facebook Application platform. Another is the Open Social platform.
- If content is a direct representation of the physical world (e.g., temperature at a geospatial location on earth) then an API can be considered an "Environmental Programming Interface" (EPI). EPIs are characterized by their ability to provide a means for universally sequencing events sufficient to utilize real-world data for decision making.

Implementations

The POSIX standard defines an API that allows writing a wide range of common computing functions in a way such that they can operate on many different systems (Mac OS X, and various Berkeley Software Distributions (BSDs) implement this interface). However, using this requires re-compiling for each platform. A compatible API, on the other hand, allows compiled object code to function with no changes to the system that implements that API. This is beneficial to both software providers (where they may distribute existing software on new systems without producing and distributing upgrades) and users (where they may install older software on their new systems without purchasing upgrades), although this generally requires that various software libraries implement the necessary APIs as well.

Microsoft has shown a strong commitment to a backward compatible API, particularly within their Windows API (Win32) library, such that older applications may run on newer versions of Windows using an executable-specific setting called "Compatibility Mode".

Among Unix-like operating systems, there are many related but incompatible operating systems running on a common hardware platform (particularly Intel 80386-compatible systems). There have been several attempts to standardize the API such that software vendors may distribute one binary application for all these systems; however, to date, none of these has met with much success. The Linux Standard Base is attempting to do this for the Linux platform, while many of the BSD Unixes, such as FreeBSD, NetBSD, and OpenBSD, implement various levels of API compatibility for both backward compatibility (allowing programs written for older versions to run on newer distributions of the system) and cross-platform compatibility (allowing execution of foreign code without recompiling).

Release policies

The main policies for releasing an API are:

- Protecting information on APIs from the general public. For example, Sony used to make its official PlayStation 2 API available only to licensed PlayStation developers. This enabled Sony to control who wrote PlayStation 2 games. This gives companies quality control privileges and can provide them with potential licensing revenue streams.
- Making APIs freely available. For example, Microsoft makes the Microsoft Windows API public, and Apple releases its APIs Carbon and Cocoa, so that software can be written for their platforms.

A mix of the two behaviors can be used as well.

Public API implications

An API can be developed for a restricted group of users, or it can be released to the public.

An important factor when an API becomes public is its *interface stability*: if the developer of an API changes a part of it, for example by adding new parameters to some function calls, it could break the compatibility with all clients that depend on or use that API.

When parts of a publicly presented API are subject to change and thus not stable, such parts of a particular API should be explicitly documented as *unstable*. For example, in the Google Guava library the parts that are considered unstable, and that might change in a near future, are marked with the Java annotation `@Beta`.

API deprecation

A public API can sometimes declare parts of itself as *deprecated*. This usually means that such part of an API should be considered candidated for being removed, or modified in a backward incompatible way.

When adopting a third-party public API, developers should consider the deprecation policy used by the producer of that API; if a developer publicly releases a solution based on an API that becomes deprecated, he/she might be unable to guarantee the provided service.

APIs and copyrights

In 2010, Oracle sued Google for having distributed a new implementation of Java embedded in the Android operating system. Google had not acquired any permission to reproduce the Java API, although a similar permission had been given to the OpenJDK project. Judge William Alsup ruled in the Oracle v. Google case that APIs cannot be copyrighted in the U.S, and that a victory for Oracle would have widely expanded copyright protection and allowed the copyrighting of simple software commands:

> To accept Oracle's claim would be to allow anyone to copyright one version of code to carry out a system of commands and thereby bar all others from writing their own different versions to carry out all or part of the same commands.

2013 saw the creation of the "API Commons" initiative. API Commons is a common place to publish and share your own API specifications and data models in any format such as Swagger, API Blueprint or RAML, as well as to explore and discover the API designs of others. The API specifications and data models declared in API Commons are available publicly under the Creative Commons license.

API examples

- ASPI for SCSI device interfacing
- Cocoa and Carbon for the Macintosh
- DirectX for Microsoft Windows
- EHLLAPI
- Java APIs
- ODBC for Microsoft Windows
- OpenAL cross-platform sound API
- OpenCL cross-platform API for general-purpose computing for CPUs & GPUs
- OpenGL cross-platform graphics API
- OpenMP API that supports multi-platform shared memory multiprocessing programming in C, C++ and Fortran on many architectures, including Unix and Microsoft Windows platforms.
- Server Application Programming Interface (SAPI)
- Simple DirectMedia Layer (SDL)

Language bindings and interface generators

APIs that are intended to be used by more than one high-level programming language often provide, or are augmented with, facilities to automatically map the API to features (syntactic or semantic) that are more natural in those languages. This is known as language binding, and is itself an API. The aim is to encapsulate most of the required functionality of the API, leaving a "thin" layer appropriate to each language.

Below are listed some interface generator tools that bind languages to APIs at compile time:

- SWIG – an open-source interfaces bindings generator supporting numerous programming languages
- F2PY – a Fortran to Python interface generator

Notes

[1] This is typically true for any class containing simple data and no link to external resources, like an open connection to a file, a remote system, or an external device.

Database transaction

A **transaction** comprises a unit of work performed within a database management system (or similar system) against a database, and treated in a coherent and reliable way independent of other transactions. Transactions in a database environment have two main purposes:

1. To provide reliable units of work that allow correct recovery from failures and keep a database consistent even in cases of system failure, when execution stops (completely or partially) and many operations upon a database remain uncompleted, with unclear status.
2. To provide isolation between programs accessing a database concurrently. If this isolation is not provided, the program's outcome are possibly erroneous.

A database transaction, by definition, must be atomic, consistent, isolated and durable.[1] Database practitioners often refer to these properties of database transactions using the acronym ACID.

Transactions provide an "all-or-nothing" proposition, stating that each work-unit performed in a database must either complete in its entirety or have no effect whatsoever. Further, the system must isolate each transaction from other transactions, results must conform to existing constraints in the database, and transactions that complete successfully must get written to durable storage.

Purpose

Databases and other data stores which treat the integrity of data as paramount often include the ability to handle transactions to maintain the integrity of data. A single transaction consists of one or more independent units of work, each reading and/or writing information to a database or other data store. When this happens it is often important to ensure that all such processing leaves the database or data store in a consistent state.

Examples from double-entry accounting systems often illustrate the concept of transactions. In double-entry accounting every debit requires the recording of an associated credit. If one writes a check for $100 to buy groceries, a transactional double-entry accounting system must record the following two entries to cover the single transaction:

1. Debit $100 to Groceries Expense Account
2. Credit $100 to Checking Account

A transactional system would make both entries pass or both entries would fail. By treating the recording of multiple entries as an atomic transactional unit of work the system maintains the integrity of the data recorded. In other words, nobody ends up with a situation in which a debit is recorded but no associated credit is recorded, or vice versa.

Transactional databases

A **transactional database** is a DBMS where write transactions on the database are able to be rolled back if they are not completed properly (e.g. due to power or connectivity loss).

Most modern[2] relational database management systems fall into the category of databases that support transactions.

In a database system a transaction might consist of one or more data-manipulation statements and queries, each reading and/or writing information in the database. Users of database systems consider consistency and integrity of data as highly important. A simple transaction is usually issued to the database system in a language like SQL wrapped in a transaction, using a pattern similar to the following:

1. Begin the transaction
2. Execute a set of data manipulations and/or queries
3. If no errors occur then commit the transaction and end it
4. If errors occur then rollback the transaction and end it

If no errors occurred during the execution of the transaction then the system commits the transaction. A transaction commit operation applies all data manipulations within the scope of the transaction and persists the results to the database. If an error occurs during the transaction, or if the user specifies a rollback operation, the data manipulations within the transaction are not persisted to the database. In no case can a partial transaction be committed to the database since that would leave the database in an inconsistent state.

Internally, multi-user databases store and process transactions, often by using a transaction ID or XID.

There are multiple varying ways for transactions to be implemented other than the simple way documented above. Nested transactions, for example, are transactions which contain statements within them that start new transactions (i.e. sub-transactions). *Multi-level transactions* are a variant of nested transactions where the sub-transactions take place at different levels of a layered system architecture (e.g., with one operation at the database-engine level, one operation at the operating-system level) [3] Another type of transaction is the compensating transaction.

In SQL

Transactions are available in most SQL database implementations, though with varying levels of robustness. (MySQL, for example, does not support transactions in the MyISAM storage engine, which was its default storage engine before version 5.5.)

A transaction is typically started using the command `BEGIN` (although the SQL standard specifies `START TRANSACTION`). When the system processes a `COMMIT` statement, the transaction ends with successful completion. A `ROLLBACK` statement can also end the transaction, undoing any work performed since `BEGIN TRANSACTION`. If autocommit was disabled using `START TRANSACTION`, autocommit will also be re-enabled at the transaction's end.

One can set the isolation level for individual transactional operations as well as globally. At the READ COMMITTED level, the result of any work done after a transaction has commenced, but before it has ended, will remain invisible to other database-users until it has ended. At the lowest level (READ UNCOMMITTED), which may occasionally be used to ensure high concurrency, such changes will be visible.

Distributed transactions

Database systems implement distributed transactions as transactions against multiple applications or hosts. A distributed transaction enforces the ACID properties over multiple systems or data stores, and might include systems such as databases, file systems, messaging systems, and other applications. In a distributed transaction a coordinating service ensures that all parts of the transaction are applied to all relevant systems. As with database and other transactions, if any part of the transaction fails, the entire transaction is rolled back across all affected systems.

Transactional filesystems

The Namesys Reiser4 filesystem for Linux[4] supports transactions, and as of Microsoft Windows Vista, the Microsoft NTFS filesystem[5] supports distributed transactions across networks.

Prepared statement

In database management systems, a **prepared statement** or **parameterized statement** is a feature used to execute the same or similar database statements repeatedly with high efficiency. Typically used with SQL statements such as queries or updates, the prepared statement takes the form of a template into which certain constant values are substituted during each execution.

The typical workflow of using a prepared statement is as follows:

1. **Prepare**: The statement template is created by the application and sent to the database management system (DBMS). Certain values are left unspecified, called *parameters*, *placeholders* or *bind variables* (labelled "?" below):
   - `INSERT INTO PRODUCT (name, price) VALUES (?, ?)`
2. The DBMS parses, compiles, and performs query optimization on the statement template, and stores the result without executing it.
3. **Execute**: At a later time, the application supplies (or *binds*) values for the parameters, and the DBMS executes the statement (possibly returning a result). The application may execute the statement as many times as it wants with different values. In this example, it might supply 'Bread' for the first parameter and '1.00' for the second parameter.

As compared to executing SQL statements directly, prepared statements offer two main advantages:

- The overhead of compiling and optimizing the statement is incurred only once, although the statement is executed multiple times. Not all optimization can be performed at the time the prepared statement is compiled, for two reasons: the best plan may depend on the specific values of the parameters, and the best plan may change as tables and indexes change over time.
- Prepared statements are resilient against SQL injection, because parameter values, which are transmitted later using a different protocol, need not be correctly escaped. If the original statement template is not derived from external input, SQL injection cannot occur.

On the other hand, if a query is executed only once, server-side prepared statements can be slower because of the additional round-trip to the server. Implementation limitations may also lead to performance penalties: some versions of MySQL did not cache results of prepared queries, and some DBMSs such as PostgreSQL do not perform additional query optimization during execution.

A stored procedure, which is also precompiled and stored on the server for later execution, has similar advantages. Unlike a stored procedure, a prepared statement is not normally written in a procedural language and cannot use or modify variables or use control flow structures, relying instead on the declarative database query language. Due to their simplicity and client-side emulation, prepared statements are more portable across vendors.

Software support

Prepared statements are widely supported by major DBMSs, including MySQL, Oracle, DB2, Microsoft SQL Server, and PostgreSQL. Prepared statements are normally executed through a non-SQL binary protocol, for efficiency and protection from SQL injection, but with some DBMSs such as MySQL are also available using a SQL syntax for debugging purposes.

A number of programming languages support prepared statements in their standard libraries and will emulate them on the client side even if the underlying DBMS does not support them, including Java's JDBC, Perl's DBI, PHP's PDO and Python's DB-API. Client-side emulation can be faster for queries which are executed only once, by reducing the number of round trips to the server, but is usually slower for queries executed many times. It resists SQL injection attacks equally effectively.

Many types of SQL injection attacks can be eliminated by *disabling literals*, effectively requiring the use of prepared statements; as of 2007 only H2 supports this feature.

Examples

Java JDBC

This example uses Java and the JDBC API:

```
java.sql.PreparedStatement stmt = connection.prepareStatement(
                "SELECT * FROM users WHERE USERNAME = ? AND ROOM = ?");
stmt.setString(1, username);
stmt.setInt(2, roomNumber);
stmt.executeQuery();
```

Java `PreparedStatement` provides "setters" (`setInt(int)`, `setString(String)`, `setDouble(double)`, etc.) for all major built-in data types.

PHP PDO

This example uses PHP and PHP Data Objects (PDO):

```
$stmt = $dbh->prepare("SELECT * FROM users WHERE USERNAME = ? AND
PASSWORD = ?");
$stmt->execute(array($username, $password));
```

PERL DBI

This example uses Perl and DBI:

```
my $stmt = $dbh->prepare('SELECT * FROM users WHERE USERNAME = ? AND
PASSWORD = ?');
$stmt->execute($username, $password);
```

C# ADO.NET

This example uses C# and ADO.NET:

```
using (SqlCommand command = connection.CreateCommand())
{
    command.CommandText = "SELECT * FROM users WHERE USERNAME =
@username AND ROOM = @room";

    command.Parameters.AddWithValue("@username", username);
    command.Parameters.AddWithValue("@room", room);

    using (SqlDataReader dataReader = command.ExecuteReader())
    {
        // ...
    }
}
```

ADO.NET `SqlCommand` will accept any type for the `value` parameter of `AddWithValue`, and type conversion occurs automatically. Note the use of "named parameters" (i.e. "@username") rather than "?" - this allows you to use a parameter multiple times and in any arbitrary order within the query command text.

However, the AddWithValue method should not be used with variable length data types, like varchar and nvarchar. This is because .NET assumes the length of the parameter to be the length of the given value, rather than getting the actual length of from the database via reflection. The consequence of this is that a different query plan is compiled and stored for each different length. In general, the maximum number of 'duplicate' plans is the product of the lengths of the variable length columns as specified in the database. For this reason, it is important to use the standard Add method for variable length columns:

command.Parameters.Add(ParamName, VarChar, ParamLength).Value = ParamValue, where ParamLength is the length as specified in the database.

Since the standard Add method needs to be used for variable length data types, it is a good habit to use it for all parameter types.

Python DB-API

This example uses Python DB-API with SQLite and `paramstyle='qmark'`:

```
import sqlite3
conn = sqlite3.connect(':memory:')
c = conn.cursor()

_users = [('mother', 'red'),
          ('father', 'green'),
          ('me', 'blue')]
c.executemany('INSERT INTO users VALUES (?,?)', _users)

params = ('B', 'green')
c.execute('SELECT * FROM users WHERE username=? AND room=?', params)
c.fetchone()
```

Open Database Connectivity

In computing, **ODBC** (**Open Database Connectivity**) is a standard programming language middleware API for accessing database management systems (DBMS). The designers of ODBC aimed to make it independent of database systems and operating systems; an application written using ODBC can be ported to other platforms, both on the client and server side, with few changes to the data access code.

ODBC accomplishes DBMS independence by using an **ODBC driver** as a translation layer between the application and the DBMS. The application uses ODBC functions through an **ODBC driver manager** with which it is linked, and the driver passes the query to the DBMS. An ODBC driver can be thought of as analogous to a printer or other driver, providing a standard set of functions for the application to use, and implementing DBMS-specific functionality. An application that can use ODBC is referred to as "ODBC-compliant". Any ODBC-compliant application can access any DBMS for which a driver is installed. Drivers exist for all major DBMSs, many other data sources like address book systems and Microsoft Excel, and even for text or CSV files.

ODBC was originally developed by Microsoft during the early 1990s, and became the basis for the Call Level Interface (CLI) standardized by SQL Access Group in the Unix and mainframe world. ODBC retained a number of features that were removed as part of the CLI effort. Full ODBC was later ported back to those platforms, and became a de facto standard considerably better known than CLI. The CLI remains similar to ODBC, and applications can be ported from one platform to the other with few changes.

History

Prior to ODBC

The introduction of the mainframe-based relational database during the 1970s led to a proliferation of data access methods. Generally these systems operated hand-in-hand with a simple command processor that allowed the user to type in English-like commands, and receive output. The best-known examples are SQL from IBM and QUEL from the Ingres project. These systems may or may not allow other applications to access the data directly, and those that did used a wide variety of methodologies. The introduction of SQL aimed to solve the problem of *language* standardization, although substantial differences in implementation remained.

Additionally, since the SQL language had only rudimentary programming features, it was often desired to use SQL within a program written in another language, say Fortran or C. This led to the concept of Embedded SQL, which allowed SQL code to be "embedded" within another language. For instance, a SQL statement like `SELECT * FROM city` could be inserted as text within C source code, and during compilation it would be converted into a custom format that directly called a function within a library that would pass the statement into the SQL system. Results returned from the statements would be interpreted back into C data formats like `char *` using similar library code.

There were a number of problems with the Embedded SQL approach. Like the different varieties of SQL, the Embedded SQL's that used them varied widely, not only from platform to platform, but even across languages on a single platform - a system that allowed calls into IBM's DB2 would look entirely different from one that called into their own SQL/DSWikipedia:Disputed statement. Another key problem to the Embedded SQL concept was that the SQL code could only be changed in the program's source code, so that even small changes to the query required considerable programmer effort to modify. The SQL market referred to this as "static SQL", as opposed to "dynamic SQL" which could be changed at any time - like the command-line interfaces that shipped with almost all SQL systems, or a programming interface that left the SQL as plain text until it was called. Dynamic SQL systems became a major focus for SQL vendors during the 1980s.

Older mainframe databases, and the newer microcomputer based systems that were based on them, generally did not have a SQL-like command processor between the user and the database engine. Instead, the data was accessed directly by the program - a programming library in the case of large mainframe systems, or a command line interface or interactive forms system in the case of dBASE and similar applications. Data from dBASE could not generally be accessed directly by other programs running on the machine. Those programs may be given a way to access this data, often through libraries, but it would not work with any other database engine, or even different databases in the same engine. In effect, all such systems were static, which presented considerable problems.

Early efforts

By the mid-1980s the rapid improvement in microcomputers, and especially the introduction of the graphical user interface and data-rich application programs like Lotus 1-2-3 led to an increasing interest in using personal computers as the client-side platform of choice in client-server computing. Under this model, large mainframes and minicomputers would be used primarily to serve up data over local area networks to microcomputers that would interpret, display and manipulate that data. For this model to work, a data access standard was a requirement - in the mainframe world it was highly likely that all of the computers in a shop were from a single vendor and clients were computer terminals talking directly to them, but in the micro world there was no such standardization and any client might access any server using any networking system.

By the late 1980s there were a number of efforts underway to provide an abstraction layer for this purpose. Some of these were mainframe related, designed to allow programs running on those machines to translate between the variety of SQL's and provide a single common interface which could then be called by other mainframe or microcomputer programs. These solutions included IBM's Distributed Relational Database Architecture (DRDA) and Apple Computer's Data Access Language. Much more common, however, were systems that ran entirely on microcomputers, including a complete protocol stack that included any required networking or file translation support.

One of the early examples of such a system was Lotus Development's DataLens, initially known as Blueprint. Blueprint, developed for 1-2-3, supported a variety of data sources, including SQL/DS, DB2, FOCUS and a variety of similar mainframe systems, as well as microcomputer systems like dBase and the early Microsoft/Ashton-Tate efforts that would eventually develop into Microsoft SQL Server.[1] Unlike the later ODBC, Blueprint was a purely code-based system, lacking anything approximating a command language like SQL. Instead, programmers used data structures to store the query information, constructing a query by linking many of these structures together. Lotus referred to these compound structures as "query trees".[2]

Around the same time, an industry team including members from Sybase, Tandem Computers and Microsoft were working on a standardized dynamic SQL concept. Much of the system was based on Sybase's DB-Library system, with the Sybase-specific sections removed and several additions to support other platforms.[3] DB-Library was aided by an industry-wide move from library systems that were tightly linked to a particular language, to library systems that were provided by the operating system and required the languages on that platform to conform to its standards. This meant that a single library could be used with (potentially) any programming language on a given platform.

The first draft of the **Microsoft Data Access API** was published in April 1989, about the same time as Lotus' announcement of Blueprint.[4] In spite of Blueprint's great lead - it was running when MSDA was still a paper project - Lotus eventually joined the MSDA efforts as it became clear that SQL would become the de facto database standard.[2] After considerable industry input, in the summer of 1989 the standard became **SQL Connectivity**, or **SQLC** for short,.[5]

SAG and CLI

In 1988 a number of vendors, mostly from the Unix and database communities, formed the SQL Access Group (SAG) in an effort to produce a single basic standard for the SQL language. At the first meeting there was considerable debate over whether or not the effort should work solely on the SQL language itself, or attempt a wider standardization which included a dynamic SQL language-embedding system as well, what they called a Call Level Interface (CLI).[6] While attending the meeting with an early draft of what was then still known as MS Data Access, Kyle Geiger of Microsoft invited Jeff Balboni and Larry Barnes of Digital Equipment Corporation (DEC) to join the SQLC meetings as well. SQLC was a potential solution to the call for the CLI, which was being led by DEC.

The new SQLC "gang of four", MS, Lotus, DEC and Sybase, brought an updated version of SQLC to the next SAG meeting in June 1990.[7] The SAG responded by opening the standard effort to any competing design, but of the many proposals, only Oracle Corp had a system that presented serious competition. In the end, SQLC won the votes and became the draft standard, but only after large portions of the API were removed - the standards document was trimmed from 120 pages to 50 during this time. It was also during this period that the name Call Level Interface was formally adopted.[7] In 1995 SQL/CLI became part of the international SQL standard, ISO/IEC 9075-3.[8] The SAG itself was taken over by the X/Open group in 1996, and, over time, became part of The Open Group's Common Application Environment.

MS continued working with the original SQLC standard, retaining many of the advanced features that were removed from the CLI version. These included features like scrollable cursors, and metadata information queries. The commands in the API were split into groups; the Core group was identical to the CLI, the Level 1 extensions were commands that would be easy to implement in drivers, while Level 2 commands contained the more advanced features like cursors. A proposed standard was released in December 1991, and industry input was gathered and worked into the system through 1992, resulting in yet another name change to **ODBC**.[9]

JET and ODBC

During this time, Microsoft was in the midst of developing their Jet database system. Jet combined three primary subsystems; an ISAM-based database engine (also known as "Jet", confusingly), a C-based interface allowing applications to access that data, and a selection of driver DLLs that allowed the same C interface to redirect input and output to other ISAM-based databases, like Paradox and xBase. Jet allowed programmers to use a single set of calls to access common microcomputer databases in a fashion similar to Blueprint (by this point known as DataLens). However, Jet did not use SQL; like DataLens, the interface was in C and consisted of data structures and function calls.

The SAG standardization efforts presented an opportunity for Microsoft to adapt their Jet system to the new CLI standard. This would not only make Windows a premier platform for CLI development, but also allow users to use SQL to access both Jet and other databases as well. What was missing was the SQL parser that could convert those calls from their text form into the C-interface used in Jet. To solve this, MS partnered with PageAhead Software to use their existing query processor, "SIMBA". SIMBA was used as a parser above Jet's C library, turning Jet into an SQL database. And because Jet could forward those C-based calls to other databases, this also allowed SIMBA to query other systems. Microsoft included drivers for Excel to turn its spreadsheet documents into SQL-accessible database tables.

Release and continued development

ODBC 1.0 was released in September 1992. At the time, there was little direct support for SQL databases (as opposed to ISAM), and early drivers were noted for poor performance. Some of this was unavoidable due to the path that the calls took through the Jet-based stack; ODBC calls to SQL databases were first converted from SIMBA's SQL dialect to Jet's internal C-based format, then passed to a driver for conversion back into SQL calls for the database. Digital Equipment and Oracle both contracted Simba to develop drivers for their databases as well.[10]

Circa 1993, OpenLink Software shipped one of the first independently developed third-party ODBC drivers, for the PROGRESS DBMS, and soon followed with their UDBC (a cross-platform API equivalent of ODBC and the SAG/CLI) SDK and associated drivers for PROGRESS, Sybase, Oracle, and other DBMS, for use on Unix-like OS (AIX, HP-UX, Solaris, Linux, etc.), VMS, Windows NT, OS/2, and other OS.

Meanwhile the CLI standard effort dragged on, and it was not until March 1995 that the definitive version was finalized. By this time Microsoft had already granted Visigenic Software a source code license to develop ODBC on non-Windows platforms. Visigenic ported ODBC to a wide variety of Unix platforms, where ODBC quickly became the de facto standard.[11] "Real" CLI is rare today. The two systems remain similar, and many applications can be ported from ODBC to CLI with few or no changes.[12]

Over time, database vendors took over the driver interfaces and provided direct links to their products. Skipping the intermediate conversions to and from Jet or similar wrappers often resulted in higher performance. However, by this time Microsoft had changed focus to their OLE DB concept, which provided direct access to a wider variety of data sources from address books to text files. Several new systems followed which further turned their attention from ODBC, including DAO, ADO and ADO.net, which interacted more or less with ODBC over their lifetimes.

As Microsoft turned its attention away from working directly on ODBC, the Unix world was increasingly embracing it. This was propelled by two changes within the market, the introduction of GUIs like GNOME that provided the need for access to these sources in non-text form, and the emergence of open software database systems like PostgreSQL and MySQL, initially under Unix. The later adoption of ODBC by Apple for using the standard Unix-side iODBC package Mac OS X 10.2 (Jaguar) (which OpenLink Software had been independently providing for Mac OS X 10.0 and even Mac OS 9 since 2001) further cemented ODBC as the standard for cross-platform data access.

Sun Microsystems used the ODBC system as the basis for their own open standard, JDBC. In most ways, JDBC can be considered a version of ODBC for the Java programming language as opposed to C. JDBC-to-ODBC "bridges" allow Java-based programs to access data sources through ODBC drivers on platforms lacking a native JDBC driver, although these are now relatively rare. Inversely, ODBC-to-JDBC "bridges" allow C-based programs to access data sources through JDBC drivers on platforms or from databases lacking suitable ODBC drivers.

ODBC today

ODBC remains largely universal today, with drivers available for most platforms and most databases. It is not uncommon to find ODBC drivers for database engines that are meant to be embedded, like SQLite, as a way to allow existing tools to act as front-ends to these engines for testing and debugging.[13]

However, the rise of thin client computing using HTML as an intermediate format has reduced the need for ODBC. Many web development platforms contain direct links to target databases - MySQL being particularly common. In these scenarios, there is no direct client-side access nor multiple client software systems to support; everything goes through the programmer-supplied HTML application. The virtualization that ODBC offers is no longer a strong requirement, and development of ODBC is no longer as active as it once was.

Version history

Version history:

- 1.0: released in September 1992
- 2.0: ca 1994
- 2.5
- 3.0: ca 1995, John Goodson of Intersolv and Frank Pellow and Paul Cotton of IBM provided significant input to ODBC 3.0[14]
- 3.5: ca 1997
- 3.8: ca 2009, with Windows 7

Drivers and Managers

Drivers

ODBC is based on the device driver model, where the driver encapsulates the logic needed to convert a standard set of commands and functions into the specific calls required by the underlying system. For instance, a printer driver presents a standard set of printing commands, the API, to applications using the printing system. Calls made to those APIs are converted by the driver into the format used by the actual hardware, say PostScript or PCL.

In the case of ODBC, the drivers encapsulate a number of functions that can be broken down into several broad categories. One set of functions is primarily concerned with finding, connecting to and disconnecting from the DBMS that driver talks to. A second set is used to send SQL commands from the ODBC system to the DBMS, converting or interpreting any commands that are not supported internally. For instance, a DBMS that does not support cursors can emulate this functionality in the driver. Finally, another set of commands, mostly used internally, is used to convert data from the DBMS's internal formats to a set of standardized ODBC formats, which are based on the C language formats.

An ODBC driver enables an ODBC-compliant application to use a *data source*, normally a DBMS. Some non-DBMS drivers exist, for such data sources as CSV files, by implementing a small DBMS inside the driver itself. ODBC drivers exist for most DBMSs, including Oracle, PostgreSQL, MySQL, Microsoft SQL Server (but not for the Compact aka CE edition), Sybase ASE, and DB2. Because different technologies have different capabilities, most ODBC drivers do not implement all functionality defined in the ODBC standard. Some drivers offer extra functionality not defined by the standard.

Driver Manager

Device drivers are normally enumerated, set up and managed by a separate Manager layer, which may provide additional functionality. For instance, printing systems often include functionality to provide spooling functionality on top of the drivers, providing print spooling for any supported printer.

In ODBC the Driver Manager (DM) provides these features. The DM can enumerate the installed drivers and present this as a list, often in a GUI-based form.

But more important to the operation of the ODBC system is the DM's concept of **Data Source Name**s, or **DSN**. DSNs collect additional information needed to connect to a *particular* data source, as opposed to the DBMS itself. For instance, the same MySQL driver can be used to connect to any MySQL server, but the connection information to connect to a local private server is different from the information needed to connect to an internet-hosted public server. The DSN stores this information in a standardized format, and the DM provides this to the driver during connection requests. The DM also includes functionality to present a list of DSNs using human readable names, and to select them at run-time to connect to different resources.

The DM also includes the ability to save partially complete DSN's, with code and logic to ask the user for any missing information at runtime. For instance, a DSN can be created without a required password. When an ODBC application attempts to connect to the DBMS using this DSN, the system will pause and ask the user to provide the password before continuing. This frees the application developer from having to create this sort of code, as well as having to know which questions to ask. All of this is included in the driver and the DSNs.

Bridging configurations

A *bridge* is a special kind of driver: a driver that uses another driver-based technology.

ODBC-to-JDBC (or simply ODBC-JDBC) bridges

An ODBC-JDBC bridge consists of an **ODBC** driver which uses the services of a JDBC driver to connect to a database. This driver translates ODBC function-calls into JDBC method-calls. Programmers usually use such a bridge when they lack an ODBC driver for a particular database but have access to a JDBC driver.

JDBC-to-ODBC (or simply JDBC-ODBC) bridges

A JDBC-ODBC bridge consists of a JDBC driver which employs an ODBC driver to connect to a target database. This driver translates JDBC method calls into ODBC function calls. Programmers usually use such a bridge when a particular database lacks a JDBC driver. Sun Microsystems included one such bridge in the JVM, but viewed it as a stop-gap measure while few JDBC drivers existed. Sun never intended its bridge for production environments, and generally recommended against its use. As of 2008[15] independent data-access vendors deliver JDBC-ODBC bridges which support current standards for both mechanisms, and which far outperform the JVM built-in.[*citation needed*]

OLE DB-to-ODBC bridges

An OLE DB-ODBC bridge consists of an OLE DB Provider which uses the services of an ODBC driver to connect to a target database. This provider translates OLE DB method calls into ODBC function calls. Programmers usually use such a bridge when a particular database lacks an OLE DB provider. Microsoft ships one, MSDASQL.DLL, as part of the MDAC system component bundle, together with other database drivers, to simplify development in COM-aware languages (e.g. Visual Basic). Third parties have also developed such, notably OpenLink Software whose 64-bit OLE DB Provider for ODBC Data Sources filled the gap when Microsoft initially deprecated this bridge for their 64-bit OS.[16] (Microsoft later relented, and 64-bit Windows starting with Windows Server 2008 and Windows Vista SP1 have shipped with a 64-bit version of MSDASQL.)

ADO.NET-to-ODBC bridges

An ADO.NET-ODBC bridge consists of an ADO.NET Provider which uses the services of an OBDC driver to connect to a target database. This provider translates ADO.NET method calls into ODBC function calls. Programmers usually use such a bridge when a particular database lacks an ADO.NET provider. Microsoft ships one as part of the MDAC system component bundle, together with other database drivers, to simplify development in C#. Third parties have also developed such.

Java Database Connectivity

JDBC

Type	Data Access API
Website	Java SE 7 [6]

JDBC is a Java-based data access technology (Java Standard Edition platform) from Oracle Corporation. This technology is an API for the Java programming language that defines how a client may access a database. It provides methods for querying and updating data in a database. JDBC is oriented towards relational databases. A JDBC-to-ODBC bridge enables connections to any ODBC-accessible data source in the JVM host environment.

History and implementation

Sun Microsystems released JDBC as part of JDK 1.1 on February 19, 1997. It has since formed part of the Java Standard Edition.

The JDBC classes are contained in the Java package `java.sql` [1] and `javax.sql` [2].

Starting with version 3.1, JDBC has been developed under the Java Community Process. JSR 54 specifies JDBC 3.0 (included in J2SE 1.4), JSR 114 specifies the JDBC Rowset additions, and JSR 221 is the specification of JDBC 4.0 (included in Java SE 6).[3]

The latest version, JDBC 4.1, is specified by a maintenance release of JSR 221[4] and is included in Java SE 7.[5]

Functionality

JDBC allows multiple implementations to exist and be used by the same application. The API provides a mechanism for dynamically loading the correct Java packages and registering them with the JDBC Driver Manager. The Driver Manager is used as a connection factory for creating JDBC connections.

JDBC connections support creating and executing statements. These may be update statements such as SQL's CREATE, INSERT, UPDATE and DELETE, or they may be query statements such as SELECT. Additionally, stored procedures may be invoked through a JDBC connection. JDBC represents statements using one of the following classes:

- `Statement` [6] – the statement is sent to the database server each and every time.
- `PreparedStatement` [7] – the statement is cached and then the execution path is pre-determined on the database server allowing it to be executed multiple times in an efficient manner.
- `CallableStatement` [8] – used for executing stored procedures on the database.

Update statements such as INSERT, UPDATE and DELETE return an update count that indicates how many rows were affected in the database. These statements do not return any other information.

Query statements return a JDBC row result set. The row result set is used to walk over the result set. Individual columns in a row are retrieved either by name or by column number. There may be any number of rows in the result set. The row result set has metadata that describes the names of the columns and their types.

There is an extension to the basic JDBC API in the `javax.sql` [2].

JDBC connections are often managed via a connection pool rather than obtained directly from the driver. Examples of connection pools include BoneCP [9], C3P0 [10] and DBCP [11]

Examples

The method `Class.forName(String)` [12] is used to load the JDBC driver class. The line below causes the JDBC driver from *some jdbc vendor* to be loaded into the application. (Some JVMs also require the class to be instantiated with `.newInstance()` [13].)

```
Class.forName( "com.somejdbcvendor.TheirJdbcDriver" );
```

In JDBC 4.0, it is no longer necessary to explicitly load JDBC drivers using `Class.forName()`. See JDBC 4.0 Enhancements in Java SE 6 [14].

When a `Driver` [15] class is loaded, it creates an instance of itself and registers it with the `DriverManager` [16]. This can be done by including the needed code in the driver class's `static` block. E.g., `DriverManager.registerDriver(Driver driver)`

Now when a connection is needed, one of the `DriverManager.getConnection()` methods is used to create a JDBC connection.

```
Connection conn = DriverManager.getConnection(
     "jdbc:somejdbcvendor:other data needed by some jdbc vendor",
     "myLogin",
     "myPassword" );
try {
     /* you use the connection here */
} finally {
    //It's important to close the connection when you are done with it
    try { conn.close(); } catch (Throwable ignore) { /* Propagate the original exception
instead of this one that you may want just logged */ }
}
```

Using Java's try-with-resources statement will make the above code cleaner:

```
try (Connection conn = DriverManager.getConnection(
     "jdbc:somejdbcvendor:other data needed by some jdbc vendor",
     "myLogin",
     "myPassword" ) ) {
     /* you use the connection here */
}  // the VM will take care of closing the connection
```

The URL used is dependent upon the particular JDBC driver. It will always begin with the "jdbc:" protocol, but the rest is up to the particular vendor. Once a connection is established, a statement can be created.

```
try (Statement stmt = conn.createStatement()) {
    stmt.executeUpdate( "INSERT INTO MyTable( name ) VALUES ( 'my name' ) " );
}
```

Note that Connections, Statements, and ResultSets often tie up operating system resources such as sockets or file descriptors. In the case of Connections to remote database servers, further resources are tied up on the server, e.g., cursors for currently open ResultSets. It is vital to `close()` any JDBC object as soon as it has played its part; garbage collection should not be relied upon. Forgetting to `close()` things properly results in spurious errors and misbehaviour. The above try-with-resources construct is a recommendedWikipedia:Manual of Style/Words to watch#Unsupported attributions code pattern to use with JDBC objects.

Data is retrieved from the database using a database query mechanism. The example below shows creating a statement and executing a query.

```
try (Statement stmt = conn.createStatement();
    ResultSet rs = stmt.executeQuery( "SELECT * FROM MyTable" )
) {
    while ( rs.next() ) {
        int numColumns = rs.getMetaData().getColumnCount();
        for ( int i = 1 ; i <= numColumns ; i++ ) {
           // Column numbers start at 1.
           // Also there are many methods on the result set to return
           //  the column as a particular type. Refer to the Sun documentation
           //  for the list of valid conversions.
           System.out.println( "COLUMN " + i + " = " + rs.getObject(i) );
        }
    }
}
```

Typically, however, it would be rare for a seasoned Java programmer to code in such a fashion. The usual practice would be to abstract the database logic into an entirely different class and to pass preprocessed strings (perhaps derived themselves from a further abstracted class) containing SQL statements and the connection to the required methods. Abstracting the data model from the application code makes it more likely that changes to the application and data model can be made independently.

An example of a `PreparedStatement` query, using `conn` and class from first example.

```
try (PreparedStatement ps =
    conn.prepareStatement( "SELECT i.*, j.* FROM Omega i, Zappa j WHERE i.name = ? AND j.num = ?" )
){
    // In the SQL statement being prepared, each question mark is a placeholder
    // that must be replaced with a value you provide through a "set" method invocation.
    // The following two method calls replace the two placeholders; the first is
    // replaced by a string value, and the second by an integer value.
    ps.setString(1, "Poor Yorick");
    ps.setInt(2, 8008);

    // The ResultSet, rs, conveys the result of executing the SQL statement.
    // Each time you call rs.next(), an internal row pointer, or cursor,
    // is advanced to the next row of the result.  The cursor initially is
    // positioned before the first row.
    try (ResultSet rs = ps.executeQuery()) {
        while ( rs.next() ) {
            int numColumns = rs.getMetaData().getColumnCount();
            for ( int i = 1 ; i <= numColumns ; i++ ) {
                // Column numbers start at 1.
                // Also there are many methods on the result set to return
                // the column as a particular type. Refer to the Sun documentation
                // for the list of valid conversions.
                System.out.println( "COLUMN " + i + " = " + rs.getObject(i) );
            } // for
```

```
        } // while
    } // try
} // try
```

If a database operation fails, JDBC raises an `SQLException` [17]. There is typically very little one can do to recover from such an error, apart from logging it with as much detail as possible. It is recommended that the SQLException be translated into an application domain exception (an unchecked one) that eventually results in a transaction rollback and a notification to the user.

An example of a database transaction:

```
boolean autoCommitDefault = conn.getAutoCommit();
try {
    conn.setAutoCommit(false);

    /* You execute statements against conn here transactionally */

    conn.commit();
} catch (Throwable e) {
    try { conn.rollback(); } catch (Throwable ignore) {}
    throw e;
} finally {
    try { conn.setAutoCommit(autoCommitDefault); } catch (Throwable ignore) {}
}
```

Here are examples of host database types which Java can convert to with a function.

`setXXX()` Methods

Oracle Datatype	`setXXX()`
CHAR	`setString()`
VARCHAR2	`setString()`
NUMBER	`setBigDecimal()`
	`setBoolean()`
	`setByte()`
	`setShort()`
	`setInt()`
	`setLong()`
	`setFloat()`
	`setDouble()`
INTEGER	`setInt()`
FLOAT	`setDouble()`
CLOB	`setClob()`
BLOB	`setBlob()`
RAW	`setBytes()`
LONGRAW	`setBytes()`

DATE	`setDate()`
	`setTime()`
	`setTimestamp()`

For an example of a `CallableStatement` (to call stored procedures in the database), see the Java SE 7 [6].

JDBC drivers

JDBC drivers are client-side adapters (installed on the client machine, not on the server) that convert requests from Java programs to a protocol that the DBMS can understand.

Types

There are commercial and free drivers available for most relational database servers. These drivers fall into one of the following types:

- Type 1 that calls native code of the locally available ODBC driver.
- Type 2 that calls database vendor native library on a client side. This code then talks to database over network.
- Type 3, the pure-java driver that talks with the server-side middleware that then talks to database.
- Type 4, the pure-java driver that uses database native protocol.

There is also a type called internal JDBC driver, driver embedded with JRE in Java-enabled SQL databases. It's used for Java stored procedures. This does not belong to the above classification, although it would likely be either a type 2 or type 4 driver (depending on whether the database itself is implemented in Java or not). An example of this is the KPRB driver supplied with Oracle RDBMS. "jdbc:default:connection" is a relatively standard way of referring making such a connection (at least Oracle and Apache Derby support it). The distinction here is that the JDBC client is actually running as part of the database being accessed, so access can be made directly rather than through network protocols.

Sources

- SQLSummit.com publishes list of drivers, including JDBC drivers and vendors
- Oracle provides a list of some JDBC drivers and vendors [18]
- Simba Technologies ships an SDK for building custom JDBC Drivers for any custom/proprietary relational data source
- RSSBus Type 4 JDBC Drivers for applications, databases, and web services [19].
- DataDirect Technologies provides a comprehensive suite of fast Type 4 JDBC drivers for all major database they advertise as Type 5
- IDS Software provides a Type 3 JDBC driver for concurrent access to all major databases. Supported features include resultset caching, SSL encryption, custom data source, dbShield
- OpenLink Software ships JDBC Drivers for a variety of databases, including Bridges to other data access mechanisms (e.g., ODBC, JDBC) which can provide more functionality than the targeted mechanism
- JDBaccess is a Java persistence library for MySQL and Oracle which defines major database access operations in an easy usable API above JDBC
- JNetDirect provides a suite of fully Sun J2EE certified high performance JDBC drivers.
- HSQLDB is a RDBMS with a JDBC driver and is available under a BSD license.
- SchemaCrawler is an open source API that leverages JDBC, and makes database metadata available as plain old Java objects (POJOs)

ODBC

In computing, **ODBC** (**Open Database Connectivity**) is a standard programming language middleware API for accessing database management systems (DBMS). The designers of ODBC aimed to make it independent of database systems and operating systems; an application written using ODBC can be ported to other platforms, both on the client and server side, with few changes to the data access code.

ODBC accomplishes DBMS independence by using an **ODBC driver** as a translation layer between the application and the DBMS. The application uses ODBC functions through an **ODBC driver manager** with which it is linked, and the driver passes the query to the DBMS. An ODBC driver can be thought of as analogous to a printer or other driver, providing a standard set of functions for the application to use, and implementing DBMS-specific functionality. An application that can use ODBC is referred to as "ODBC-compliant". Any ODBC-compliant application can access any DBMS for which a driver is installed. Drivers exist for all major DBMSs, many other data sources like address book systems and Microsoft Excel, and even for text or CSV files.

ODBC was originally developed by Microsoft during the early 1990s, and became the basis for the Call Level Interface (CLI) standardized by SQL Access Group in the Unix and mainframe world. ODBC retained a number of features that were removed as part of the CLI effort. Full ODBC was later ported back to those platforms, and became a de facto standard considerably better known than CLI. The CLI remains similar to ODBC, and applications can be ported from one platform to the other with few changes.

History

Prior to ODBC

The introduction of the mainframe-based relational database during the 1970s led to a proliferation of data access methods. Generally these systems operated hand-in-hand with a simple command processor that allowed the user to type in English-like commands, and receive output. The best-known examples are SQL from IBM and QUEL from the Ingres project. These systems may or may not allow other applications to access the data directly, and those that did used a wide variety of methodologies. The introduction of SQL aimed to solve the problem of *language* standardization, although substantial differences in implementation remained.

Additionally, since the SQL language had only rudimentary programming features, it was often desired to use SQL within a program written in another language, say Fortran or C. This led to the concept of Embedded SQL, which allowed SQL code to be "embedded" within another language. For instance, a SQL statement like `SELECT * FROM city` could be inserted as text within C source code, and during compilation it would be converted into a custom format that directly called a function within a library that would pass the statement into the SQL system. Results returned from the statements would be interpreted back into C data formats like `char *` using similar library code.

There were a number of problems with the Embedded SQL approach. Like the different varieties of SQL, the Embedded SQL's that used them varied widely, not only from platform to platform, but even across languages on a single platform - a system that allowed calls into IBM's DB2 would look entirely different from one that called into their own SQL/DSWikipedia:Disputed statement. Another key problem to the Embedded SQL concept was that the SQL code could only be changed in the program's source code, so that even small changes to the query required considerable programmer effort to modify. The SQL market referred to this as "static SQL", as opposed to "dynamic SQL" which could be changed at any time - like the command-line interfaces that shipped with almost all SQL systems, or a programming interface that left the SQL as plain text until it was called. Dynamic SQL systems became a major focus for SQL vendors during the 1980s.

Older mainframe databases, and the newer microcomputer based systems that were based on them, generally did not have a SQL-like command processor between the user and the database engine. Instead, the data was accessed directly by the program - a programming library in the case of large mainframe systems, or a command line interface or interactive forms system in the case of dBASE and similar applications. Data from dBASE could not generally be accessed directly by other programs running on the machine. Those programs may be given a way to access this data, often through libraries, but it would not work with any other database engine, or even different databases in the same engine. In effect, all such systems were static, which presented considerable problems.

Early efforts

By the mid-1980s the rapid improvement in microcomputers, and especially the introduction of the graphical user interface and data-rich application programs like Lotus 1-2-3 led to an increasing interest in using personal computers as the client-side platform of choice in client-server computing. Under this model, large mainframes and minicomputers would be used primarily to serve up data over local area networks to microcomputers that would interpret, display and manipulate that data. For this model to work, a data access standard was a requirement - in the mainframe world it was highly likely that all of the computers in a shop were from a single vendor and clients were computer terminals talking directly to them, but in the micro world there was no such standardization and any client might access any server using any networking system.

By the late 1980s there were a number of efforts underway to provide an abstraction layer for this purpose. Some of these were mainframe related, designed to allow programs running on those machines to translate between the variety of SQL's and provide a single common interface which could then be called by other mainframe or microcomputer programs. These solutions included IBM's Distributed Relational Database Architecture (DRDA) and Apple Computer's Data Access Language. Much more common, however, were systems that ran entirely on microcomputers, including a complete protocol stack that included any required networking or file translation support.

One of the early examples of such a system was Lotus Development's DataLens, initially known as Blueprint. Blueprint, developed for 1-2-3, supported a variety of data sources, including SQL/DS, DB2, FOCUS and a variety of similar mainframe systems, as well as microcomputer systems like dBase and the early Microsoft/Ashton-Tate efforts that would eventually develop into Microsoft SQL Server.[1] Unlike the later ODBC, Blueprint was a purely code-based system, lacking anything approximating a command language like SQL. Instead, programmers used data structures to store the query information, constructing a query by linking many of these structures together. Lotus referred to these compound structures as "query trees".[2]

Around the same time, an industry team including members from Sybase, Tandem Computers and Microsoft were working on a standardized dynamic SQL concept. Much of the system was based on Sybase's DB-Library system, with the Sybase-specific sections removed and several additions to support other platforms.[3] DB-Library was aided by an industry-wide move from library systems that were tightly linked to a particular language, to library systems that were provided by the operating system and required the languages on that platform to conform to its standards. This meant that a single library could be used with (potentially) any programming language on a given platform.

The first draft of the **Microsoft Data Access API** was published in April 1989, about the same time as Lotus' announcement of Blueprint.[4] In spite of Blueprint's great lead - it was running when MSDA was still a paper project - Lotus eventually joined the MSDA efforts as it became clear that SQL would become the de facto database standard.[2] After considerable industry input, in the summer of 1989 the standard became **SQL Connectivity**, or **SQLC** for short,.[5]

SAG and CLI

In 1988 a number of vendors, mostly from the Unix and database communities, formed the SQL Access Group (SAG) in an effort to produce a single basic standard for the SQL language. At the first meeting there was considerable debate over whether or not the effort should work solely on the SQL language itself, or attempt a wider standardization which included a dynamic SQL language-embedding system as well, what they called a Call Level Interface (CLI).[6] While attending the meeting with an early draft of what was then still known as MS Data Access, Kyle Geiger of Microsoft invited Jeff Balboni and Larry Barnes of Digital Equipment Corporation (DEC) to join the SQLC meetings as well. SQLC was a potential solution to the call for the CLI, which was being led by DEC.

The new SQLC "gang of four", MS, Lotus, DEC and Sybase, brought an updated version of SQLC to the next SAG meeting in June 1990.[7] The SAG responded by opening the standard effort to any competing design, but of the many proposals, only Oracle Corp had a system that presented serious competition. In the end, SQLC won the votes and became the draft standard, but only after large portions of the API were removed - the standards document was trimmed from 120 pages to 50 during this time. It was also during this period that the name Call Level Interface was formally adopted.[7] In 1995 SQL/CLI became part of the international SQL standard, ISO/IEC 9075-3.[8] The SAG itself was taken over by the X/Open group in 1996, and, over time, became part of The Open Group's Common Application Environment.

MS continued working with the original SQLC standard, retaining many of the advanced features that were removed from the CLI version. These included features like scrollable cursors, and metadata information queries. The commands in the API were split into groups; the Core group was identical to the CLI, the Level 1 extensions were commands that would be easy to implement in drivers, while Level 2 commands contained the more advanced features like cursors. A proposed standard was released in December 1991, and industry input was gathered and worked into the system through 1992, resulting in yet another name change to **ODBC**.[9]

JET and ODBC

During this time, Microsoft was in the midst of developing their Jet database system. Jet combined three primary subsystems; an ISAM-based database engine (also known as "Jet", confusingly), a C-based interface allowing applications to access that data, and a selection of driver DLLs that allowed the same C interface to redirect input and output to other ISAM-based databases, like Paradox and xBase. Jet allowed programmers to use a single set of calls to access common microcomputer databases in a fashion similar to Blueprint (by this point known as DataLens). However, Jet did not use SQL; like DataLens, the interface was in C and consisted of data structures and function calls.

The SAG standardization efforts presented an opportunity for Microsoft to adapt their Jet system to the new CLI standard. This would not only make Windows a premier platform for CLI development, but also allow users to use SQL to access both Jet and other databases as well. What was missing was the SQL parser that could convert those calls from their text form into the C-interface used in Jet. To solve this, MS partnered with PageAhead Software to use their existing query processor, "SIMBA". SIMBA was used as a parser above Jet's C library, turning Jet into an SQL database. And because Jet could forward those C-based calls to other databases, this also allowed SIMBA to query other systems. Microsoft included drivers for Excel to turn its spreadsheet documents into SQL-accessible database tables.

Release and continued development

ODBC 1.0 was released in September 1992. At the time, there was little direct support for SQL databases (as opposed to ISAM), and early drivers were noted for poor performance. Some of this was unavoidable due to the path that the calls took through the Jet-based stack; ODBC calls to SQL databases were first converted from SIMBA's SQL dialect to Jet's internal C-based format, then passed to a driver for conversion back into SQL calls for the database. Digital Equipment and Oracle both contracted Simba to develop drivers for their databases as well.[10]

Circa 1993, OpenLink Software shipped one of the first independently developed third-party ODBC drivers, for the PROGRESS DBMS, and soon followed with their UDBC (a cross-platform API equivalent of ODBC and the SAG/CLI) SDK and associated drivers for PROGRESS, Sybase, Oracle, and other DBMS, for use on Unix-like OS (AIX, HP-UX, Solaris, Linux, etc.), VMS, Windows NT, OS/2, and other OS.

Meanwhile the CLI standard effort dragged on, and it was not until March 1995 that the definitive version was finalized. By this time Microsoft had already granted Visigenic Software a source code license to develop ODBC on non-Windows platforms. Visigenic ported ODBC to a wide variety of Unix platforms, where ODBC quickly became the de facto standard.[11] "Real" CLI is rare today. The two systems remain similar, and many applications can be ported from ODBC to CLI with few or no changes.[12]

Over time, database vendors took over the driver interfaces and provided direct links to their products. Skipping the intermediate conversions to and from Jet or similar wrappers often resulted in higher performance. However, by this time Microsoft had changed focus to their OLE DB concept, which provided direct access to a wider variety of data sources from address books to text files. Several new systems followed which further turned their attention from ODBC, including DAO, ADO and ADO.net, which interacted more or less with ODBC over their lifetimes.

As Microsoft turned its attention away from working directly on ODBC, the Unix world was increasingly embracing it. This was propelled by two changes within the market, the introduction of GUIs like GNOME that provided the need for access to these sources in non-text form, and the emergence of open software database systems like PostgreSQL and MySQL, initially under Unix. The later adoption of ODBC by Apple for using the standard Unix-side iODBC package Mac OS X 10.2 (Jaguar) (which OpenLink Software had been independently providing for Mac OS X 10.0 and even Mac OS 9 since 2001) further cemented ODBC as the standard for cross-platform data access.

Sun Microsystems used the ODBC system as the basis for their own open standard, JDBC. In most ways, JDBC can be considered a version of ODBC for the Java programming language as opposed to C. JDBC-to-ODBC "bridges" allow Java-based programs to access data sources through ODBC drivers on platforms lacking a native JDBC driver, although these are now relatively rare. Inversely, ODBC-to-JDBC "bridges" allow C-based programs to access data sources through JDBC drivers on platforms or from databases lacking suitable ODBC drivers.

ODBC today

ODBC remains largely universal today, with drivers available for most platforms and most databases. It is not uncommon to find ODBC drivers for database engines that are meant to be embedded, like SQLite, as a way to allow existing tools to act as front-ends to these engines for testing and debugging.[13]

However, the rise of thin client computing using HTML as an intermediate format has reduced the need for ODBC. Many web development platforms contain direct links to target databases - MySQL being particularly common. In these scenarios, there is no direct client-side access nor multiple client software systems to support; everything goes through the programmer-supplied HTML application. The virtualization that ODBC offers is no longer a strong requirement, and development of ODBC is no longer as active as it once was.

Version history

Version history:

- 1.0: released in September 1992
- 2.0: ca 1994
- 2.5
- 3.0: ca 1995, John Goodson of Intersolv and Frank Pellow and Paul Cotton of IBM provided significant input to ODBC 3.0[14]
- 3.5: ca 1997
- 3.8: ca 2009, with Windows 7

Drivers and Managers

Drivers

ODBC is based on the device driver model, where the driver encapsulates the logic needed to convert a standard set of commands and functions into the specific calls required by the underlying system. For instance, a printer driver presents a standard set of printing commands, the API, to applications using the printing system. Calls made to those APIs are converted by the driver into the format used by the actual hardware, say PostScript or PCL.

In the case of ODBC, the drivers encapsulate a number of functions that can be broken down into several broad categories. One set of functions is primarily concerned with finding, connecting to and disconnecting from the DBMS that driver talks to. A second set is used to send SQL commands from the ODBC system to the DBMS, converting or interpreting any commands that are not supported internally. For instance, a DBMS that does not support cursors can emulate this functionality in the driver. Finally, another set of commands, mostly used internally, is used to convert data from the DBMS's internal formats to a set of standardized ODBC formats, which are based on the C language formats.

An ODBC driver enables an ODBC-compliant application to use a *data source*, normally a DBMS. Some non-DBMS drivers exist, for such data sources as CSV files, by implementing a small DBMS inside the driver itself. ODBC drivers exist for most DBMSs, including Oracle, PostgreSQL, MySQL, Microsoft SQL Server (but not for the Compact aka CE edition), Sybase ASE, and DB2. Because different technologies have different capabilities, most ODBC drivers do not implement all functionality defined in the ODBC standard. Some drivers offer extra functionality not defined by the standard.

Driver Manager

Device drivers are normally enumerated, set up and managed by a separate Manager layer, which may provide additional functionality. For instance, printing systems often include functionality to provide spooling functionality on top of the drivers, providing print spooling for any supported printer.

In ODBC the Driver Manager (DM) provides these features. The DM can enumerate the installed drivers and present this as a list, often in a GUI-based form.

But more important to the operation of the ODBC system is the DM's concept of **Data Source Name**s, or **DSN**. DSNs collect additional information needed to connect to a *particular* data source, as opposed to the DBMS itself. For instance, the same MySQL driver can be used to connect to any MySQL server, but the connection information to connect to a local private server is different from the information needed to connect to an internet-hosted public server. The DSN stores this information in a standardized format, and the DM provides this to the driver during connection requests. The DM also includes functionality to present a list of DSNs using human readable names, and to select them at run-time to connect to different resources.

The DM also includes the ability to save partially complete DSN's, with code and logic to ask the user for any missing information at runtime. For instance, a DSN can be created without a required password. When an ODBC application attempts to connect to the DBMS using this DSN, the system will pause and ask the user to provide the password before continuing. This frees the application developer from having to create this sort of code, as well as having to know which questions to ask. All of this is included in the driver and the DSNs.

Bridging configurations

A *bridge* is a special kind of driver: a driver that uses another driver-based technology.

ODBC-to-JDBC (or simply ODBC-JDBC) bridges

An ODBC-JDBC bridge consists of an **ODBC** driver which uses the services of a JDBC driver to connect to a database. This driver translates ODBC function-calls into JDBC method-calls. Programmers usually use such a bridge when they lack an ODBC driver for a particular database but have access to a JDBC driver.

JDBC-to-ODBC (or simply JDBC-ODBC) bridges

A JDBC-ODBC bridge consists of a JDBC driver which employs an ODBC driver to connect to a target database. This driver translates JDBC method calls into ODBC function calls. Programmers usually use such a bridge when a particular database lacks a JDBC driver. Sun Microsystems included one such bridge in the JVM, but viewed it as a stop-gap measure while few JDBC drivers existed. Sun never intended its bridge for production environments, and generally recommended against its use. As of 2008[15] independent data-access vendors deliver JDBC-ODBC bridges which support current standards for both mechanisms, and which far outperform the JVM built-in.[*citation needed*]

OLE DB-to-ODBC bridges

An OLE DB-ODBC bridge consists of an OLE DB Provider which uses the services of an ODBC driver to connect to a target database. This provider translates OLE DB method calls into ODBC function calls. Programmers usually use such a bridge when a particular database lacks an OLE DB provider. Microsoft ships one, MSDASQL.DLL, as part of the MDAC system component bundle, together with other database drivers, to simplify development in COM-aware languages (e.g. Visual Basic). Third parties have also developed such, notably OpenLink Software whose 64-bit OLE DB Provider for ODBC Data Sources filled the gap when Microsoft initially deprecated this bridge for their 64-bit OS.[15] (Microsoft later relented, and 64-bit Windows starting with Windows Server 2008 and Windows Vista SP1 have shipped with a 64-bit version of MSDASQL.)

ADO.NET-to-ODBC bridges

An ADO.NET-ODBC bridge consists of an ADO.NET Provider which uses the services of an OBDC driver to connect to a target database. This provider translates ADO.NET method calls into ODBC function calls. Programmers usually use such a bridge when a particular database lacks an ADO.NET provider. Microsoft ships one as part of the MDAC system component bundle, together with other database drivers, to simplify development in C#. Third parties have also developed such.

OLE DB provider

An **OLE DB provider** is a software component enabling an OLE DB consumer to interact with a data source. OLE DB providers are analogous to ODBC drivers, JDBC drivers, and ADO.NET data providers.

OLE DB providers can be created to access such simple data stores as a text file and spreadsheet, through to such complex databases as Oracle, Microsoft SQL Server, Sybase ASE, and many others. It can also provide access to hierarchical data stores such as email systems.

However, because different data store technologies can have different capabilities, every OLE DB provider cannot implement every possible interface available in the OLE DB standard. The capabilities that are available are implemented through the use of COM objects; an OLE DB provider will map the data store technologies functionality to a particular COM interface. Microsoft describes the availability of an interface as "provider-specific," as it may not be applicable depending on the data store technology involved. Note also that providers may augment the capabilities of a data store; these capabilities are known as *services* in Microsoft parlance.

OLE DB providers

- SQLSummit.com: Catalogue of OLE DB Providers [1]
- Microsoft [2] ships a few OLE DB Providers as part of its MDAC and JET kits
- Simba Technologies ships SimbaProvider, an SDK used to build custom OLE DB for OLAP providers for multi-dimensional and star schema database connectivity.
- OpenLink Software ships components supporting OLE DB access [3] to a number of data sources, including several SQL DBMS, as well as Bridges to ODBC- and JDBC-accessible data sources
- OLE DB Provider for Interbase and Firebird (supports 14 database types, free and pro versions are available) [4]
- OLE DB Provider for PostgreSQL [5]

OLE DB

OLE DB (*Object Linking and Embedding, Database*, sometimes written as **OLEDB** or **OLE-DB**), an API designed by Microsoft, allows accessing data from a variety of sources in a uniform manner. The API provides a set of interfaces implemented using the Component Object Model (COM); it is otherwise unrelated to OLE. Microsoft originally intended OLE DB as a higher-level replacement for, and successor to, ODBC, extending its feature set to support a wider variety of non-relational databases, such as object databases and spreadsheets that do not necessarily implement SQL.

Methodology

OLE DB separates the data store from the application that needs access to it through a set of abstractions that include the datasource, session, command, and rowsets. This was done because different applications need access to different types and sources of data, and do not necessarily want to know how to access functionality with technology-specific methods. OLE DB is conceptually divided into *consumers* and *providers*. The consumers are the applications that need access to the data, and the providers are the software components that implement the interface and thereby provides the data to the consumer. OLE DB is part of the Microsoft Data Access Components (MDAC) stack.

Support status

Microsoft's release of SQL Server 2012 (internal code: 'Denali') is the last to include an OLE DB provider for SQL Server, but support will continue for 7 years.[1] According to a related Microsoft FAQ,[2] "Providers like ADO.Net which can run on top of OLE DB will not support OLE DB once the latter is deprecated", but the same answer in the FAQ states that the original post relates only to the OLE DB provider for SQL Server, so the position of OLE DB itself remains unclear. The same FAQ states that ODBC performs better than OLE DB in most cases.

UnixODBC

unixODBC

Stable release	2.3.2 / October 8, 2013
Operating system	Cross-platform
Type	Data Access API
License	GNU GPL/LGPL
Website	www.unixODBC.org [1]

unixODBC is an open source project that implements the ODBC API. The code is provided under the GNU GPL/LGPL license and can be built and used on many different operating systems, including most versions of Unix, Linux, Mac OS X, IBM OS/2 and Microsoft's Interix.

The goals of the project include:

- Provide developers with the tools to port Microsoft Windows ODBC applications to other platforms with the minimum of code changes.
- Maintain the project as a vendor neutral interface database SDK
- Provide people who write ODBC drivers the tools to port their drivers to non Windows platforms
- Provide the user with a set of GUI and command line tools for managing their database access
- Maintain links with both the free software community and commercial database vendors, to ensure interoperability

History

1999

The unixODBC project was first started in the early months of 1999 (by Peter Harvey) and was created as at that time the developers of iODBC (another open source ODBC implementation) were not then willing to LGPL the code, expand the API to include the current ODBC 3 API specification, and did not consider the addition of GUI based configuration tools worthwhile. iODBC now has these parts added, and applications that use the ODBC interface may use both iODBC and unixODBC, without change in most cases, as a result of both projects adhering to the single ODBC specification.

1999 July

The original driver manager was very basic. The driver manager was rewritten by Easysoft's [2] Nick Gorham soon after the project started. Nick assumed leadership of the project in July 1999 with Peter Harvey continuing work on supporting code.

The development of unixODBC progressed since its origin, with contributions from many developers, both in the open source community and also from commercial database companies, including IBM, Oracle Corporation and SAP.

It is included as part of the standard installation of many Linux distributions.

2009

The unixODBC project was split into several projects (all hosted on SourceForge);

- unixODBC [3] ("Core" and "Dev" bits)
- unixODBC-GUI-Qt [4] (Qt based GUI bits)
- unixODBC-Test [5] (multiple test frameworks)

This split was done to allow faster releases of supporting work while maintaining focus on stability and consistency for the core code.

IODBC

iODBC

Stable release	3.52.7 / September 10, 2009
Operating system	Cross-platform
Type	Data Access API
License	BSD, LGPL
Website	www.iodbc.org [1]

iODBC is an open source initiative managed by OpenLink Software. It is a platform-independent ODBC SDK and runtime offering that enables the development of ODBC-compliant applications and drivers outside the Windows platform. The prime goals of this project are as follows:

- Simplify the effort of porting ODBC applications from Windows to other platforms
- Simplify the effort of porting ODBC drivers from Windows to other platforms
- Create consistent ODBC-utilization experience across all platforms

History

iODBC emerged from a cooperative effort between OpenLink Software and Ke Jin. OpenLink Software produced a Driver Manager-less ODBC SDK that it branded as Universal DataBase Connectivity (UDBC) in 1993, because of the sporadic nature of shared library implementations across Unix platforms. Ke Jin used UDBC as inspiration for building a Driver Manager for ODBC outside the windows platform.

Over time Ke Jin and OpenLink Software decided to merge this effort into a single Open Source offering under the LGPL license.

This process occurred at a time when the Free Software Foundation sought to have iODBC as a GPL offering. The delay in determining final licensing status for iODBC led to the emergence of UnixODBC and led to a fork in the platform-independent ODBC SDK and runtime that exists today. Drivers and applications written using either SDK have remained compatible (a tribute to both projects).

Pool (computer science)

A **pool** in computer science is a set of initialised resources that are kept ready to use, rather than allocated and destroyed on demand. A client of the pool will request an object from the pool and perform operations on the returned object. When the client has finished with an object (or resource), it returns it to the pool, rather than destroying it.

Pooling of resources can offer a significant performance boost in situations where the cost of initializing a class instance is high, the rate of instantiation of a class is high, and the number of instances in use at any one time is low. The pooled resource is obtained in predictable time when creation of the new objects (especially over network) may take variable time.

However these benefits are mostly true for objects which are expensive with respect to time, such as database connections, socket connections, threads and large graphic objects like fonts or bitmaps. In certain situations, simple object pooling (which hold no external resources, but only occupy memory) may not be efficient and could decrease performance.

Special cases are:

- Connection pool
- Thread pool
- Memory pool

Pool can also refer to a design pattern for implementing them in object-oriented languages, such as the object pool pattern.

References

Connection pool

In software engineering, a **connection pool** is a cache of database connections maintained so that the connections can be reused when future requests to the database are required. Connection pools are used to enhance the performance of executing commands on a database. Opening and maintaining a database connection for each user, especially requests made to a dynamic database-driven website application, is costly and wastes resources. In connection pooling, after a connection is created, it is placed in the pool and it is used over again so that a new connection does not have to be established. If all the connections are being used, a new connection is made and is added to the pool. Connection pooling also cuts down on the amount of time a user must wait to establish a connection to the database.

Applications

Connection pooling is used in web-based and enterprise applications and is handled by the application server. Dynamic web pages without connection pooling open connections to database services when they are needed and close them when the page is done servicing a particular request. Pages that use connection pooling instead maintain open connections in a pool. When the page requires access to the database, it simply uses an existing connection from the pool, and establishes a new connection only if no pooled connections are available. This reduces the overhead associated with connecting to the database to service individual requests.

Local applications that need frequent access to databases can also benefit from connection pooling. Open connections can be maintained in local applications that don't need to service separate remote requests like application servers, but implementations of connection pooling can be complicated. There are a number of libraries available that implement connection pooling and related SQL query pooling, simplifying implementation of connection pools in database-intensive applications.

Connection pools can be configured with restrictions on the numbers of minimum connections, maximum connections and idle connections to optimize the performance of pooling in specific problem contexts and environments.

Database support

Connection pooling is supported by IBM DB2,[1] Microsoft SQL Server,[2] Oracle,[3] MySQL,[4] and PostgreSQL.[5]

Remote Database Access

Remote database access (RDA) is a protocol standard for database access.

Purpose

RDA describes the connection of a database client to a database server. It includes features for

- communicating database operations and parameters from the client to the server,
- in return, transporting result data from the server to the client,
- database transaction management.
- exchange of information.

RDA is an application-level protocol, inasmuch that it builds on an existing network connection between client and server. In the case of TCP/IP connections, RFC 1066 is used for implementing RDA.

History

RDA was published in 1993, as a combined standard of ANSI, ISO and IEC. The standards definition comprises two parts:

- ANSI/ISO/IEC 9579-1:1993
- ANSI/ISO/IEC 9579-2:1993

SQLJ

SQLJ is an outdated working title for efforts to combine Java and SQL. It was a common effort started around 1997 by engineers from IBM, Oracle, Compaq, Informix, Sybase, Cloudscape and Sun Microsystems.

It consists of the three parts: 0, 1 and 2. Part 0 describes the embedding of SQL statements into Java programs. SQLJ part 0 is the basis for part 10 of the SQL:1999 standard, aka SQL Object Language Bindings (SQL/OLB). SQLJ parts 1 and 2 describes the converse possibility to use Java classes (routines and types) from SQL statements. Parts 1 and 2 are the basis for part 13 of the SQL standard, SQL Routines and Types Using the Java Programming Language (SQL/JRT).

"SQLJ" is commonly used to refer to just SQLJ part 0, usually when it is contrasted with other means of embedding SQL in Java, like JDBC.

ANSI and ISO standards

- SQLJ part 0: ANSI X3.135.10-1998, "Database Language SQL—Part 10: Object Language Bindings (SQL/OLB)"
- SQLJ part 1: ANSI NCITS 331.1-1999, "SQLJ—Part 1: SQL Routines Using the Java Programming Language"
- SQLJ part 2: ANSI NCITS 331.2-2000, "SQLJ—Part 2: SQL Types Using the Java Programming Language"

Part 0 was updated for JDBC 2.0 compatibility and ratified by ISO in 2000. The last two parts were combined when submitted to ISO. Part 2 was substantially rewritten for the ISO submission because the ANSI version was not formal enough for a specification, being closer to the style of a user manual. The combined version was ratified in 2002.

- ISO/IEC 9075-10:2000, *Information technology—Database languages—SQL—Part 10: Object Language Bindings (SQL/OLB)*
- ISO/IEC 9075-13:2002, *Information technology—Database languages—SQL—Part 13: SQL Routines and Types Using the Java Programming Language (SQL/JRT)*.

SQLJ part 0

The SQLJ part 0 specification largely originated from Oracle, who also provided the first reference implementation.

In the following SQLJ is a synonym for SQLJ part 0.

Whereas JDBC provides an API, SQLJ consists of a language extension. Thus programs containing SQLJ must be run through a preprocessor (the SQLJ translator) before they can be compiled.

Advantages and disadvantages

Some advantages of SQLJ over JDBC include:

- SQLJ commands tend to be shorter than equivalent JDBC programs.
- SQL syntax can be checked at compile time. The returned query results can also be checked strictly.
- Preprocessor might generate static SQL which performs better than dynamic SQL because query plan is created on program compile time, stored in database and reused at runtime. Static SQL can guarantee access plan stability. IBM DB2 supports static SQL use in SQLJ programs.

Disadvantages include:

- SQLJ requires a preprocessing step.
- Many IDEs do not have SQLJ support.
- SQLJ lacks support for most of the common persistence frameworks, such as Hibernate.

Examples

The following examples compare SQLJ syntax with JDBC usage.

Multi-row query

JDBC

```
 size="7.22">
iredStatement stmt = conn.prepareStatement(
ELECT LASTNAME"
, FIRSTNME"
, SALARY"
FROM DSN8710.EMP"
WHERE SALARY BETWEEN ? AND ?");
setBigDecimal(1, min);
setBigDecimal(2, max);
tSet rs = stmt.executeQuery();
 (rs.next()) {
tname = rs.getString(1);
rstname = rs.getString(2);
ary = rs.getBigDecimal(3);
Print row...

ose();
close();
t>
```

SQLJ

```
<font size="7.22">
#sql private static iterator EmployeeIterator(String, Str
BigDecimal);
...
EmployeeIterator iter;
#sql [ctx] iter = {
  SELECT LASTNAME
       , FIRSTNME
       , SALARY
    FROM DSN8710.EMP
   WHERE SALARY BETWEEN :min AND :max
};
do {
  #sql {
    FETCH :iter
     INTO :lastname, :firstname, :salary
  };
  // Print row...
} while (!iter.endFetch());
iter.close();
</font>
```

Single-row query

JDBC

```
PreparedStatement stmt = conn.prepareStatement(
    "SELECT MAX(SALARY), AVG(SALARY)"
  + " FROM DSN8710.EMP");
rs = stmt.executeQuery();
if (!rs.next()) {
  // Error—no rows found
}
maxSalary = rs.getBigDecimal(1);
avgSalary = rs.getBigDecimal(2);
if (rs.next()) {
  // Error—more than one row found
}
rs.close();
stmt.close();
```

SQLJ

```
#sql [ctx] {
  SELECT MAX(SALARY), AVG(SALARY)
    INTO :maxSalary, :avgSalary
    FROM DSN8710.EMP
};
```

INSERT

JDBC

```
16">
epareStatement(
O DSN8710.EMP " +
RSTNME, MIDINIT, LASTNAME, HIREDATE, SALARY) "
 ?, ?, ?, CURRENT DATE, ?)");
(1, empno);
(2, firstname);
(3, midinit);
(4, lastname);
imal(5, salary);
date();
```

SQLJ

```
<font size="6.16">
#sql [ctx] {
  INSERT INTO DSN8710.EMP
    (EMPNO,  FIRSTNME,  MIDINIT,  LASTNAME,  HIREDATI
  VALUES
    (:empno, :firstname, :midinit, :lastname, CURRENT
};
</font>
```

Native Queries

Native Queries are a concise and type-safe way to express queries directly as Java and C# methods.

Native Queries are based on Safe Queries by Cook and Rai and were first[*citation needed*] implemented in db4o's open source object database as well as POJQ on Java.net.

Products

- db4o [1] - database for objects
- JODB [2] - Java Objects Database
- pojq [3] - Plain Old Java Queries
- NeoDatis [4] - NeoDatis ODB

Meta-SQL

'**Meta-SQL**' Use (with reference to PeopleSoft)

Meta-SQL expands to platform-specific SQL substrings, causes another function to be called, or substitutes a value. Meta-SQL constructs are used in functions that pass SQL strings, such as the following:

- SQLExec.
- Scroll buffer functions (ScrollSelect and its relatives)
- PeopleSoft Application Designer dynamic and SQL views
- Some Rowset class methods (Select, SelectNew, Fill, and so on.)
- The SQL class
- PeopleSoft Application Engine programs
- Some Record class methods (Insert, Update, and so on.)
    - COBOL functions

Meta-SQL Element

Types There are three types of meta-SQL elements:

- Constructs are a direct substitution of a value, and help to build or modify a SQL statement. Examples include %Bind, %InsertSelect, and %List.
- Functions perform actions or cause another function to be called. Examples include %ClearCursor, %Execute, and %ExecuteEdits.
- Meta-variables enable substitution of text within SQL statements. Examples include %AsOfDate, %Comma, and %JobInstance.

Meta-SQL Placement Considerations: Not all meta-SQL can be used by all programs. Some meta-SQL can be used only in Application Engine programs. Other meta-SQL can only be used as part of a SQL statement in a SQL or dynamic view. The following table lists available meta-SQL elements and where each element can be used.

If a meta-SQL construct, function, or meta-variable is supported in PeopleCode, it is supported in all types of PeopleCode programs; that is, in Application Engine PeopleCode programs (actions), component interface PeopleCode programs, and so on.

Note: Even if a meta-SQL element is used in PeopleCode, you cannot use meta-SQL like a built-in function. You can use meta-SQL in the SQLExec function, the Select method, the Fill method, and so on. Note: Meta-SQL is not available in SQR

ADO.NET

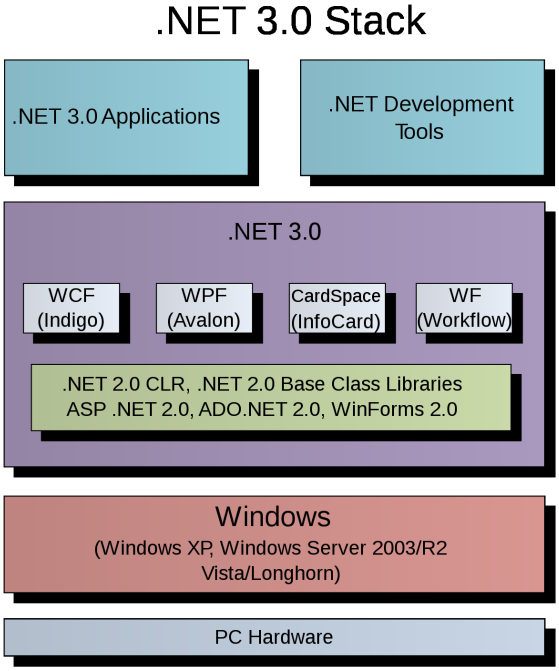
ADO.NET

Operating system	Microsoft Windows
Type	Software framework
License	MS-EULA, BCL under Microsoft Reference License
Website	ADO.NET Overview on MSDN [1]

ADO.NET is a set of computer software components that programmers can use to access data and data services based on disconnected DataSets and XML. It is a part of the base class library that is included with the Microsoft .NET Framework. It is commonly used by programmers to access and modify data stored in relational database systems, though it can also access data in non-relational sources. ADO.NET is sometimes considered an evolution of ActiveX Data Objects (ADO) technology, but was changed so extensively that it can be considered an entirely new product.

Architecture

ADO.NET is conceptually divided into *consumers* and *data providers*. The consumers are the applications that need access to the data, and the providers are the software components that implement the interface and thereby provide the data to the consumer.



This technology forms a Batata part of .NET Framework 3.0 (having been part of the framework since version 1.0)

ADO.NET and Visual Studio

Functionality exists in Visual Studio IDE to create specialized subclasses of the DataSet classes for a particular database schema, allowing convenient access to each field through strongly typed properties. This helps catch more programming errors at compile-time and enhances the IDE's Intellisense feature.

ADO.NET and O/R Mapping

Entity Framework

The **ADO.NET Entity Framework** is a set of data-access APIs for the Microsoft .NET Framework, similar to the Java Persistence API, targeting the version of ADO.NET that ships with .NET Framework 4.0. ADO.NET Entity Framework is included with .NET Framework 4.0 and Visual Studio 2010, released in April 2010. An Entity Framework *Entity* is an object which has a key representing the primary key of a logical datastore entity. A conceptual *Entity Data Model* (Entity-relationship model) is mapped to a datastore schema model. Using the Entity Data Model, the Entity Framework allows data to be treated as entities independently of their underlying datastore representations.

Entity SQL, a SQL-like language, serves for querying the Entity Data Model (instead of the underlying datastore). Similarly, LINQ extension *LINQ to Entities* provides typed querying on the Entity Data Model. Entity SQL and LINQ to Entities queries are converted internally into a *Canonical Query Tree* which is then converted into a query understandable to the underlying database.

Software and Tools

List of relational database management systems

This is a **list of relational database management systems**.

List of Software

- 4th Dimension
- Adabas D
- Alpha Five
- Apache Cassandra
- Apache Derby
- Aster Data
- Altibase
- BlackRay
- CA-Datacom
- Clarion
- Clustrix
- CSQL
- CUBRID
- Daffodil database
- DataEase
- Database Management Library
- Dataphor
- dBase
- Derby aka Java DB
- Empress Embedded Database
- EXASolution
- EnterpriseDB
- eXtremeDB
- FileMaker Pro
- Firebird
- Greenplum
- GroveSite
- H2
- Helix database
- HSQLDB
- IBM DB2
- IBM Lotus Approach
- IBM DB2 Express-C
- Infobright
- Informix
- Ingres
- InterBase

- InterSystems Caché
- GT.M
- Linter
- MariaDB
- MaxDB
- MemSQL
- Microsoft Access
- Microsoft Jet Database Engine (part of Microsoft Access)
- Microsoft SQL Server
- Microsoft SQL Server Express
- Microsoft Visual FoxPro
- Mimer SQL
- MonetDB
- MongoDB
- mSQL
- MySQL
- Netezza
- NexusDB
- NonStop SQL
- NoSQL
- Openbase
- OpenLink Virtuoso (Open Source Edition)
- OpenLink Virtuoso Universal Server
- OpenOffice.org Base
- Oracle
- Oracle Rdb for OpenVMS
- Panorama
- Pervasive PSQL
- Polyhedra
- PostgreSQL
- Postgres Plus Advanced Server
- Progress Software
- RDM Embedded
- RDM Server
- The SAS system
- SAND CDBMS
- SAP HANA
- SAP Sybase Adaptive Server Enterprise
- SAP Sybase IQ
- SQL Anywhere (formerly known as Sybase Adaptive Server Anywhere and Watcom SQL)
- ScimoreDB
- SmallSQL
- solidDB
- SQLBase
- SQLite
- Sybase Advantage Database Server
- Teradata

- TimesTen
- txtSQL
- mizanSQL
- Unisys RDMS 2200
- UniData
- UniVerse
- Vectorwise
- Vertica
- VMDS

Historical

- Britton Lee IDMs
- Cornerstone
- IBM System R
- MICRO Information Management System
- Oracle Rdb
- Paradox
- Pick
- PRTV
- QBE
- IBM SQL/DS
- Sybase SQL Server

Relational by the Date-Darwen-Pascal Model

Current

- Alphora Dataphor (a proprietary virtual, federated DBMS and RAD MS .Net IDE).
- Rel (free Java implementation).

Obsolete

- IBM Business System 12
- IBM IS1
- IBM PRTV (ISBL)
- Multics Relational Data Store

Comparison of relational database management systems

The following tables compare general and technical information for a number of relational database management systems. Please see the individual products' articles for further information. Unless otherwise specified in footnotes, comparisons are based on the stable versions without any add-ons, extensions or external programs.

General information

	Maintainer	First public release date	Latest stable version	Latest release date	Software license
4D (4th Dimension)	4D S.A.S.	1984	v13.2	2012-11-12	Proprietary

RDM Server	Yes	Yes	Yes	Yes	SQL & API
ScimoreDB	Yes	Yes	Yes	Partial	SQL
SQL Anywhere	Yes	Yes	Yes	Yes	SQL
SQLBase	Yes	Yes	Yes	Yes	API & GUI & SQL
SQLite	Yes	Yes	Yes	Optional[5]	API & SQL
Teradata	Yes	Yes	Yes	Yes	SQL
UniData	Yes	No	Yes	Yes	Multiple
UniVerse	Yes	No	Yes	Yes	Multiple
Xeround Cloud Database	Yes	No	Yes	Yes	SQL
	ACID	**Referential integrity**	**Transactions**	**Unicode**	**Interface**

Note (1): Currently only supports read uncommited transaction isolation. Version 1.9 adds serializable isolation and version 2.0 will be fully ACID compliant.

Note (2): MySQL provides ACID compliance through the default InnoDB storage engine.

Note (3): "For other [than InnoDB] storage engines, MySQL Server parses and ignores the FOREIGN KEY and REFERENCES syntax in CREATE TABLE statements. The CHECK clause is parsed but ignored by all storage engines."

Note (4): Support for Unicode is new in version 10.0.

Note (5): MySQL provides GUI interface through MySQL Workbench.

Note (6): Pervasive PSQL provides UTF-8 storage.

Limits

Information about data size limits.

	Max DB size	Max table size	Max row size	Max columns per row	Max Blob/Clob size	Max CHAR size	Max NUMBER size	Min DATE value	Max DATE value	Max column name size

Teradata	Unlimited	Unlimited	64 KB wo/lobs (64 GB w/lobs)	2,048	2 GB	10,000	64 bits	?	9999-12-31 Select 80991231 (date);	30
UniVerse	Unlimited	Unlimited	Unlimited	Unlimited	Unlimited	Unlimited	Unlimited	Unlimited	Unlimited	Unlimited
Xeround Cloud Database	Unlimited	Unlimited	32 GB, depending on available memory	1,000	4 GB	64 KB	64 bits	1000	9999	64
	Max DB size	**Max table size**	**Max row size**	**Max columns per row**	**Max Blob/Clob size**	**Max CHAR size**	**Max NUMBER size**	**Min DATE value**	**Max DATE value**	**Max column name size**

Note (1): Firebird 2.x maximum database size is effectively unlimited with the largest known database size >980 GB. Firebird 1.5.x maximum database size: 32 TB.

Note (2): Limit is 10^{38} using `DECIMAL` datatype.

Note (3): InnoDB is limited to 8,000 bytes (excluding `VARBINARY`, `VARCHAR`, `BLOB`, or `TEXT` columns).

Note (4): InnoDB is limited to 1,000 columns.

Note (6): Using `VARCHAR (MAX)` in SQL 2005 and later.

Note (7): When using a page size of 32 KB, and when BLOB/CLOB data is stored in the database file.

Note (8): Java array size limit of 2,147,483,648 (2^{31}) objects per array applies. This limit applies to number of characters in names, rows per table, columns per table, and characters per `CHAR`/`VARCHAR`.

Note (9): Despite the lack of a date datatype, SQLite does include date and time functions, which work for timestamps between 0000-01-01 00:00:00 and 5352-11-01 10:52:47.

Note (10): Informix DATETIME type has adjustable range from YEAR only through 1/10000th second. DATETIME date range is 0001-01-01 00:00:00.00000 through 9999-12-31 23:59:59.99999.

Note (11): Since version 12c. Earlier versions support up to 4000 B.

Tables and views

Information about what tables and views (other than basic ones) are supported natively.

	Temporary table	Materialized view
4th Dimension	Yes	Planned for inclusion in next major release
ADABAS	*?*	*?*
Adaptive Server Enterprise	Yes[1]	Yes - see precomputed result sets
Advantage Database Server	Yes	No (only common views)

SQL Anywhere	Yes	Yes
ScimoreDB	No	No
SQLite	Yes	No
Teradata	Yes	Yes
UniData	Yes	No
UniVerse	Yes	No
Xeround Cloud Database	Yes	No

Note (1): Server provides tempdb, which can be used for public and private (for the session) temp tables.

Note (2): Materialized views are not supported in Informix; the term is used in IBM's documentation to refer to a temporary table created to run the view's query when it is too complex, but one cannot for example define the way it is refreshed or build an index on it. The term is defined in the Informix Performance Guide.

Note (3): Query optimizer support only in Developer and Enterprise Editions. In other versions, a direct reference to materialized view and a query hint are required.

Note (4): Materialized views can be emulated using stored procedures and triggers.

Note (5): Materialized views are now standard but can be emulated in versions prior to 9.3 with stored procedures and triggers using PL/pgSQL, PL/Perl, PL/Python, or other procedural languages.

Indices

Information about what indices (other than basic B-/B+ tree indices) are supported natively.

	R-/R+ tree	**Hash**	**Expression**	**Partial**	**Reverse**	**Bitmap**	**GiST**	**GIN**	**Full-text**	**Spatial**	**FOT**

Note (1): The users need to use a function from freeAdhocUDF library or similar.

Note (2): Can be implemented for most data types using expression-based indexes.

Note (3): Can be emulated by indexing a computed column (doesn't easily update) or by using an "Indexed View" (proper name not just any view works).

Note (4): Can be implemented by using an indexed view.

Note (5): InnoDB automatically generates adaptive hash index entries as needed.

Note (6): Can be implemented using Function-based Indexes in Oracle 8i and higher, but the function needs to be used in the sql for the index to be used.

Note (7): A PostgreSQL functional index can be used to reverse the order of a field.

Note (8): PostgreSQL will likely support on-disk bitmap indexes in a future version. Version 8.2 supports a related technique known as "in-memory bitmap scans".

Note (10): B+ tree and full-text only for now.

Note (11): R-Tree indexing available in base edition with Locator but some functionality requires Personal Edition or Enterprise Edition with Spatial option.

	Data Domain	**Cursor**	**Trigger**	**Function** [1]	**Procedure** [1]	**External routine** [1]

Note (1): Both **function** and **procedure** refer to internal routines written in SQL and/or procedural language like PL/SQL. **External routine** refers to the one written in the host languages, such as C, Java, Cobol, etc. "Stored procedure" is a commonly used term for these routine types. However, its definition varies between different database vendors.

Note (2): In Derby, H2, LucidDB, and CUBRID, users code **functions** and **procedures** in Java.

Note (3): ENUM datatype exist. CHECK clause is parsed, but not enforced in runtime.

Note (4): In Drizzle the user codes **functions** and **procedures** in C++.

Note (5): Informix supports external functions written in Java, C, & C++.

Partitioning

Information about what partitioning methods are supported natively.

SQLite	No (not relevant, only file permissions)	No (not relevant)	No (not relevant)	No (not relevant)	Partial (no security page)	Yes (file access)	Yes	Yes	No	No	*?*

Xeround Cloud Database	Yes (SSL with 4.0)	No	No	No	N/A - database as a service	Yes	No	No	No	No	*?*
	Native network encryption[1]	**Brute-force protection**	**Enterprise directory compatibility**	**Password complexity rules**[2]	**Patch access**[3]	**Run unprivileged**[4]	**Audit**	**Resource limit**	**Separation of duties (RBAC)**[5]	**Security Certification**	**Label Based Access Control (LBAC)**

Note (1): Network traffic could be transmitted in a secure way (not clear-text, in general SSL encryption). Precise if option is default, included option or an extra modules to buy.

Note (2): Options are present to set a minimum size for password, respect complexity like presence of numbers or special characters.

Note (3): How do you get security updates? Is it free access, do you need a login or to pay? Is there easy access through a Web/FTP portal or RSS feed or only through offline access (mail CD-ROM, phone).

Note (4): Does database process run as root/administrator or unprivileged user? What is default configuration?

Note (5): Is there a separate user to manage special operation like backup (only dump/restore permissions), security officer (audit), administrator (add user/create database), etc.? Is it default or optional?

Note (6): Common Criteria certified product list.

Note (7): FirebirdSQL seems to only have SYSDBA user and DB owner. There are no separate roles for backup operator and security administrator.

Note (8): User can define a dedicated backup user but nothing particular in default install.

Note (9): Authentication methods.

Note (10): Informix Dynamic Server supports PAM and other configurable authentication. By default uses OS authentication.

Note (11): Authentication methods.

Note (12): With the use of Pervasive AuditMaster.

Note (13): User-based security is optional in Polyhedra, but when enabled can be enhanced to a role-based model with auditing.

Databases vs schemas (terminology)

The SQL specification makes clear what an "SQL schema" is; however, different databases implement it incorrectly. To compound this confusion the functionality can, when incorrectly implemented, overlap with that of the parent-database. An SQL schema is simply a namespace within a database, things within this namespace are addressed using the member operator dot ".". This seems to be a universal amongst all of the implementations.

A true fully (database, schema, and table) qualified query is exemplified as such: `SELECT * FROM database.schema.table`

Now, the issue, both a schema and a database can be used to isolate one table, "foo" from another like named table "foo". The following is pseudo code:

- `SELECT * FROM db1.foo` vs. `SELECT * FROM db2.foo` (no explicit schema between db and table)
- `SELECT * FROM [db1.]default.foo` vs. `SELECT * FROM [db1.]alternate.foo` (no explicit db prefix)

The problem that arises is that former MySQL users will create multiple databases for one project. In this context, MySQL databases are analogous in function to Postgres-schemas, insomuch as Postgres lacks off-the-shelf

cross-database functionality that MySQL has. Conversely, PostgreSQL has applied more of the specification implementing cross-table, cross-schema, and then left room for future cross-database functionality.

MySQL aliases *schema* with *database* behind the scenes, such that `CREATE SCHEMA` and `CREATE DATABASE` are analogs. It can therefore be said that MySQL has implemented cross-database functionality, skipped schema functionality entirely, and provided similar functionality into their implementation of a database. In summary, Postgres fully supports schemas but lacks some functionality MySQL has with databases, while MySQL does not even attempt to support true schemas.

Oracle has its own spin where creating a user is synonymous with creating a schema. Thus a database administrator can create a user called PROJECT and then create a table PROJECT.TABLE. Users can exist without schema objects, but an object is always associated with an owner (though that owner may not have privileges to connect to the database). With the Oracle 'shared-everything' RAC architecture, the same database can be opened by multiple servers concurrently. This is independent of replication, which can also be used, whereby the data is copied for use by different server. In the Oracle view, the 'database' is a set of files which contains the data while the 'instance' is a set of processes (and memory) through which a database is accessed.

Informix supports multiple databases in a server instance, like MySQL. It supports the CREATE SCHEMA syntax as a way to group DDL statements into a single unit creating all objects created as a part of the schema as a single owner. Informix supports a database mode called ANSI mode which supports creating objects with the same name but owned by different users.

The end result is confusion between the database factions. The Postgres and Oracle communities maintain that one database is all that is needed for one project, per the definition of database. MySQL and Informix proponents maintain that schemas have no legitimate purpose when the functionality can be achieved with databases. Postgres adheres to the SQL specification, in a more intuitive fashion (bottom-up), while MySQL's pragmatic counterargument allows their users to get the job done while creating conceptual confusion.

Features

Legend

- Create/alter table:
  - Yes - can create table, alter its definition and data, and add new rows
  - Some - can only create/alter table definition, not data
- Browse table:
  - Yes - can browse table definition and data
  - Some - can only browse table definition
- Multi-server support:
  - Yes - can manage from the same window/session multiple servers
  - Some - can manage from a different window/session multiple servers
- Monitoring server:
  - Yes - includes a headless server, that runs checks and reports failures

Features - visual design and reverse engineering

Legend:

- Visual schema/E-R design: the ability to draw entity-relationship diagrams for the database. If missing, the following two features will also be missing
- Reverse engineering - the ability to produce an ER diagram from a database, complete with foreign key relationships
  - Yes - supports incremental reverse engineering, preserving user modifications to the diagram and importing only changes from the database
  - Some - can only reverse engineer the entire database at once and drops any user modifications to the diagram (can't "refresh" the diagram to match the database)

- Forward engineering - the ability to update the database schema with changes made to its entities and relationships via the ER diagram visual designer
  - Yes - can update user-selected entities
  - Some - can only update the entire database at once

Comparison of object-relational database management systems

This is a **comparison of object-relational database management systems** (ORDBMSs). Each system has at least some features of an object-relational database; they vary widely in their completeness and the approaches taken.

The following tables compare general and technical information; please see the individual products' articles for further information. Unless otherwise specified in footnotes, comparisons are based on the stable versions without any add-ons, extensions or external programs.

Basic data

Name	Vendor	License	OS	Notes
Adaptive Server Enterprise	SAP	Proprietary	Cross-platform	
CUBRID	NHN Corporation	GPL/BSD	Linux, Windows	
DB2	IBM	Proprietary	Cross-platform

Transactions per second

In a very generic sense, the term **Transactions Per Second** refers to the number of atomic actions performed by certain entity per second. In a more restricted view, the term is usually used by DBMS vendor and user community to refer to the number of database transactions performed per second.

SQL Server

Microsoft SQL Server

Microsoft SQL Server

Developer(s)	Microsoft
Stable release	SQL Server 2012 / April 2012
Development status	Active
Written in	C, C++
Operating system	Microsoft Windows Windows Server
Platform	IA-32, x64 or IA-64 .NET Framework 3.5
Available in	English, Chinese, French, German, Italian, Japanese, Korean, Portuguese (Brazil), Russian and Spanish
Type	Relational database management system
License	Proprietary software; both commercial and freeware editions are available
Website	www.microsoft.com/sqlserver [1]

Microsoft SQL Server is a relational database management system developed by Microsoft. As a database, it is a software product whose primary function is to store and retrieve data as requested by other software applications, be it those on the same computer or those running on another computer across a network (including the Internet). There are at least a dozen different editions of Microsoft SQL Server aimed at different audiences and for workloads ranging from small single-machine applications to large Internet-facing applications with many concurrent users. Its primary query languages are T-SQL and ANSI SQL.

History

Genesis

SQL Server Release History

Version	Year	Release Name	Codename
1.0 (OS/2)	1989	SQL Server 1.0 (16 bit)	-
1.1 (OS/2)	1991	SQL Server 1.1 (16 bit)	-
4.21 (WinNT)	1993	SQL Server 4.21	SQLNT
6.0	1995	SQL Server 6.0	SQL95
6.5	1996	SQL Server 6.5	Hydra
7.0	1998	SQL Server 7.0	Sphinx

-	1999	SQL Server 7.0 OLAP Tools	Palato mania
8.0	2000	SQL Server 2000	Shiloh
8.0	2003	SQL Server 2000 64-bit Edition	Liberty
9.0	2005	SQL Server 2005	Yukon
10.0	2008	SQL Server 2008	Katmai
10.25	2010	SQL Azure DB	CloudDatabase
10.5	2010	SQL Server 2008 R2	Kilimanjaro (aka KJ)
11.0	2012	SQL Server 2012	Denali
12.0	2014	SQL Server 2014	Hekaton

Prior to version 7.0 the code base for MS SQL Server was sold by Sybase SQL Server to Microsoft, and was Microsoft's entry to the enterprise-level database market, competing against Oracle, IBM, and, later, Sybase. Microsoft, Sybase and Ashton-Tate originally worked together to create and market the first version named SQL Server 1.0 for OS/2 (about 1989) which was essentially the same as Sybase SQL Server 3.0 on Unix, VMS, etc. Microsoft SQL Server 4.2 was shipped around 1992 (available bundled with IBM OS/2 version 1.3). Later Microsoft SQL Server 4.21 for Windows NT was released at the same time as Windows NT 3.1. Microsoft SQL Server v6.0 was the first version designed for NT, and did not include any direction from Sybase.

About the time Windows NT was released in July 1993, Sybase and Microsoft parted ways and each pursued its own design and marketing schemes. Microsoft negotiated exclusive rights to all versions of SQL Server written for Microsoft operating systems. (In 1996 Sybase changed the name of its product to Adaptive Server Enterprise to avoid confusion with Microsoft SQL Server.) Until 1994, Microsoft's SQL Server carried three Sybase copyright notices as an indication of its origin.

SQL Server 7.0 and SQL Server 2000 included modifications and extensions to the Sybase code base, adding support for the IA-64 architecture. By SQL Server 2005 the legacy Sybase code had been completely rewritten.[2]

Since the release of SQL Server 2000, advances have been made in performance, the client IDE tools, and several complementary systems that are packaged with SQL Server 2005. These include:

- an extract-transform-load (ETL) tool (SQL Server Integration Services or SSIS)
- a Reporting Server
- an OLAP and data mining server (Analysis Services)
- several messaging technologies, specifically Service Broker and Notification Services

SQL Server 2005

SQL Server 2005 (formerly codenamed "Yukon") released in October 2005. It included native support for managing XML data, in addition to relational data. For this purpose, it defined an `xml` data type that could be used either as a data type in database columns or as literals in queries. XML columns can be associated with XSD schemas; XML data being stored is verified against the schema. XML is converted to an internal binary data type before being stored in the database. Specialized indexing methods were made available for XML data. XML data is queried using XQuery; SQL Server 2005 added some extensions to the T-SQL language to allow embedding XQuery queries in T-SQL. In addition, it also defines a new extension to XQuery, called XML DML, that allows query-based modifications to XML data. SQL Server 2005 also allows a database server to be exposed over web services using Tabular Data Stream (TDS) packets encapsulated within SOAP (protocol) requests. When the data is accessed over web services, results are returned as XML.

Common Language Runtime (CLR) integration was introduced with this version, enabling one to write SQL code as Managed Code by the CLR. For relational data, T-SQL has been augmented with error handling features (try/catch) and support for recursive queries with CTEs (Common Table Expressions). SQL Server 2005 has also been enhanced with new indexing algorithms, syntax and better error recovery systems. Data pages are checksummed for better error resiliency, and optimistic concurrency support has been added for better performance. Permissions and access control have been made more granular and the query processor handles concurrent execution of queries in a more efficient way. Partitions on tables and indexes are supported natively, so scaling out a database onto a cluster is easier. SQL CLR was introduced with SQL Server 2005 to let it integrate with the .NET Framework.

SQL Server 2005 introduced "MARS" (Multiple Active Results Sets), a method of allowing usage of database connections for multiple purposes.[3]

SQL Server 2005 introduced DMVs (Dynamic Management Views), which are specialized views and functions that return server state information that can be used to monitor the health of a server instance, diagnose problems, and tune performance.[4]

Service Pack 1 (SP1) of SQL Server 2005 introduced Database Mirroring,[5] a high availability option that provides redundancy and failover capabilities at the database level. Failover can be performed manually or can be configured for automatic failover. Automatic failover requires a witness partner and an operating mode of synchronous (also known as high-safety or full safety).

SQL Server 2008

SQL Server 2008 (formerly codenamed "Katmai") was released on August 6, 2008[6] and aims to make data management self-tuning, self organizing, and self maintaining with the development of *SQL Server Always On* technologies, to provide near-zero downtime. SQL Server 2008 also includes support for structured and semi-structured data, including digital media formats for pictures, audio, video and other multimedia data. In current versions, such multimedia data can be stored as BLOBs (binary large objects), but they are generic bitstreams. Intrinsic awareness of multimedia data will allow specialized functions to be performed on them. According to Paul Flessner, senior Vice President, Server Applications, Microsoft Corp., SQL Server 2008 can be a data storage backend for *different varieties of data: XML, email, time/calendar, file, document, spatial, etc* as well as perform *search, query, analysis, sharing, and synchronization* across all data types.

Other new data types include specialized date and time types and a *Spatial* data type for location-dependent data. Better support for unstructured and semi-structured data is provided using the new *FILESTREAM* data type, which can be used to reference any file stored on the file system. Structured data and metadata about the file is stored in SQL Server database, whereas the unstructured component is stored in the file system. Such files can be accessed both via Win32 file handling APIs as well as via SQL Server using T-SQL; doing the latter accesses the file data as a BLOB. Backing up and restoring the database backs up or restores the referenced files as well. SQL Server 2008 also natively supports hierarchical data, and includes T-SQL constructs to directly deal with them, without using recursive queries.

The Full-text search functionality has been integrated with the database engine. According to a Microsoft technical article, this simplifies management and improves performance.

Spatial data will be stored in two types. A "Flat Earth" (GEOMETRY or planar) data type represents geospatial data which has been projected from its native, spherical, coordinate system into a plane. A "Round Earth" data type (GEOGRAPHY) uses an ellipsoidal model in which the Earth is defined as a single continuous entity which does not suffer from the singularities such as the international dateline, poles, or map projection zone "edges". Approximately 70 methods are available to represent spatial operations for the Open Geospatial Consortium Simple Features for SQL, Version 1.1.

SQL Server includes better compression features, which also helps in improving scalability. It enhanced the indexing algorithms and introduced the notion of filtered indexes. It also includes *Resource Governor* that allows reserving

resources for certain users or workflows. It also includes capabilities for transparent encryption of data (TDE) as well as compression of backups. SQL Server 2008 supports the ADO.NET Entity Framework and the reporting tools, replication, and data definition will be built around the Entity Data Model. SQL Server Reporting Services will gain charting capabilities from the integration of the data visualization products from Dundas Data Visualization, Inc., which was acquired by Microsoft. On the management side, SQL Server 2008 includes the *Declarative Management Framework* which allows configuring policies and constraints, on the entire database or certain tables, declaratively. The version of SQL Server Management Studio included with SQL Server 2008 supports IntelliSense for SQL queries against a SQL Server 2008 Database Engine. SQL Server 2008 also makes the databases available via Windows PowerShell providers and management functionality available as Cmdlets, so that the server and all the running instances can be managed from Windows PowerShell.

SQL Server 2008 R2

SQL Server 2008 R2 (10.50.1600.1, formerly codenamed "Kilimanjaro") was announced at TechEd 2009, and was released to manufacturing on April 21, 2010. SQL Server 2008 R2 adds certain features to SQL Server 2008 including a master data management system branded as Master Data Services, a central management of master data entities and hierarchies. Also Multi Server Management, a centralized console to manage multiple SQL Server 2008 instances and services including relational databases, Reporting Services, Analysis Services & Integration Services.

SQL Server 2008 R2 includes a number of new services, including PowerPivot for Excel and SharePoint, Master Data Services, StreamInsight, Report Builder 3.0, Reporting Services Add-in for SharePoint, a Data-tier function in Visual Studio that enables packaging of tiered databases as part of an application, and a SQL Server Utility named UC (Utility Control Point), part of AMSM (Application and Multi-Server Management) that is used to manage multiple SQL Servers.

The first SQL Server 2008 R2 service pack (10.50.2500, Service Pack 1) was released on July 11, 2011.

The second SQL Server 2008 R2 service pack (10.50.4000, Service Pack 2) was released on July 26, 2012.

SQL Server 2012

At the 2011 Professional Association for SQL Server (PASS) summit on October 11, Microsoft announced that the next major version of SQL Server (codenamed "Denali"), would be SQL Server 2012. It was released to manufacturing on March 6, 2012. SQL Server 2012 Service Pack 1 was released to manufacturing on November 9, 2012.

It was announced to be the last version to natively support OLE DB and instead to prefer ODBC for native connectivity.

SQL Server 2012's new features and enhancements include AlwaysOn SQL Server Failover Cluster Instances and Availability Groups which provides a set of options to improve database availability, Contained Databases which simplify the moving of databases between instances, new and modified Dynamic Management Views and Functions, programmability enhancements including new spatial features, metadata discovery, sequence objects and the THROW statement, performance enhancements such as ColumnStore Indexes as well as improvements to OnLine and partition level operations and security enhancements including provisioning during setup, new permissions, improved role management, and default schema assignment for groups.

SQL Server 2014

SQL Server 2014 is still in Community Technology Preview stage. As of November, 2013 there have been two such revisions, CTP1 and CTP2.[7] SQL Server 2014 will provide a new in-memory capability for tables that can fit entirely in memory (also known as Hekaton). Whilst small tables may be entirely resident in memory in all versions of SQL Server, they also may reside on disk, so work is involved in reserving RAM, writing evicted pages to disk, loading new pages from disk, locking the pages in ram while they are being operated on, and many other tasks. By treating a table as guaranteed to be entirely resident in memory much of the 'plumbing' of disk-based databases can be avoided.[8]

For disk-based SQL Server applications, it also provides SSD bufferpool extension, which can improve application performance transparently by leveraging SSD as the intermediate memory hierarchy between DRAM and spinning media.

SQL Server 2014 also enhances AlwaysOn (HADR) solution by increasing the readable secondaries count and sustaining read operations upon secondary-primary disconnections, and it provides new hybrid disaster recovery and backup solutions with Windows Azure, enabling customers to use their existing skills with the on-premises product offerings to take advantage of Microsoft's global datacenters. In addition, it takes advantage of new Windows Server 2012 and Windows Server 2012 R2 capabilities for database application scalability in a physical or virtual environment.

Editions

Microsoft makes SQL Server available in multiple editions, with different feature sets and targeting different users. These editions are:

Mainstream editions

Datacenter

> SQL Server 2008 R2 Datacenter is the full-featured edition of SQL Server and is designed for datacenters that need the high levels of application support and scalability. It supports 256 logical processors and virtually unlimited memory. Comes with StreamInsight Premium edition. The Datacenter edition has been retired in SQL Server 2012, all its features are available in SQL Server 2012 Enterprise Edition.[9]

Enterprise

> SQL Server Enterprise Edition includes both the core database engine and add-on services, with a range of tools for creating and managing a SQL Server cluster. It can manage databases as large as 524 petabytes and address 2 terabytes of memory and supports 8 physical processors. SQL Server 2012 Enterprise Edition supports 160 physical processors

Standard

> SQL Server Standard edition includes the core database engine, along with the stand-alone services. It differs from Enterprise edition in that it supports fewer active instances (number of nodes in a cluster) and does not include some high-availability functions such as hot-add memory (allowing memory to be added while the server is still running), and parallel indexes.

Web

> SQL Server Web Edition is a low-TCO option for Web hosting.

Business Intelligence

> Introduced in SQL Server 2012 and focusing on Self Service and Corporate Business Intelligence. It includes the Standard Edition capabilities and Business Intelligence tools: PowerPivot, Power View, the BI Semantic Model, Master Data Services, Data Quality Services and xVelocity in-memory analytics.

Workgroup

SQL Server Workgroup Edition includes the core database functionality but does not include the additional services. Note that this edition has been retired in SQL Server 2012.

Express

SQL Server Express Edition is a scaled down, free edition of SQL Server, which includes the core database engine. While there are no limitations on the number of databases or users supported, it is limited to using one processor, 1 GB memory and 10 GB database files (4 GB database files prior to SQL Server Express 2008 R2). It is intended as a replacement for MSDE. Two additional editions provide a superset of features not in the original Express Edition. The first is **SQL Server Express with Tools**, which includes SQL Server Management Studio Basic. **SQL Server Express with Advanced Services** adds full-text search capability and reporting services.

Specialized editions

Azure

Microsoft SQL Azure Database is the cloud-based version of Microsoft SQL Server, presented as software as a service on Azure Services Platform.

Compact (SQL CE)

The compact edition is an embedded database engine. Unlike the other editions of SQL Server, the SQL CE engine is based on SQL Mobile (initially designed for use with hand-held devices) and does not share the same binaries. Due to its small size (1 MB DLL footprint), it has a markedly reduced feature set compared to the other editions. For example, it supports a subset of the standard data types, does not support stored procedures or Views or multiple-statement batches (among other limitations). It is limited to 4 GB maximum database size and cannot be run as a Windows service, Compact Edition must be hosted by the application using it. The 3.5 version includes support for ADO.NET Synchronization Services. SQL CE does not support ODBC connectivity, unlike SQL Server proper.

Developer

SQL Server Developer Edition includes the same features as SQL Server 2012 Enterprise Edition, but is limited by the license to be only used as a development and test system, and not as production server. This edition is available to download by students free of charge as a part of Microsoft's DreamSpark program.

Embedded (SSEE)

SQL Server 2005 Embedded Edition is a specially configured named instance of the SQL Server Express database engine which can be accessed only by certain Windows Services.

Evaluation

SQL Server Evaluation Edition, also known as the *Trial Edition*, has all the features of the Enterprise Edition, but is limited to 180 days, after which the tools will continue to run, but the server services will stop.

Fast Track

SQL Server Fast Track is specifically for enterprise-scale data warehousing storage and business intelligence processing, and runs on reference-architecture hardware that is optimized for Fast Track.

LocalDB

Introduced in SQL Server Express 2012, LocalDB is a minimal, on-demand, version of SQL Server that is designed for application developers. It can also be used as an embedded database.

Parallel Data Warehouse (PDW)

A massively parallel processing (MPP) SQL Server appliance optimized for large-scale data warehousing such as hundreds of terabytes.

Datawarehouse Appliance Edition

Pre-installed and configured as part of an appliance in partnership with Dell & HP base on the Fast Track architecture. This edition does not include SQL Server Integration Services, Analysis Services, or Reporting Services.

Architecture

The protocol layer implements the external interface to SQL Server. All operations that can be invoked on SQL Server are communicated to it via a Microsoft-defined format, called Tabular Data Stream (TDS). TDS is an application layer protocol, used to transfer data between a database server and a client. Initially designed and developed by Sybase Inc. for their Sybase SQL Server relational database engine in 1984, and later by Microsoft in Microsoft SQL Server, TDS packets can be encased in other physical transport dependent protocols, including TCP/IP, Named pipes, and Shared memory. Consequently, access to SQL Server is available over these protocols. In addition, the SQL Server API is also exposed over web services.

Data storage

Data storage is a database, which is a collection of tables with typed columns. SQL Server supports different data types, including primary types such as *Integer*, *Float*, *Decimal*, *Char* (including character strings), *Varchar* (variable length character strings), binary (for unstructured blobs of data), *Text* (for textual data) among others. The rounding of floats to integers uses either Symmetric Arithmetic Rounding or Symmetric Round Down (*Fix*) depending on arguments: `SELECT Round(2.5, 0)` gives 3.

Microsoft SQL Server also allows user-defined composite types (UDTs) to be defined and used. It also makes server statistics available as virtual tables and views (called Dynamic Management Views or DMVs). In addition to tables, a database can also contain other objects including views, stored procedures, indexes and constraints, along with a transaction log. A SQL Server database can contain a maximum of 2^{31} objects, and can span multiple OS-level files with a maximum file size of 2^{60} bytes. The data in the database are stored in primary data files with an extension `.mdf`. Secondary data files, identified with a `.ndf` extension, are used to store optional metadata. Log files are identified with the `.ldf` extension.

Storage space allocated to a database is divided into sequentially numbered *pages*, each 8 KB in size. A *page* is the basic unit of I/O for SQL Server operations. A page is marked with a 96-byte header which stores metadata about the page including the page number, page type, free space on the page and the ID of the object that owns it. Page type defines the data contained in the page - data stored in the database, index, allocation map which holds information about how pages are allocated to tables and indexes, change map which holds information about the changes made to other pages since last backup or logging, or contain large data types such as image or text. While page is the basic unit of an I/O operation, space is actually managed in terms of an *extent* which consists of 8 pages. A database object can either span all 8 pages in an extent ("uniform extent") or share an extent with up to 7 more objects ("mixed extent"). A row in a database table cannot span more than one page, so is limited to 8 KB in size. However, if the data exceeds 8 KB and the row contains *Varchar* or *Varbinary* data, the data in those columns are moved to a new page (or possibly a sequence of pages, called an *Allocation unit*) and replaced with a pointer to the data.

For physical storage of a table, its rows are divided into a series of partitions (numbered 1 to n). The partition size is user defined; by default all rows are in a single partition. A table is split into multiple partitions in order to spread a database over a cluster. Rows in each partition are stored in either B-tree or heap structure. If the table has an associated index to allow fast retrieval of rows, the rows are stored in-order according to their index values, with a B-tree providing the index. The data is in the leaf node of the leaves, and other nodes storing the index values for the

leaf data reachable from the respective nodes. If the index is non-clustered, the rows are not sorted according to the index keys. An indexed view has the same storage structure as an indexed table. A table without an index is stored in an unordered heap structure. Both heaps and B-trees can span multiple allocation units.

Buffer management

SQL Server buffers pages in RAM to minimize disc I/O. Any 8 KB page can be buffered in-memory, and the set of all pages currently buffered is called the buffer cache. The amount of memory available to SQL Server decides how many pages will be cached in memory. The buffer cache is managed by the *Buffer Manager*. Either reading from or writing to any page copies it to the buffer cache. Subsequent reads or writes are redirected to the in-memory copy, rather than the on-disc version. The page is updated on the disc by the Buffer Manager only if the in-memory cache has not been referenced for some time. While writing pages back to disc, asynchronous I/O is used whereby the I/O operation is done in a background thread so that other operations do not have to wait for the I/O operation to complete. Each page is written along with its checksum when it is written. When reading the page back, its checksum is computed again and matched with the stored version to ensure the page has not been damaged or tampered with in the meantime.

Concurrency and locking

SQL Server allows multiple clients to use the same database concurrently. As such, it needs to control concurrent access to shared data, to ensure data integrity—when multiple clients update the same data, or clients attempt to read data that is in the process of being changed by another client. SQL Server provides two modes of concurrency control: pessimistic concurrency and optimistic concurrency. When pessimistic concurrency control is being used, SQL Server controls concurrent access by using locks. Locks can be either shared or exclusive. Exclusive lock grants the user exclusive access to the data—no other user can access the data as long as the lock is held. Shared locks are used when some data is being read—multiple users can read from data locked with a shared lock, but not acquire an exclusive lock. The latter would have to wait for all shared locks to be released. Locks can be applied on different levels of granularity—on entire tables, pages, or even on a per-row basis on tables. For indexes, it can either be on the entire index or on index leaves. The level of granularity to be used is defined on a per-database basis by the database administrator. While a fine grained locking system allows more users to use the table or index simultaneously, it requires more resources. So it does not automatically turn into higher performing solution. SQL Server also includes two more lightweight mutual exclusion solutions—latches and spinlocks—which are less robust than locks but are less resource intensive. SQL Server uses them for DMVs and other resources that are usually not busy. SQL Server also monitors all worker threads that acquire locks to ensure that they do not end up in deadlocks—in case they do, SQL Server takes remedial measures, which in many cases is to kill one of the threads entangled in a deadlock and rollback the transaction it started. To implement locking, SQL Server contains the *Lock Manager*. The Lock Manager maintains an in-memory table that manages the database objects and locks, if any, on them along with other metadata about the lock. Access to any shared object is mediated by the lock manager, which either grants access to the resource or blocks it.

SQL Server also provides the optimistic concurrency control mechanism, which is similar to the multiversion concurrency control used in other databases. The mechanism allows a new version of a row to be created whenever the row is updated, as opposed to overwriting the row, i.e., a row is additionally identified by the ID of the transaction that created the version of the row. Both the old as well as the new versions of the row are stored and maintained, though the old versions are moved out of the database into a system database identified as `Tempdb`. When a row is in the process of being updated, any other requests are not blocked (unlike locking) but are executed on the older version of the row. If the other request is an update statement, it will result in two different versions of the rows—both of them will be stored by the database, identified by their respective transaction IDs.

Data retrieval

The main mode of retrieving data from an SQL Server database is querying for it. The query is expressed using a variant of SQL called T-SQL, a dialect Microsoft SQL Server shares with Sybase SQL Server due to its legacy. The query declaratively specifies what is to be retrieved. It is processed by the query processor, which figures out the sequence of steps that will be necessary to retrieve the requested data. The sequence of actions necessary to execute a query is called a query plan. There might be multiple ways to process the same query. For example, for a query that contains a join statement and a select statement, executing join on both the tables and then executing select on the results would give the same result as selecting from each table and then executing the join, but result in different execution plans. In such case, SQL Server chooses the plan that is expected to yield the results in the shortest possible time. This is called query optimization and is performed by the query processor itself.

SQL Server includes a cost-based query optimizer which tries to optimize on the cost, in terms of the resources it will take to execute the query. Given a query, then the query optimizer looks at the database schema, the database statistics and the system load at that time. It then decides which sequence to access the tables referred in the query, which sequence to execute the operations and what access method to be used to access the tables. For example, if the table has an associated index, whether the index should be used or not - if the index is on a column which is not unique for most of the columns (low "selectivity"), it might not be worthwhile to use the index to access the data. Finally, it decides whether to execute the query concurrently or not. While a concurrent execution is more costly in terms of total processor time, because the execution is actually split to different processors might mean it will execute faster. Once a query plan is generated for a query, it is temporarily cached. For further invocations of the same query, the cached plan is used. Unused plans are discarded after some time.

SQL Server also allows stored procedures to be defined. Stored procedures are parameterized T-SQL queries, that are stored in the server itself (and not issued by the client application as is the case with general queries). Stored procedures can accept values sent by the client as input parameters, and send back results as output parameters. They can call defined functions, and other stored procedures, including the same stored procedure (up to a set number of times). They can be selectively provided access to. Unlike other queries, stored procedures have an associated name, which is used at runtime to resolve into the actual queries. Also because the code need not be sent from the client every time (as it can be accessed by name), it reduces network traffic and somewhat improves performance. Execution plans for stored procedures are also cached as necessary.

SQL CLR

Microsoft SQL Server 2005 includes a component named **SQL CLR** ("Common Language Runtime") via which it integrates with .NET Framework. Unlike most other applications that use .NET Framework, SQL Server itself hosts the .NET Framework runtime, i.e., memory, threading and resource management requirements of .NET Framework are satisfied by SQLOS itself, rather than the underlying Windows operating system. SQLOS provides deadlock detection and resolution services for .NET code as well. With SQL CLR, stored procedures and triggers can be written in any managed .NET language, including C# and VB.NET. Managed code can also be used to define UDT's (user defined types), which can persist in the database. Managed code is compiled to CLI assemblies and after being verified for type safety, registered at the database. After that, they can be invoked like any other procedure. However, only a subset of the Base Class Library is available, when running code under SQL CLR. Most APIs relating to user interface functionality are not available.

When writing code for SQL CLR, data stored in SQL Server databases can be accessed using the ADO.NET APIs like any other managed application that accesses SQL Server data. However, doing that creates a new database session, different from the one in which the code is executing. To avoid this, SQL Server provides some enhancements to the ADO.NET provider that allows the connection to be redirected to the same session which already hosts the running code. Such connections are called context connections and are set by setting `context connection` parameter to `true` in the connection string. SQL Server also provides several other enhancements

to the ADO.NET API, including classes to work with tabular data or a single row of data as well as classes to work with internal metadata about the data stored in the database. It also provides access to the XML features in SQL Server, including XQuery support. These enhancements are also available in T-SQL Procedures in consequence of the introduction of the new XML Datatype (query,value,nodes functions).

Services

SQL Server also includes an assortment of add-on services. While these are not essential for the operation of the database system, they provide value added services on top of the core database management system. These services either run as a part of some SQL Server component or out-of-process as Windows Service and presents their own API to control and interact with them.

Service Broker

Used inside an instance, programming environment. For cross instance applications, Service Broker communicates over TCP/IP and allows the different components to be synchronized together, via exchange of messages. The Service Broker, which runs as a part of the database engine, provides a reliable messaging and message queuing platform for SQL Server applications.

Replication Services

SQL Server Replication Services are used by SQL Server to replicate and synchronize database objects, either in entirety or a subset of the objects present, across replication agents, which might be other database servers across the network, or database caches on the client side. Replication follows a publisher/subscriber model, i.e., the changes are sent out by one database server ("publisher") and are received by others ("subscribers"). SQL Server supports three different types of replication:

Transaction replication

> Each transaction made to the publisher database (master database) is synced out to subscribers, who update their databases with the transaction. Transactional replication synchronizes databases in near real time.

Merge replication

> Changes made at both the publisher and subscriber databases are tracked, and periodically the changes are synchronized bi-directionally between the publisher and the subscribers. If the same data has been modified differently in both the publisher and the subscriber databases, synchronization will result in a conflict which has to be resolved - either manually or by using pre-defined policies. rowguid needs to be configured on a column if merge replication is configured.

Snapshot replication

> Snapshot replication publishes a copy of the entire database (the then-snapshot of the data) and replicates out to the subscribers. Further changes to the snapshot are not tracked.

Analysis Services

SQL Server Analysis Services adds OLAP and data mining capabilities for SQL Server databases. The OLAP engine supports MOLAP, ROLAP and HOLAP storage modes for data. Analysis Services supports the XML for Analysis standard as the underlying communication protocol. The cube data can be accessed using MDX and LINQ queries. Data mining specific functionality is exposed via the DMX query language. Analysis Services includes various algorithms - Decision trees, clustering algorithm, Naive Bayes algorithm, time series analysis, sequence clustering algorithm, linear and logistic regression analysis, and neural networks - for use in data mining.

Reporting Services

SQL Server Reporting Services is a report generation environment for data gathered from SQL Server databases. It is administered via a web interface. Reporting services features a web services interface to support the development of custom reporting applications. Reports are created as RDL files.

Reports can be designed using recent versions of Microsoft Visual Studio (Visual Studio.NET 2003, 2005, and 2008) with Business Intelligence Development Studio, installed or with the included Report Builder. Once created, RDL files can be rendered in a variety of formats[10] including Excel, PDF, CSV, XML, TIFF (and other image formats),[11] and HTML Web Archive.

Notification Services

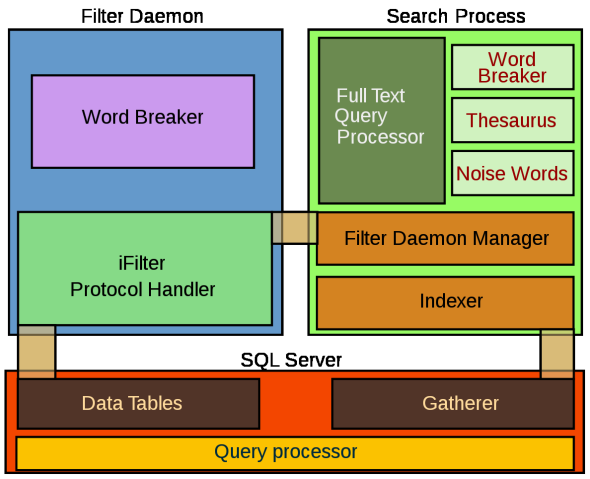
Originally introduced as a post-release add-on for SQL Server 2000, Notification Services was bundled as part of the Microsoft SQL Server platform for the first and only time with SQL Server 2005. SQL Server Notification Services is a mechanism for generating data-driven notifications, which are sent to Notification Services subscribers. A subscriber registers for a specific event or transaction (which is registered on the database server as a trigger); when the event occurs, Notification Services can use one of three methods to send a message to the subscriber informing about the occurrence of the event. These methods include SMTP, SOAP, or by writing to a file in the filesystem. Notification Services was discontinued by Microsoft with the release of SQL Server 2008 in August 2008, and is no longer an officially supported component of the SQL Server database platform.

Integration Services

SQL Server Integration Services (SSIS) provides ETL capabilities for SQL Server for data import, data integration and data warehousing needs. Integration Services includes GUI tools to build workflows such as extracting data from various sources, querying data, transforming data—including aggregation, de-duplication, de-/normalization and merging of data—and then exporting the transformed data into destination databases or files.

Full Text Search Service

SQL Server Full Text Search service is a specialized indexing and querying service for unstructured text stored in SQL Server databases. The full text search index can be created on any column with character based text data. It allows for words to be searched for in the text columns. While it can be performed with the SQL `LIKE` operator, using SQL Server Full Text Search service can be more efficient. Full allows for inexact matching of the source string, indicated by a *Rank* value which can range from 0 to 1000 - a higher rank means a more accurate match. It also allows linguistic matching ("inflectional search"), i.e., linguistic variants of a word (such as a verb in a different tense) will also be a match for a given word (but with a lower rank than an exact match). Proximity searches are also supported, i.e., if the words searched for do not occur in the sequence they are specified in the query but are near each other, they are also considered a match. T-SQL exposes special operators that can be used to access the FTS capabilities.



The SQL Server Full Text Search service architecture

The Full Text Search engine is divided into two processes - the *Filter Daemon* process (`msftefd.exe`) and the *Search* process (`msftesql.exe`). These processes interact with the SQL Server. The Search process includes the indexer (that creates the full text indexes) and the full text query processor. The indexer scans through text columns in the database. It can also index through binary columns, and use iFilters to extract meaningful text from the binary blob (for example, when a Microsoft Word document is stored as an unstructured binary file in a database). The iFilters are hosted by the Filter Daemon process. Once the text is extracted, the Filter Daemon process breaks it up into a sequence of words and hands it over to the indexer. The indexer filters out *noise words*, i.e., words like *A*, *And* etc., which occur frequently and are not useful for search. With the remaining words, an inverted index is created, associating each word with the columns they were found in. SQL Server itself includes a *Gatherer* component that monitors changes to tables and invokes the indexer in case of updates.

When a full text query is received by the SQL Server query processor, it is handed over to the FTS query processor in the Search process. The FTS query processor breaks up the query into the constituent words, filters out the noise words, and uses an inbuilt thesaurus to find out the linguistic variants for each word. The words are then queried against the inverted index and a rank of their accurateness is computed. The results are returned to the client via the SQL Server process.

SQLCMD

SQLCMD is a command line application that comes with Microsoft SQL Server, and exposes the management features of SQL Server. It allows SQL queries to be written and executed from the command prompt. It can also act as a scripting language to create and run a set of SQL statements as a script. Such scripts are stored as a `.sql` file, and are used either for management of databases or to create the database schema during the deployment of a database.

SQLCMD was introduced with SQL Server 2005 and this continues with SQL Server 2012 and 2014. Its predecessor for earlier versions was OSQL and ISQL, which is functionally equivalent as it pertains to TSQL execution, and many of the command line parameters are identical, although SQLCMD adds extra versatility.

Visual Studio

Microsoft Visual Studio includes native support for data programming with Microsoft SQL Server. It can be used to write and debug code to be executed by SQL CLR. It also includes a *data designer* that can be used to graphically create, view or edit database schemas. Queries can be created either visually or using code. SSMS 2008 onwards, provides intellisense for SQL queries as well.

SQL Server Management Studio

SQL Server Management Studio is a GUI tool included with SQL Server 2005 and later for configuring, managing, and administering all components within Microsoft SQL Server. The tool includes both script editors and graphical tools that work with objects and features of the server. SQL Server Management Studio replaces Enterprise Manager as the primary management interface for Microsoft SQL Server since SQL Server 2005. A version of SQL Server Management Studio is also available for SQL Server Express Edition, for which it is known as *SQL Server Management Studio Express* (SSMSE).

A central feature of SQL Server Management Studio is the Object Explorer, which allows the user to browse, select, and act upon any of the objects within the server. It can be used to visually observe and analyze query plans and optimize the database performance, among others. SQL Server Management Studio can also be used to create a new database, alter any existing database schema by adding or modifying tables and indexes, or analyze performance. It includes the query windows which provide a GUI based interface to write and execute queries.

Business Intelligence Development Studio

Business Intelligence Development Studio (**BIDS**) is the IDE from Microsoft used for developing data analysis and Business Intelligence solutions utilizing the Microsoft SQL Server Analysis Services, Reporting Services and Integration Services. It is based on the Microsoft Visual Studio development environment but is customized with the SQL Server services-specific extensions and project types, including tools, controls and projects for reports (using Reporting Services), Cubes and data mining structures (using Analysis Services).

Programmability

T-SQL

T-SQL (Transact-SQL) is the Secondary means of programming and managing SQL Server. It exposes keywords for the operations that can be performed on SQL Server, including creating and altering database schemas, entering and editing data in the database as well as monitoring and managing the server itself. Client applications that consume data or manage the server will leverage SQL Server functionality by sending T-SQL queries and statements which are then processed by the server and results (or errors) returned to the client application. SQL Server allows it to be managed using T-SQL. For this it exposes read-only tables from which server statistics can be read. Management functionality is exposed via system-defined stored procedures which can be invoked from T-SQL queries to perform the management operation. It is also possible to create linked Server using T-SQL. Linked server allows operation to multiple server as one query.

SQL Native Client (aka SNAC)

SQL Native Client is the native client side data access library for Microsoft SQL Server, version 2005 onwards. It natively implements support for the SQL Server features including the Tabular Data Stream implementation, support for mirrored SQL Server databases, full support for all data types supported by SQL Server, asynchronous operations, query notifications, encryption support, as well as receiving multiple result sets in a single database session. SQL Native Client is used under the hood by SQL Server plug-ins for other data access technologies, including ADO or OLE DB. The SQL Native Client can also be directly used, bypassing the generic data access layers.

On 28 Nov 2011 a preview release of the SQL Server ODBC driver for Linux was released.

Microsoft SQL Server Master Data Services

Microsoft SQL Server Master Data Services is a Master Data Management (MDM) product from Microsoft, which will ship as a part of the Microsoft SQL Server database. Originally code-named **Bulldog**, Master Data Services is the rebranding of the Stratature MDM product titled **+EDM**, which Microsoft acquired in June 2007. Master Data Services is architecturally similar to +EDM, with increased integration with other Microsoft applications as well as some new features. Master Data Services first shipped with Microsoft SQL Server 2008 R2. Microsoft SQL Server 2012 improved the analytical capabilities, transactional capabilities, and integration with other software.

Overview

Like other MDM products, Master Data Services aims to create a centralized data source and keep it synchronized, and thus reduce redundancies, across the applications which process the data.

Sharing the architectural core with Stratature +EDM, Master Data Services uses a Microsoft SQL Server database as the physical data store. It is a part of the *Master Data Hub*, which uses the database to store and manage data entities. It is a database with the software to validate and manage the data, and keep it synchronized with the systems that use the data. The master data hub has to extract the data from the source system, validate, sanitize and shape the data, remove duplicates, and update the hub repositories, as well as synchronize the external sources. The entity schemas, attributes, data hierarchies, validation rules and access control information are specified as metadata to the Master Data Services runtime. Master Data Services does not impose any limitation on the data model. Master Data Services also allows custom *Business rules*, used for validating and sanitizing the data entering the data hub, to be defined, which is then run against the data matching the specified criteria. All changes made to the data are validated against the rules, and a log of the transaction is stored persistently. Violations are logged separately, and optionally the owner is notified, automatically. All the data entities can be versioned.

Master Data Services allows the master data to be categorized by hierarchical relationships, such as employee data are a subtype of organization data. Hierarchies are generated by relating data attributes. Data can be automatically categorized using rules, and the categories are introspected programmatically. Master Data Services can also expose the data as Microsoft SQL Server views, which can be pulled by any SQL-compatible client. It uses a role-based access control system to restrict access to the data. The views are generated dynamically, so they contain the latest

data entities in the master hub. It can also push out the data by writing to some external journals. Master Data Services also includes a web-based UI for viewing and managing the data. It uses AJAX in the front-end and ASP.NET in the back-end.

Master Data Services also includes certain features not available in the Stratature +EDM product. It gains an Web service interface to expose the data, as well as an API, which internally uses the exposed web services, exposing the feature set, programmatically, to access and manipulate the data. It also integrates with Active Directory for authentication purposes. Unlike +EDM, Master Data Services supports Unicode characters, as well as support multilingual user interfaces.

Terminology

- *Model* is the highest level of an MDS instance. It is the primary container for specific groupings of master data. In many ways it is very similar to the idea of a database.
- *Entities* are containers created within a model. Entities provide a home for members, and are in many ways analogous to database tables. (e.g. Customer)
- *Members* are analogous to the records in a database table (Entity) e.g. Will Smith. Members are contained within entities. Each member is made up of two or more attributes.
- *Attributes* are analogous to the columns within a database table (Entity) e.g. Surname. Attributes exist within entities and help describe members (the records within the table). Name and Code attributes are created by default for each entity and serve to describe and uniquely identify leaf members. Attributes can be related to other attributes from other entities which are called 'domain-based' attributes. Other attributes will be of type 'free-form' (most common) or 'file'.

Master data service is the part of the sql server now the question is what are master data service

- *Attribute Groups* are explicitly defined collections of particular attributes. Say you have an entity "customer" that has 50 attributes — too much information for many of your users. Attribute groups enable the creation of custom sets of hand-picked attributes that are relevant for specific audiences. (e.g. "customer - delivery details" that would include just their name and last known delivery address)
- *Hierarchies* organise members into either Derived or Explicit hierarchical structures. Derived hierarchies, as the name suggests, are derived by the MDS engine based on the relationships that exist between attributes. Explicit hierarchies are created by hand using both leaf and consolidated members.
- *Business Rules* can be created and applied against model data to ensure that custom business logic is adhered to. In order to be committed into the system data must pass all business rule validations applied to them. e.g. Within the Customer Entity you may want to create a business rule that ensures all members of the 'Country' Attribute contain either the text "USA" or "Canada". The Business Rule once created and ran will then verify all the data is correct before it accepts it into the approved model.
- *Versions* provide system owners / administrators with the ability to Open, Lock or Commit a particular version of a model and the data contained within it at a particular point in time. As the content within a model varies, grows or shrinks over time versions provide a way of managing metadata so that subscribing systems can access to the correct content.

Transact-SQL

Transact-SQL (**T-SQL**) is Microsoft's and Sybase's proprietary extension to SQL. SQL, the acronym for Structured Query Language, is a standardized computer language that was originally developed by IBM for querying, altering and defining relational databases, using declarative statements. T-SQL expands on the SQL standard to include procedural programming, local variables, various support functions for string processing, date processing, mathematics, etc. and changes to the DELETE and UPDATE statements. These additional features make Transact-SQL Turing complete.

Transact-SQL is central to using Microsoft SQL Server. All applications that communicate with an instance of SQL Server do so by sending Transact-SQL statements to the server, regardless of the user interface of the application.

Variables

Keywords for flow control in Transact-SQL include `BEGIN` and `END`, `BREAK`, `CONTINUE`, `GOTO`, `IF` and `ELSE`, `RETURN`, `WAITFOR`, and `WHILE`.

`IF` and `ELSE` allow conditional execution. This batch statement will print "It is the weekend" if the current date is a weekend day, or "It is a weekday" if the current date is a weekday. (Note: This code assumes that Sunday is configured as the first day of the week in the `@@DATEFIRST` setting.)

```
IF DATEPART(dw, GETDATE()) = 7 OR DATEPART(dw, GETDATE()) = 1
   PRINT 'It is the weekend.'
ELSE
   PRINT 'It is a weekday.'
```

`BEGIN` and `END` mark a block of statements. If more than one statement is to be controlled by the conditional in the example above, we can use `BEGIN` and `END` like this:

```
IF DATEPART(dw, GETDATE()) = 7 OR DATEPART(dw, GETDATE()) = 1
BEGIN
   PRINT 'It is the weekend.'
   PRINT 'Get some rest on the weekend!'
END
ELSE
BEGIN
   PRINT 'It is a weekday.'
   PRINT 'Get to work on a weekday!'
END
```

`WAITFOR` will wait for a given amount of time, or until a particular time of day. The statement can be used for delays or to block execution until the set time.

`RETURN` is used to immediately return from a stored procedure or function.

`BREAK` ends the enclosing `WHILE` loop, while `CONTINUE` causes the next iteration of the loop to execute. An example of a `WHILE` loop is given below.

```
DECLARE @i INT
SET @i = 0

WHILE @i < 5
BEGIN
   PRINT 'Hello world.'
   SET @i = @i + 1
END
```

Changes to DELETE and UPDATE statements

In Transact-SQL, both the `DELETE` and `UPDATE` statements allow a `FROM` clause to be added, which allows joins to be included.

This example deletes all `users` who have been flagged with the 'Idle' flag.

```
DELETE u
  FROM users AS u
  INNER JOIN user_flags AS f
    ON u.id = f.id
WHERE f.name = 'idle'
```

BULK INSERT

`BULK INSERT` is a Transact-SQL statement that implements a bulk data-loading process, inserting multiple rows into a table, reading data from an external sequential file. Use of `BULK INSERT` results in better performance than processes that issue individual `INSERT` statements for each row to be added. Additional details are available in MSDN [1].

TRY CATCH

Beginning with SQL Server 2005, Microsoft introduced additional `TRY CATCH` logic to support exception type behaviour. This behaviour enables developers to simplify their code and leave out `@@ERROR` checking after each SQL execution statement.

```
-- begin transaction
BEGIN TRAN

BEGIN TRY
   -- execute each statement
   INSERT INTO MYTABLE(NAME) VALUES ('ABC')
   INSERT INTO MYTABLE(NAME) VALUES ('123')

   -- commit the transaction
   COMMIT TRAN
END TRY
BEGIN CATCH
   -- rollback the transaction because of error
```

```
   ROLLBACK TRAN
END CATCH
```

WCF Data Services

WCF Data Services (formerly **ADO.NET Data Services**, codename **"Astoria"**) is a platform for what Microsoft calls *Data Services*. It is actually a combination of the runtime and a web service through which the services are exposed. In addition, it also includes the **Data Services Toolkit** which lets Astoria Data Services be created from within ASP.NET itself. The Astoria project was announced at MIX 2007, and the first developer preview was made available on April 30, 2007. The first CTP was made available as a part of the ASP.NET 3.5 Extensions Preview. The final version was released as part of Service Pack 1 of the .NET Framework 3.5 on August 11, 2008. The name change from ADO.NET Data Services to WCF data Services was announced at the 2009 PDC.

Overview

WCF Data Services exposes data, represented as Entity Data Model (EDM) objects, via web services accessed over HTTP. The data can be addressed using a REST-like URI. The data service, when accessed via the HTTP GET method with such a URI, will return the data. The web service can be configured to return the data in either plain XML, JSON or RDF+XML. In the initial release, formats like RSS and ATOM are not supported, though they may be in the future. In addition, using other HTTP methods like PUT, POST or DELETE, the data can be updated as well. POST can be used to create new entities, PUT for updating an entity, and DELETE for deleting an entity.

The URIs representing the data will contain the physical location of the service, as well as the service name. In addition, it will also need to specify an EDM Entity-Set or a specific entity instance, as in respectively

```
http://dataserver/service.svc/MusicCollection
```

or

```
http://dataserver/service.svc/MusicCollection[SomeArtist]
```

The former will list all entities in the *Collection* set whereas the latter will list only for the entity which is indexed by *SomeArtist*.

In addition, the URIs can also specify a traversal of a relationship in the Entity Data Model. For example,

```
http://dataserver/service.svc/MusicCollection[SomeSong]/Genre
```

traverses the relationship *Genre* (in SQL parlance, joins with the *Genre* table) and retrieves all instances of *Genre* that are associated with the entity *SomeSong*. Simple predicates can also be specified in the URI, like

```
http://dataserver/service.svc/MusicCollection[SomeArtist]/ReleaseDate[Year eq 2006]
```

will fetch the items that are indexed by *SomeArtist* and had their *release* in *2006*. Filtering and partition information can also be encoded in the URL as

```
http://dataserver/service.svc/MusicCollection?$orderby=ReleaseDate&$skip=100&$top=50
```

It is important to note that although the presence of skip and top keywords indicate paging support, in Data Services version 1 there is no method of determining the number of records available and thus impossible to determine how many pages there may be. The OData 2.0 spec adds support for the **$count** path segment (to return just a count of entities) and **$inlineCount** (to retrieve a page worth of entities and a total count without a separate round-trip....).[1]

Windows Internal Database

Windows Internal Database (codenamed WYukon, sometimes referred to as SQL Server Embedded Edition) is a variant of SQL Server Express 2005-2012 that is included with Windows Server 2008 (SQL 2005), Windows Server 2008 R2 (SQL 2005) and Windows Server 2012 (SQL 2012), and is included with other free Microsoft products released after 2007 that require an SQL Server database backend. Windows SharePoint Services 3.0 and Windows Server Update Services 3.0 both include Windows Internal Database, which can be used as an alternative to using a retail edition of SQL Server. WID was a 32-bit application, even as component of Windows Server 2008 64-bit, which installs in the path C:\Program Files (x86)\Microsoft SQL Server. In Windows Server 2012, it is a 64-bit application, installed in C:\Windows\WID.

Windows Internal Database is not available as a standalone product for use by end-user applications; Microsoft provides SQL Server Express and Microsoft SQL Server for this purpose. Additionally, it is designed to only be accessible to Windows Services running on the same machine.

Several components of Windows Server 2008 and 2012 use Windows Internal Database for their data storage: Active Directory Rights Management Services, Windows System Resource Manager, UDDI Services, Active Directory Federation Services 2.0, IPAM and Windows SharePoint Services. On Windows Server 2003, SharePoint and Windows Server Update Services will install Windows Internal Database and use it as a default data store if a retail SQL Server database instance is not provided. A Knowledge Base article published by Microsoft states that Windows Internal Database does not identify itself as a removable component, and provides instructions how it may be uninstalled by calling Windows Installer directly.

SQL Server Management Studio Express can be used to connect to an instance of Windows Internal Database using `\\.\pipe\MSSQL$MICROSOFT##SSEE\sql\query` (2003-2008) or `\\.\pipe\MICROSOFT##WID\tsql\query` (2012) as instance name. But this will only work locally, as Remote Connections cannot be enabled for this edition of SQL Server. *Also note that "Windows Authentication" should be used (as opposed to SQL Server Authentication), and administrators seem to have the best results of authenticating successfully when logged on using the same administrative account that was created when Windows was installed.*

SQL Server Agent

SQL Server Agent is a component of Microsoft SQL Server which schedules jobs and handles other automated tasks. It runs as a Windows service so can start automatically when the system boots or it can be started manually. It is .

Typical system tasks performed include scheduling maintenance plans (such as backups), handling Reporting Services subscriptions and performing log shipping sub-tasks (backup, copy, restore & check). User tasks, such as scheduling some T-SQL or command line statement are also common.

SQLAgent has support for operators and alerts, so that administrators can be notified, e.g. by email.

SQL Server Compact

SQL Server Compact

Filename extension	`.sdf`
Developed by	Microsoft
Type of format	Relational database

Microsoft SQL Server Compact (**SQL CE**) is a compact relational database produced by Microsoft for applications that run on mobile devices and desktops. Prior to the introduction of the desktop platform, it was known as *SQL Server for Windows CE* and *SQL Server Mobile Edition*. The latest release is the SQL Server Compact 4.0 supporting .NET Framework 4.0, and dropping support for Windows Mobile in this release. It includes both 32-bit and 64-bit native support. SQL CE targets occasionally connected applications and applications with an embedded database. It is free to download and redistribute. An ODBC driver for SQL CE does not exist, nor is one planned. Native applications may use SQL CE via OLE DB.

Overview

SQL Server Compact shares a common API with the other Microsoft SQL Server editions. It also includes ADO.NET providers for data access using ADO.NET APIs, and built-in synchronization capabilities, as well as support for LINQ and Entity Framework. Future releases will unify the synchronization capabilities with Microsoft Synchronization Services. Unlike other editions of Microsoft SQL Server, SQL CE runs in-process with the application which is hosting it. It has a disk footprint of less than 2 MB and a memory footprint of approximately 5 MB. SQL CE is optimized for an architecture where all applications share the same memory pool. Windows Store apps for Windows 8 cannot use SQL Server Compact edition, or any other edition of SQL Server.

Support

SQL CE databases can support ACID-compliance, but do not meet the durability requirement by default because AutoFlush buffers changes in memory (including enlisted ambient transactions and explicit SQL CE transactions that do not override the Commit() call with an CommitMode.Immediate value). Therefore committed transaction changes can be lost. To meet the durability requirement the commit call on the transaction must specify the immediate flag. Like Microsoft SQL Server, SQL CE supports transactions, referential integrity constraints, locking as well as multiple connections to the database store. However, nested transactions are not supported, even though parallel transactions (on different tables) are. The current release does not support stored procedures or native XML data type either. It uses a subset of T-SQL for querying and due to lack of XML support, XQuery is not supported either. Queries are processed by an optimizing query processor. SQL CE databases also support indexing, as well as support remote data replication (local caching of data in remote databases) and merge replication (bidirectional synchronization with master databases).

SQL CE databases can be created and managed from Microsoft Visual Studio and some older versions of SQL Server Management Studio as well.

File Format

SQL CE databases reside in a single ***.sdf*** file, which can be up to 4 GB in size. The *.sdf* file can be encrypted with 128-bit encryption for data security. SQL CE runtime mediates concurrent multi-user access to the *.sdf* file. The *.sdf* file can simply be copied to the destination system for deployment, or be deployed through ClickOnce. SQL CE runtime has support for **DataDirectories**. Applications using an SQL CE database need not specify the entire path to an *.sdf* file in the ADO.NET connection string, rather it can be specified as |*DataDirectory*|\\<*database_name*>.*sdf*, defining the data directory (where the *.sdf* database file resides) being defined in the assembly manifest for the application.

SQL Server Management Studio 2005 can read and modify CE 3.0 and 3.1 database files (with the latest service pack), but SQL Server Management Studio 2008 (or later) is required to read version 3.5 files. Microsoft Visual Studio Express 2008 SP1 can create, modify and query CE 3.5 SP1 database files. SQL Server Management Studio cannot read CE 4.0 files. Visual Studio 2010 SP1 can handle CE 4.0 database files.

The .sdf (Sqlce Database File) naming convention is optional and any extension can be used.

Setting a password for the database file is optional. The database can be compressed and repaired with the option of the compacted/repaired database to be placed into a new database file.

SQL CLR

SQL CLR or **SQLCLR** (SQL Common Language Runtime) is technology for hosting of the Microsoft .NET common language runtime engine within SQL Server. The SQLCLR allows managed code to be hosted by, and run in, the Microsoft SQL Server environment.

This technology, introduced in Microsoft SQL Server 2005, allow users for example to create the following types of managed code objects in SQL Server in .NET languages such as C# or VB.NET.

- Stored procedures (SPs) which are analogous to *procedures* or *void functions* in procedural languages like VB or C,
- triggers which are stored procedures that fire in response to Data Manipulation Language (DML) or Data Definition Language (DDL) events,
- User-defined functions (UDFs) which are analogous to functions in procedural languages,
- User-defined aggregates (UDAs) which allow developers to create custom aggregates that act on sets of data instead of one row at a time,
- User-defined types (UDTs) that allow users to create simple or complex data types which can be serialized and deserialized within the database.

The SQL CLR relies on the creation, deployment, and registration of CLI assemblies, which are physically stored in managed code dynamic load libraries (DLLs). These assemblies may contain CLI namespaces, classes, functions and properties.

Microsoft Transaction Server

Microsoft Transaction Server (**MTS**) was software that provided services to Component Object Model (COM) software components, to make it easier to create large distributed applications. The major services provided by MTS were automated transaction management, instance management (or *just-in-time activation*) and role-based security. MTS is considered to be the first major software to implement aspect-oriented programming.

MTS was first offered in the Windows NT 4.0 Option Pack. In Windows 2000, MTS was enhanced and better integrated with the operating system and COM, and was renamed COM+. COM+ added object pooling, loosely-coupled events and user-defined simple transactions (compensating resource managers) to the features of MTS.

COM+ is still provided with Windows Server 2003 and Windows Server 2008, and the Microsoft .NET Framework provides a wrapper for COM+ in the EnterpriseServices namespace. The Windows Communication Foundation (WCF) provides a way of calling COM+ applications with web services. However, COM+ is based on COM, and Microsoft's strategic software architecture is now web services and .NET, not COM. There are pure .NET-based alternatives for many of the features provided by COM+, and in the long term it is likely COM+ will be phased out.

Architecture

A basic MTS architecture comprises:

- the MTS Executive (mtxex.dll)
- the Factory Wrappers and Context Wrappers for each component
- the MTS Server Component
- MTS clients
- auxiliary systems like:
  - COM runtime services
  - the Service Control Manager (SCM)
  - the Microsoft Distributed Transaction Coordinator (MS-DTC)
  - the Microsoft Message Queue (MSMQ)
  - the COM-Transaction Integrator (COM-TI)
  - etc.

COM components that run under the control of the MTS Executive are called MTS components. In COM+, they are referred to as COM+ Applications. MTS components are in-process DLLs. MTS components are deployed and run in the MTS Executive which manages them. As with other COM components, an object implementing the IClassFactory interface serves as a Factory Object to create new instances of these components.

MTS inserts a Factory Wrapper Object and an Object Wrapper between the actual MTS object and its client. This interposing of wrappers is called *interception*. Whenever the client makes a call to the MTS component, the wrappers (Factory and Object) intercept the call and inject their own instance-management algorithm called the Just-In-Time Activation (JITA) into the call. The wrapper then makes this call on the actual MTS component. Interception was considered difficult at the time due to a lack of extensible metadata.

In addition, based on the information from the component's deployment properties, transaction logic and security checks also take place in these wrapper objects.

For every MTS-hosted object, there also exists a Context Object, which implements the IObjectContext interface. The Context Object maintains specific information about that object, such as its transactional information, security information and deployment information. Methods in the MTS component call into the Context Object through its IObjectContext interface.

MTS does not create the actual middle-tier MTS object until the call from a client reaches the container. Since the object is not running all the time, it does not use up a lot of system resources (even though an object wrapper and skeleton for the object do persist).

As soon as the call comes in from the client, the MTS wrapper process activates its Instance Management algorithm called JITA. The actual MTS object is created "just in time" to service the request from the wrapper. And when the request is serviced and the reply is sent back to the client, the component either calls SetComplete()/SetAbort(), or its transaction ends, or the client calls Release() on the reference to the object, and the actual MTS object is destroyed. In short, MTS uses a stateless component model.

Generally, when a client requests services from a typical MTS component, the following sequence occurs on the server :

1. acquire a database connection
2. read the component's state from either the Shared Property Manager or from an already existing object or from the client
3. perform the business logic
4. write the component's changed state, if any, back to the database
5. close and release the database connection
6. *vote* on the result of the transaction. MTS components do not directly commit transactions, rather they communicate their success or failure to MTS.

It is thus possible to implement high-latency resources as asynchronous resource pools, which should take advantage of the stateless JIT activation afforded by the middleware server.

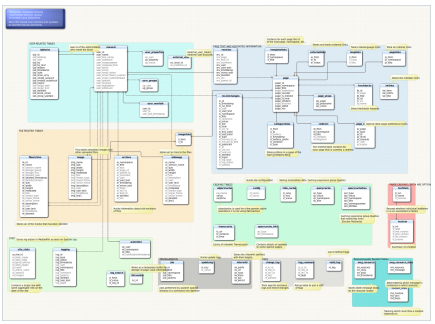
Oracle

Database schema

A **database schema** (/ˈski.mə/ ***SKEE**-mə*) of a database system is its structure described in a formal language supported by the database management system (DBMS) and refers to the organization of data as a blueprint of how a database is constructed (divided into database tables in case of Relational Databases). The formal definition of database schema is a set of formulas (sentences) called integrity constraints imposed on a database. These integrity constraints ensure compatibility between parts of the schema. All constraints are expressible in the same language. A database can be considered a structure in realization of the database language. The states of a created conceptual schema are transformed into an explicit mapping, the database schema. This describes how real world entities are modeled in the database.



A depiction of MediaWiki database schema.

"A database schema specifies, based on the database administrator's knowledge of possible applications, the facts that can enter the database, or those of interest to the possible end-users." The notion of a database schema plays the same role as the notion of theory in predicate calculus. A model of this “theory” closely corresponds to a database, which can be seen at any instant of time as a mathematical object. Thus a schema can contain formulas representing integrity constraints specifically for an application and the constraints specifically for a type of database, all expressed in the same database language. In a relational database, the schema defines the tables, fields, relationships, views, indexes, packages, procedures, functions, queues, triggers, types, sequences, materialized views, synonyms, database links, directories, XML schemas, and other elements.

Schemas are generally stored in a data dictionary. Although a schema is defined in text database language, the term is often used to refer to a graphical depiction of the database structure. In other words, schema is the structure of the database that defines the objects in the database.

In an Oracle Database system, the term "schema" has a slightly different connotation.

Ideal requirements for schema integration

Completeness

All information in the source data should be included in the database schema.

Overlap preservation

Each of the overlapping elements specified in the input mapping is also in a database schema relation.

Extended overlap preservation

Source-specific elements that are associated with a source's overlapping elements are passed through to the database schema.

Normalization

Independent entities and relationships in the source data should not be grouped together in the same relation in the database schema. In particular, source specific schema elements should not be grouped with overlapping schema elements, if the grouping co-locates independent entities or relationships.

Minimality

If any elements of the database schema are dropped then the database schema is not ideal.

These requirements influence the detailed structure of schemas that are produced. Certain applications will not require that all of these conditions are met, but these five requirements are the most ideal.

Example of two schema integrations

Example: Suppose we want a mediated (database) schema to integrate two travel databases, Go-travel and Ok-travel.

***Go-travel* has three relations:**

Go-flight(f-num, time, meal)
Go-price(f-num, date, price)

f-num is the flight number and meal is a boolean.

***Ok-travel* has just one relation:**

Ok-flight(f-num, date, time, price, nonstop)

'nonstop' is a boolean.

The overlapping information in Ok-travel's and Go-travel's schemas could be represented in a mediated schema:

Flight(f-num, date, time, price)

Oracle database specificity

In the context of Oracle databases, a **schema object** is a logical data storage structure.

In an Oracle database, associated with each database **user** is a schema. A schema comprises a collection of schema objects. Examples of schema objects include:

- tables
- views
- sequences
- synonyms
- indexes
- clusters
- database links
- snapshots
- procedures
- functions
- packages

On the other hand, non-schema objects may include:

- users
- roles
- contexts
- directory objects

Schema objects do not have a one-to-one correspondence to physical files on disk that store their information. However, Oracle databases store schema objects logically within a tablespace of the database. The data of each object is physically contained in one or more of the tablespace's datafiles. For some objects (such as tables, indexes, and clusters) a database administrator can specify how much disk space the Oracle RDBMS allocates for the object within the tablespace's datafiles.

There is no necessary relationship between schemas and tablespaces: a tablespace can contain objects from different schemas, and the objects for a single schema can reside in different tablespaces.

Oracle Database

Oracle Database

ORACLE®	
Developer(s)	Oracle Corporation
Development status	Active
Written in	Assembly language, C, C++
Available in	Multilingual
Type	ORDBMS
License	Proprietary
Website	Oracle RDBMS [1]

The **Oracle Database** (commonly referred to as **Oracle RDBMS** or simply as **Oracle**) is an object-relational database management system produced and marketed by Oracle Corporation.

Larry Ellison and his friends, former co-workers Bob Miner and Ed Oates, started the consultancy Software Development Laboratories (SDL) in 1977. SDL developed the original version of the Oracle software. The name *Oracle* comes from the code-name of a CIA-funded project Ellison had worked on while previously employed by Ampex.

Physical and logical structures

An Oracle database system—identified by an alphanumeric system identifier or SID—comprises at least one instance of the application, along with data storage. An instance—identified persistently by an instantiation number (or activation id: SYS.V_$DATABASE.ACTIVATION#)—comprises a set of operating-system processes and memory-structures that interact with the storage. (Typical processes include PMON (the process monitor) and SMON (the system monitor).) Oracle documentation can refer to an active database instance as a "shared memory realm".

Users of Oracle databases refer to the server-side memory-structure as the SGA (System Global Area). The SGA typically holds cache information such as data-buffers, SQL commands, and user information. In addition to storage, the database consists of online redo logs (or logs), which hold transactional history. Processes can in turn archive the online redo logs into archive logs (offline redo logs), which provide the basis (if necessary) for data recovery and for the physical-standby forms of data replication using Oracle Data Guard.

If the Oracle database administrator has implemented Oracle RAC (Real Application Clusters), then multiple instances, usually on different servers, attach to a central storage array. This scenario offers advantages such as better performance, scalability and redundancy. However, support becomes more complex, and many sites do not use RAC. In version 10*g*, grid computing introduced shared resources where an instance can use (for example) CPU resources from another node (computer) in the grid.

The Oracle DBMS can store and execute stored procedures and functions within itself. PL/SQL (Oracle Corporation's proprietary procedural extension to SQL), or the object-oriented language Java can invoke such code objects and/or provide the programming structures for writing them.

Storage

The Oracle RDBMS stores data logically in the form of tablespaces and physically in the form of data files ("datafiles"). Tablespaces can contain various types of memory segments, such as Data Segments, Index Segments, etc. Segments in turn comprise one or more extents. Extents comprise groups of contiguous data blocks. Data blocks form the basic units of data storage.

A DBA can impose maximum quotas on storage per user within each tablespace.

Partitioning

Newer versions of the database can also include a partitioning feature: this allows the partitioning of tables based on different set of keys. Specific partitions can then be easily added or dropped to help manage large data sets.

Monitoring

Oracle database management tracks its computer data storage with the help of information stored in the `SYSTEM` tablespace. The `SYSTEM` tablespace contains the data dictionary—and often (by default) indexes and clusters. A data dictionary consists of a special collection of tables that contains information about all user-objects in the database. Since version 8*i*, the Oracle RDBMS also supports "locally managed" tablespaces which can store space management information in bitmaps in their own headers rather than in the `SYSTEM` tablespace (as happens with the default "dictionary-managed" tablespaces). Version 10*g* and later introduced the `SYSAUX` tablespace which contains some of the tables formerly stored in the `SYSTEM` tablespace, along with objects for other tools such as OEM which previously required its own tablespace.

Disk files

Disk files primarily represent one of the following structures:

- Data and index files: These files provide the physical storage of data, which can consist of the data-dictionary data (associated to the tablespace SYSTEM), user data, or index data. These files can be managed manually or managed by Oracle itself ("Oracle-managed files"). Note that a datafile has to belong to exactly one tablespace, whereas a tablespace can consist of multiple datafiles.
- Redo log files, consisting of all changes to the database, used to recover from an instance failure. Note that often a database will store these files multiple times, for extra security in case of disk failure. The identical redo log files are said to belong to the same group.
- Undo files: These special datafiles, which can only contain undo information, aid in recovery, rollbacks, and read-consistency.
- Archive log files: These files, copies of the redo log files, are usually stored at different locations. They are necessary (for example) when applying changes to a standby database, or when performing recovery after a media failure. It is possible to archive to multiple locations.
- Tempfiles: These special datafiles serve exclusively for temporary storage data (used for example for large sorts or for global temporary tables)
- Control file, necessary for database startup. "A binary file that records the physical structure of a database and contains the names and locations of redo log files, the time stamp of the database creation, the current log sequence number, checkpoint information, and so on."[2]

At the physical level, data files comprise one or more data blocks, where the block size can vary between data files.

Data files can occupy pre-allocated space in the file system of a computer server, utilize raw disk directly, or exist within ASM logical volumes.

Database schema

Most Oracle database installations traditionally came with a default schema called `SCOTT`. After the installation process has set up the sample tables, the user can log into the database with the username `scott` and the password `tiger`. The name of the `SCOTT` schema originated with Bruce Scott, one of the first employees at Oracle (then Software Development Laboratories), who had a cat named Tiger.[3]

Oracle Corporation has de-emphasized the use of the `SCOTT` schema, as it uses few of the features of the more recent releases of Oracle. Most recent[4] examples supplied by Oracle Corporation reference the default HR or OE schemas.

Other default schemas include:

- `SYS` (essential core database structures and utilities)
- `SYSTEM` (additional core database structures and utilities, and privileged account)
- `OUTLN` (utilized to store metadata for stored outlines for stable query-optimizer execution plans.)
- `BI`, `IX`, `HR`, `OE`, `PM`, and `SH` (expanded sample schemas containing more data and structures than the older `SCOTT` schema).

System Global Area

Each Oracle instance uses a System Global Area or SGA—a shared-memory area—to store its data and control-information.

Each Oracle instance allocates itself an SGA when it starts and de-allocates it at shut-down time. The information in the SGA consists of the following elements, each of which has a fixed size, established at instance startup:

- Datafiles

Every Oracle database has one or more physical datafiles, which contain all the database data. The data of logical database structures, such as tables and indexes, is physically stored in the datafiles allocated for a database.

Datafiles have the following characteristics:

- One or more datafiles form a logical unit of database storage called a tablespace.
- A datafile can be associated with only one tablespace.
- Datafiles can be defined to extend automatically when they are full.

Data in a datafile is read, as needed, during normal database operation and stored in the memory cache of Oracle Database. For example, if a user wants to access some data in a table of a database, and if the requested information is not already in the memory cache for the database, then it is read from the appropriate datafiles and stored in memory.

Modified or new data is not necessarily written to a datafile immediately. To reduce the amount of disk access and to increase performance, data is pooled in memory and written to the appropriate datafiles all at once

- the redo log buffer: this stores redo entries—a log of changes made to the database. The instance writes redo log buffers to the redo log as quickly and efficiently as possible. The redo log aids in instance recovery in the event of a system failure.
- the shared pool: this area of the SGA stores shared-memory structures such as shared SQL areas in the library cache and internal information in the data dictionary. An insufficient amount of memory allocated to the shared pool can cause performance degradation.
- the Large pool Optional area that provides large memory allocations for certain large processes, such as Oracle backup and recovery operations, and I/O server processes
- Database buffer cache: Caches blocks of data retrieved from the database
- KEEP buffer pool: A specialized type of database buffer cache that is tuned to retain blocks of data in memory for long periods of time

- RECYCLE buffer pool: A specialized type of database buffer cache that is tuned to recycle or remove block from memory quickly
- nK buffer cache: One of several specialized database buffer caches designed to hold block sizes different than the default database block size
- Java pool:Used for all session-specific Java code and data in the Java Virtual Machine (JVM)
- Streams pool: Used by Oracle Streams to store information required by capture and apply

When you start the instance by using Enterprise Manager or SQL*Plus, the amount of memory allocated for the SGA is displayed.[5]

Library cache

The library cache stores shared SQL, caching the parse tree and the execution plan for every unique SQL statement. If multiple applications issue the same SQL statement, each application can access the shared SQL area. This reduces the amount of memory needed and reduces the processing-time used for parsing and execution planning.

Data dictionary cache

The data dictionary comprises a set of tables and views that map the structure of the database.

Oracle databases store information here about the logical and physical structure of the database. The data dictionary contains information such as:

- user information, such as user privileges
- integrity constraints defined for tables in the database
- names and datatypes of all columns in database tables
- information on space allocated and used for schema objects

The Oracle instance frequently accesses the data dictionary in order to parse SQL statements. The operation of Oracle depends on ready access to the data dictionary: performance bottlenecks in the data dictionary affect all Oracle users. Because of this, database administrators should make sure that the data dictionary cache has sufficient capacity to cache this data. Without enough memory for the data-dictionary cache, users see a severe performance degradation. Allocating sufficient memory to the shared pool where the data dictionary cache resides precludes these particular performance problem.

Program Global Area

The Program Global Area[6] or PGA memory-area of an Oracle instance contains data and control-information for Oracle's server-processes.

The size and content of the PGA depends on the Oracle-server options installed. This area consists of the following components:

- stack-space: the memory that holds the session's variables, arrays, and so on
- session-information: unless using the multithreaded server, the instance stores its session-information in the PGA. (In a multithreaded server, the session-information goes in the SGA.)
- private SQL-area: an area which holds information such as bind-variables and runtime-buffers
- sorting area: an area in the PGA which holds information on sorts, hash-joins, etc.

DBAs can monitor PGA usage via the `V$SESSTAT` system view.

Dynamic performance views

The dynamic performance views (also known as "fixed views") within an Oracle database present information from virtual tables (X$ tables) built on the basis of database memory. Database users can access the V$ views (named after the prefix of their synonyms) to obtain information on database structures and performance.

Process architectures

Oracle processes

The Oracle RDBMS typically relies on a group of processes running simultaneously in the background and interacting to monitor and expedite database operations. Typical operating environments might include some of the following individual processes (shown along with their abbreviated nomenclature):

- advanced queueing processes (Qnnn)
- archiver processes (ARCn)
- checkpoint process (CKPT) *REQUIRED*
- coordinator-of-job-queues process (CJQn): dynamically spawns slave processes for job-queues
- database writer processes (DBWn) *REQUIRED*
- dispatcher processes (Dnnn): multiplex server-processes on behalf of users
- main Data Guard Broker monitor process (DMON)
- job-queue slave processes (Jnnn)
- log-writer process (LGWR) *REQUIRED*
- log-write network-server (LNSn): transmits redo logs in Data Guard environments
- logical standby coordinator process (LSP0): controls Data Guard log-application
- media-recovery process (MRP): detached recovery-server process
- memory-manager process (MMAN): used for internal database tasks such as Automatic Shared Memory Management
- memory-monitor process (MMON): process for automatic problem-detection, self-tuning and statistics-gathering[7]
- memory-monitor light process (MMNL): gathers and stores Automatic Workload Repository (AWR) data
- mmon slaves (Mnnnn—M0000, M0001, etc.): background slaves of the MMON process[8]
- process-monitor process (PMON) *REQUIRED*
- process-spawner (PSP0): spawns Oracle processes
- queue-monitor coordinator process (QMNC): dynamically spawns queue monitor slaves
- queue-monitor processes (QMNn)
- recoverer process (RECO)
- remote file-server process (RFS)
- shared server processes (Snnn): serve client-requests
- system monitor process (SMON) *REQUIRED*

User processes, connections and sessions

Oracle Database terminology distinguishes different computer-science terms in describing how end-users interact with the database:

- user processes involve the invocation of application software
- a connection refers to the pathway linking a user process to an Oracle instance
- sessions consist of specific connections to an Oracle instance. Each session within an instance has a session identifier or "SID" (distinct from the system-identifier SID).

Concurrency and locking

Oracle databases control simultaneous access to data resources with locks (alternatively documented as "enqueues"). The databases also utilize "latches" - low-level serialization mechanisms to protect shared data structures in the System Global Area.

Configuration

Database administrators control many of the tunable variations in an Oracle instance by means of values in a parameter file. This file in its ASCII default form ("pfile") normally has a name of the format `init<SID-name>.ora`. The default binary equivalent server parameter file ("spfile") (dynamically reconfigurable to some extent) defaults to the format `spfile<SID-name>.ora`. Within an SQL-based environment, the views `V$PARAMETER` and `V$SPPARAMETER` give access to reading parameter values.

Administration

The "Scheduler" (from Oracle 10g) and the Job subsystem permit the automation of predictable processing.

Oracle Resource Manager aims to allocate CPU resources between users and groups of users when such resources become scarce.

Oracle Corporation stated in product announcements that manageability for DBAs had improved from Oracle9i to 10g. Lungu and Vătuiu (2008) assessed the relative manageability by performing common DBA tasks and measuring timings. They performed their tests on a single Pentium CPU (1.7 GHz) with 512 MB RAM,running Windows Server 2000. From Oracle9i to 10g, installation improved 36%,day-to-day administration 63%, backup and recovery 63%, and performance diagnostics and tuning 74%, for a weighted total improvement of 56%. The researchers concluded that "Oracle10g represents a giant step forward from Oracle9i in making the database easier to use and manage".

Internationalization

Oracle Database software comes in 63 language-versions (including regional variations such as British English and American English). Variations between versions cover the names of days and months, abbreviations, time-symbols (such as A.M. and A.D.), and sorting.

Oracle Corporation has translated Oracle Database error-messages into Arabic, Catalan, Chinese, Czech, Danish, Dutch, English, Finnish, French, German, Greek, Hebrew, Hungarian, Italian, Japanese, Korean, Norwegian, Polish, Portuguese, Romanian, Russian, Slovak, Spanish, Swedish, Thai and Turkish.

Oracle Corporation provides database developers with tools and mechanisms for producing internationalized database applications: referred to internally as "Globalization".

History

Corporate/technical timeline

- 1977: Larry Ellison and friends founded Software Development Laboratories (SDL).
- 1978: Oracle Version 1, written in assembly language, runs on PDP-11 under RSX, in 128K of memory. Implementation separates Oracle code and user code. Oracle V1 is never officially released.[9]
- 1979: SDL changed its company-name to "Relational Software, Inc." (RSI) and introduced its product Oracle V2 as an early relational database system - often citedWikipedia:Manual of Style/Words to watch#Unsupported attributions as the first commercially sold RDBMS. The version did not support transactions, but implemented the basic SQL functionality of queries and joins. (RSI never released a version 1 - instead calling the first version *version 2* as a marketing gimmick.)[10]
- 1982: RSI in its turn changed its name, becoming known as "Oracle Corporation",[11] to align itself more closely with its flagship product.
- 1983: The company released Oracle version 3, which it had re-written using the C programming language and which supported `COMMIT` and `ROLLBACK` functionality for transactions. Version 3 extended platform support from the existing Digital VAX/VMS systems to include Unix environments.
- 1984: Oracle Corporation released Oracle version 4, which supported read-consistency. In October it also released the first Oracle for the IBM PC.
- 1985: Oracle Corporation released Oracle version 5, which supported the client–server model—a sign of networks becoming more widely available in the mid-1980s.
- 1986: Oracle version 5.1 started supporting distributed queries.
- 1988: Oracle RDBMS version 6 came out with support for PL/SQL embedded within Oracle Forms v3 (version 6 could not store PL/SQL in the database proper), row-level locking and hot backups.[12]
- 1989: Oracle Corporation entered the application-products market and developed its ERP product, (later to become part of the Oracle E-Business Suite), based on the Oracle relational database.
- 1990: the release of Oracle Applications release 8
- 1992: Oracle version 7 appeared with support for referential integrity, stored procedures and triggers.
- 1997: Oracle Corporation released version 8, which supported object-oriented development and multimedia applications.
- 1999: The release of Oracle8*i* aimed to provide a database inter-operating better with the Internet (the *i* in the name stands for "Internet"). The Oracle8*i* database incorporated a native Java virtual machine (Oracle JVM, also known as "Aurora").
- 2000: Oracle E-Business Suite 11*i* pioneers integrated enterprise application software
- 2001: Oracle9*i* went into release with 400 new features, including the ability to read and write XML documents. 9*i* also provided an option for Oracle RAC, or "Real Application Clusters", a computer-cluster database, as a replacement for the Oracle Parallel Server (OPS) option.
- 2002: the release of Oracle 9i Database Release 2 (9.2.0)
- 2003: Oracle Corporation released Oracle Database 10*g*, which supported regular expressions. (The *g* stands for "grid"; emphasizing a marketing thrust of presenting 10*g* as "grid computing ready".)
- 2005: Oracle Database 10.2.0.1—also known as Oracle Database 10*g* Release 2 (10*g*R2)—appeared.
- 2006: Oracle Corporation announces Unbreakable Linux and acquires i-flex
- 2007: Oracle Database 10*g* release 2 sets a new world record TPC-H 3000 GB benchmark result
- 2007: Oracle Corporation released Oracle Database 11*g* for Linux and for Microsoft Windows.
- 2008: Oracle Corporation acquires BEA Systems.
- 2010: Oracle Corporation acquires Sun Microsystems.
- 2011: Oracle Corporation acquires web content management system FatWire Software.

- 2011: On October 18, Oracle Corporation acquires Endeca Technologies Inc. faceted search engine software vendor.
- 2013: Oracle Corporation released Oracle Database 12*c* for Linux, Solaris and Windows. (The *c* stands for "cloud".)

Patch Updates and Security Alerts

Oracle Corporation releases Critical Patch Updates (CPUs) or Security Patch Updates (SPUs) and Security Alerts to close security holes through which data theft may occur. Critical Patch Updates (CPUs) and Security Alerts [13] come out quarterly on the Tuesday closest to 17th day of the month.

- Customers may receive release notification by email [14].
- White Paper: Critical Patch Update Implementation Best Practices [15]

Version numbering

Oracle products follow a custom release numbering and naming convention. With the Oracle RDBMS 10*g* release, Oracle Corporation began using the "10*g*" label in all versions of its major products, although some sources refer to Oracle Applications Release 11*i* as Oracle 11*i*.Wikipedia:Please clarify The suffixes "i", "g" and "c" do not actually represent a low-order part of the version number, as letters typically represent in software industry version numbering; that is, there is no predecessor version of Oracle 10*g* called Oracle 10*f*. Instead, the letters stand for "internet", "grid" and "cloud", respectively.[16] Consequently many simply drop the "g" or "i" suffix when referring to specific versions of an Oracle product.

Major database-related products and some of their versions include:

- Oracle Application Server 10*g* (also known as "Oracle AS 10*g*"): a middleware product;
- Oracle Applications Release 11*i* (aka Oracle e-Business Suite, Oracle Financials or Oracle 11i): a suite of business applications;
- Oracle Developer Suite 10*g* (9.0.4);
- Oracle JDeveloper 10*g*: a Java integrated development environment;

Since version 2, Oracle's RDBMS release numbering has used the following codes:

- Oracle v2 : 2.3
- Oracle v3 : 3.1.3
- Oracle v4 : 4.1.4.0-4.1.4.4
- Oracle v5 : 5.0.22, 5.1.17, 5.1.22
- Oracle v6 : 6.0.17-6.0.36 (no OPS code), 6.0.37 (with OPS)
- Oracle7: 7.0.12–7.3.4
- Oracle8 Database: 8.0.3–8.0.6
- Oracle8*i* Database Release 1: 8.1.5.0–8.1.5.1
- Oracle8*i* Database Release 2: 8.1.6.0–8.1.6.3
- Oracle8*i* Database Release 3: 8.1.7.0–8.1.7.4
- Oracle9*i* Database Release 1: 9.0.1.0–9.0.1.5 (Patchset as of December 2003[4])
- Oracle9*i* Database Release 2: 9.2.0.1–9.2.0.8 (Patchset as of April 2007[4])
- Oracle Database 10*g* Release 1: 10.1.0.2–10.1.0.5 (Patchset as of February 2006[4])
- Oracle Database 10*g* Release 2: 10.2.0.1–10.2.0.5 (Patchset as of April 2010[4])
- Oracle Database 11*g* Release 1: 11.1.0.6–11.1.0.7 (Patchset as of September 2008[4])
- Oracle Database 11*g* Release 2: 11.2.0.1–11.2.0.4 (Patchset as of August 2013[4])
- Oracle Database 12*c* Release 1: 12.1 (Patchset as of June 2013[4])
- Oracle Database 12*c* Release 1: 12.1.0.2.0 (Patchset 16994047as of February 2014[4])

The version-numbering syntax within each release follows the pattern: major.maintenance.application-server.component-specific.platform-specific.

For example, "10.2.0.1 for 64-bit Solaris" means: 10th major version of Oracle, maintenance level 2, Oracle Application Server (OracleAS) 0, level 1 for Solaris 64-bit.

The *Oracle Database Administrator's Guide* [17] offers further information on Oracle release numbers.

Marketing editions

Over and above the different versions of the Oracle database management software developed over time, Oracle Corporation subdivides its product into varying "editions" - apparently for marketing and license-tracking reasons. (Do not confuse the marketing "editions" with the internal virtual versioning "editions" introduced with Oracle 11.2). In approximate order of decreasing scale:

- Enterprise Edition[18] (EE) includes more features than the 'Standard Edition', especially in the areas of performance and security. Oracle Corporation licenses this product on the basis of users or of processors, typically for servers running 4 or more CPUs. EE has no memory limits, and can utilize clustering using Oracle RAC software.
- Standard Edition[19] (SE) contains base database functionality. Oracle Corporation licenses this product on the basis of users or of processors, typically for servers running from one to four CPUs. If the number of CPUs exceeds 4 CPUs, the user must convert to an Enterprise license. SE has no memory limits, and can utilize clustering with Oracle RAC at no additional charge.
- Standard Edition One,[20] (SE1 or SEO) introduced with Oracle 10*g*, has some additional feature-restrictions. Oracle Corporation markets it for use on systems with one or two CPUs. It has no memory limitations.
- Express Edition ("Oracle Database XE")
  - The first Express Edition, introduced in 2005, offered Oracle 10*g* free to distribute on Windows and Linux platforms. It had a footprint of only 150 MB, had a limitation to a maximum of 4 GB of user data and could use only a single CPU. Although it could install on a server with any amount of memory, it used a maximum of 1 GB. Support for this version came exclusively through on-line forums and not through Oracle support.
  - Oracle 11g Express Edition, released by Oracle Corporation on 24 September 2011, can support 11 GB of user data.
- Oracle Database Lite, intended for running on mobile devices. The embedded mobile database located on the mobile device can synchronize with a server-based installation. Includes support for Win32, Windows CE, Palm OS, and EPOC database clients, integration with Oracle's Advanced Queuing (AQ) mechanism, and data and application synchronization software (to enterprise Oracle databases). Supports 100% Java development (through JDBC drivers and the database's native support for embedded SQLJ and Java stored procedures).

Host platforms

Prior to releasing Oracle 9*i* in 2001, Oracle Corporation ported its database product to a wide variety of platforms. Subsequently Oracle Corporation consolidated on a smaller range of operating-system platforms.

As of November 2011[4], Oracle Corporation supported the following operating systems and hardware platforms for Oracle Database 11*g* (11.2.0.2.0):[21]

- zLinux64
- Microsoft Windows (32-bit)
- Microsoft Windows (x64)
- Linux x86
- Linux x86-64
- Solaris (SPARC)

- Solaris (x86-64)
- HP-UX Itanium
- HP-UX PA-RISC (64-bit)
- AIX (PPC64)
- OpenVMS (IA64)

In 2011, Oracle Corporation announced the availability of Oracle Database Appliance, a pre-built, pre-tuned, highly available clustered database server built using two SunFire X86 servers and direct attached storage.

Some Oracle Enterprise edition databases running on certain Oracle-supplied hardware can utilize Hybrid Columnar Compression for more efficient storage.

Related software

Oracle products

- Oracle Database Firewall analyzes database traffic on a network to prevent threats such as SQL injection.

Database options

Oracle Corporation refers to some extensions to the core functionality of the Oracle database as "database options".[22] As of 2013[4] such options include:

- Active Data Guard [23] (extends Oracle Data Guard physical standby functionality in 11*g*)
- Advanced Compression (compresses tables, backups and redo-data)
- Advanced Security [24] (adds data encryption methods for both data at rest and on the network)
- Content database [25] (provides a centralized repository for unstructured information)
- Data Mining [26] (ODM) (mines for patterns in existing data)
- Database Vault [27] (enforces extra security on data access)
- In-Memory Database Cache [28] (utilizes TimesTen technology)
- Label Security [29] (enforces row-level security)
- Management Packs [30] (various). For example:
  - Oracle Database Change Management Pack (tracks and manages schema changes)
- Oracle Answers [31] (for *ad-hoc* analysis and reporting)
- Oracle Application Express, a no-cost environment for database-oriented software-development
- Oracle GoldenGate 11*g* [32] (distributed real-time data acquisition)
- Oracle Multitenant - a container database holding pluggable databases (PDBs) (from 12c)
- Oracle OLAP [33] (adds analytical processing)
- Oracle Programmer (provides programmatic access to Oracle databases via precompilers, interfaces and bindings)[34]
- Oracle Real Application Testing (new at version 11*g*)—including Database Replay (for testing workloads) and SQL Performance Analyzer (SPA) (for preserving SQL efficiency in changing environments)
- Oracle Spatial and Graph (includes 2D,3D and Raster geospatial data types, indexes, and spatial analytics and data models used in business applications and geographic information systems (GIS)) as well as World Wide Web Consortium Resource Description Framework (RDF) graph management and analysis
- Oracle Text [35] (standard SQL to index, search, and analyze text and documents stored in the Oracle database)
- Oracle XML DB [36], a no-cost component in each edition of the database which provides high-performance technology for storing and retrieving native XML
- Oracle Warehouse Builder (in various forms and sub-options)
- Partitioning [37] (granularizes tables and indexes for efficiency)
- Real Application Clusters (RAC) (coordinates multiple database servers, together accessing the same database)

- Records database [38] (a records management application)
- Transparent Gateway [39] for connecting to non-Oracle systems. Offers optimized solution, with more functionality and better performance than Oracle Generic Connectivity.
- Total Recall [40] (optimizes long-term storage of historical data)

This list is incomplete; you can help by expanding it [4].

In most cases, using these options entails extra licensing costs.[41]

Suites

In addition to its RDBMS, Oracle Corporation has released several related suites of tools and applications relating to implementations of Oracle databases. For example:

- Oracle Application Server, a J2EE-based application server, aids in developing and deploying applications which utilise Internet technologies and a browser.
- Oracle Collaboration Suite contains messaging, groupware and collaboration applications.
- Oracle Developer Suite contains software development tools, including JDeveloper.
- Oracle E-Business Suite collects together applications for enterprise resource planning (including Oracle Financials), customer relationship management and human resources management (Oracle HR).
- Oracle Enterprise Manager (OEM) used by database administrators (DBAs) to manage the DBMS, and recently[4] in version 10*g*, a web-based rewrite of OEM called "Oracle Enterprise Manager Database Control". Oracle Corporation has dubbed the super-Enterprise-Manager used to manage a grid of multiple DBMS and Application Servers "Oracle Enterprise Manager Grid Control".
- Oracle Programmer/2000, a bundling of interfaces for 3GL programming languages, marketed with Oracle7 and Oracle8.
- Oracle WebCenter Suite

Database "features"

Apart from the clearly defined database options, Oracle databases may include many semi-autonomous software sub-systems, which Oracle Corporation sometimes refers to as "features" in a sense subtly different from the normal usage of the word. For example, Oracle Data Guard counts officially as a "feature", but the command-stack within SQL*Plus, though a usability feature, does not appear in the list of "features" in Oracle's list [42].Wikipedia:No original research Such "features" may include (for example):

- Active Session History (ASH), the collection of data for immediate monitoring of very recent database activity.
- Automatic Workload Repository (AWR) [43], providing monitoring services to Oracle database installations from Oracle version 10. Prior to the release of Oracle version 10, the Statspack facility provided similar functionality.
- Clusterware
- Data Aggregation and Consolidation [44]
- Data Guard [45] for high availability
- Generic Connectivity [39] for connecting to non-Oracle systems.
- Data Pump utilities, which aid in importing and exporting data and metadata between databases
- Database Resource Manager (DRM), which controls the use of computing resources.
- Fast-start parallel rollback
- Fine-grained auditing (FGA) (in Oracle Enterprise Edition) supplements standard security-auditing features
- Flashback for selective data recovery and reconstruction[46]
- iSQL*Plus [47], a web-browser-based graphical user interface (GUI) for Oracle database data-manipulation (compare SQL*Plus)
- Oracle Data Access Components (ODAC), tools which consist of:
  - Oracle Data Provider for .NET (ODP.NET)

  - Oracle Developer Tools (ODT) for Visual Studio
  - Oracle Providers for ASP.NET
  - Oracle Database Extensions for .NET
  - Oracle Provider for OLE DB
  - Oracle Objects for OLE
  - Oracle Services for Microsoft Transaction Server
- Oracle-managed files [48] (OMF) -- a feature allowing automated naming, creation and deletion of datafiles at the operating-system level.
- Oracle Multimedia (known as "Oracle *inter*Media" before Oracle 11g) for storing and integrating multimedia data within a database
- Recovery Manager [49] (rman) for database backup, restoration and recovery
- SQL*Plus, a program that allows users to interact with Oracle database(s) via SQL and PL/SQL commands on a command-line. Compare iSQL*Plus.
- Universal Connection Pool (UCP), a connection pool based on Java and supporting JDBC, LDAP, and JCA
- Virtual Private Database[50] (VPD), an implementation of fine-grained access control.

This list is incomplete; you can help by expanding it [4].

Tools

Users can develop their own applications in Java and PL/SQL using tools such as:

- Oracle Forms
- Oracle JDeveloper
- Oracle Reports

As of 2007[4] Oracle Corporation had startedWikipedia:Please clarify a drive toward "wizard"-driven environments with a view to enabling non-programmers to produce simple data-driven applications.

The **Database Upgrade Assistant** (**DBUA**) provides a GUI for the upgrading of an Oracle dastabase.

JAccelerator (NCOMP) - a native-compilation Java "accelerator", integrates hardware-optimized Java code into an Oracle 10g database.

Oracle SQL Developer, a free graphical tool for database development, allows developers to browse database objects, run SQL statements and SQL scripts, and edit and debug PL/SQL statements. It incorporates standard and customized reporting.

Oracle's **OPatch** provides patch management for Oracle databases.

The **SQLTXPLAIN** tool (or **SQLT**) provides tuning assistance for Oracle SQL queries.

Other databases marketed by Oracle Corporation

By acquiring other technology in the database field, Oracle Corporation can also offer:

- TimesTen, a memory-resident database that can cache transactions and synchronize data with a centralized Oracle database server. It functions as a real-time infrastructure software product intended for the management of low-latency, high-volume data, of events and of transactions.
- BerkeleyDB, a simple, high-performance, embedded database
- Oracle Rdb, a legacy relational database for the OpenVMS operating-system
- MySQL a relational database purchased as part of Oracle Corporation's takeover of its immediate previous owner, Sun Microsystems
- Oracle NoSQL Database, a scalable, distributed key-value NoSQL database

Use

The Oracle RDBMS has had a reputation among novice users as difficult to install on Linux systems.[*citation needed*] Oracle Corporation has packaged recent[4] versions for several popular Linux distributions in an attempt to minimize installation challenges beyond the level of technical expertise required to install a database server.[*citation needed*]

Official support

Users who have Oracle support contracts can use Oracle's "My Oracle Support" web site. The "My Oracle Support" site was known as MetaLink until a re-branding exercise completed in October 2010. The support site provides users of Oracle Corporation products with a repository of reported problems, diagnostic scripts and solutions. It also integrates with the provision of support tools, patches and upgrades.

The *Remote Diagnostic Agent* or *RDA* can operate as a command-line diagnostic tool executing a script. The data captured provides an overview of the Oracle Database environment intended for diagnostic and trouble-shooting. Within RDA, the *HCVE* (Health Check Validation Engine) can verify and isolate host system environmental issues that may affect the performance of Oracle software.

Database-related guidelines

Oracle Corporation also endorses certain practices and conventions as enhancing the use of its database products. These include:

- Oracle Maximum Availability Architecture (MAA) guidelines on developing high-availability systems
- Optimal Flexible Architecture (OFA), blueprints for mapping Oracle-database objects to file-systems

Oracle Certification Program

The Oracle Certification Program, a professional certification program, includes the administration of Oracle Databases as one of its main certification paths. It contains three levels:

1. Oracle Certified Associate (OCA)
2. Oracle Certified Professional (OCP)
3. Oracle Certified Master (OCM)

User groups

A variety of official (Oracle-sponsored) and unofficial Oracle User Groups has grown up of users and developers of Oracle databases. They include:

- Geographical/regional user groups
- Independent Oracle Users Group
- Industry-centric user groups
- Oracle Technology Network
- Product-centric user groups
- The OakTable Network
- Usenet newsgroups

Market position

Competition

In the market for relational databases, Oracle Database competes against commercial products such as IBM's DB2 UDB and Microsoft SQL Server. Oracle and IBM tend to battle for the mid-range database market on UNIX and Linux platforms, while Microsoft dominates the mid-range database market on Microsoft Windows platforms. However, since they share many of the same customers, Oracle and IBM tend to support each other's products in many middleware and application categories (for example: WebSphere, PeopleSoft, and Siebel Systems CRM), and IBM's hardware divisions work closely[*citation needed*] with Oracle on performance-optimizing server-technologies (for example, Linux on zSeries). The two companies have a relationship perhapsWikipedia:No original research best described as "coopetition". Niche commercial competitors include Teradata (in data warehousing and business intelligence), Software AG's ADABAS, Sybase, and IBM's Informix, among many others.

In 2007, competition with SAP AG occasioned litigation from Oracle Corporation.[51]

Increasingly, the Oracle database products compete against such open-source software relational database systems as PostgreSQL, Firebird, and MySQL. Oracle acquired Innobase, supplier of the InnoDB codebase to MySQL, in part to compete better against open source alternatives, and acquired Sun Microsystems, owner of MySQL, in 2010. Database products licensed as open source are, by the legal terms of the Open Source Definition, free to distribute and free of royalty or other licensing fees.

Pricing

Oracle Corporation offers term licensing for all Oracle products. It bases the list price for a term-license on a specific percentage of the perpetual license price. Prospective purchasers can obtain licenses based either on the number of processors in their target server machines or on the number of potential seats ("named users").

Enterprise Edition (DB EE)

> As of July 2010[4], the database that costs the most per machine-processor among Oracle database editions, at $47,500 per processor. The term "per processor" for Enterprise Edition is defined with respect to physical cores and a processor core multiplier (common processors = 0.5*cores). e.g. An 8-processor, 32-core server using Intel Xeon 56XX CPUs would require 16 processor licenses.

Standard Edition (DB SE)

> Cheaper: it can run on up to four processors but has fewer features than Enterprise Edition—it lacks proper parallelization,[52] etc.; but remains quite suitable for running medium-sized applications. There are not additional cost for Oracle RAC on the latest Oracle 11g R2 standard edition release.

Standard ONE (DB SE1 or DB SEO)

> Sells even more cheaply, but remains limited to two CPUs. Standard Edition ONE sells on a per-seat basis with a five-user minimum. Oracle Corporation usually sells the licenses with an extra 22% cost for support and upgrades (access to My Oracle Support—Oracle Corporation's support site) which customers need to renew annually.

Oracle Express Edition (DB XE) (Oracle XE)

> An addition to the Oracle database product family (beta version released in 2005, production version released in February 2006), offers a free version of the Oracle RDBMS, but one limited to 11 GB of user data and to 1 GB of memory used by the database (SGA+PGA).[53] XE will use no more than one CPU and lacks an internal JVM. XE runs only on 32-bit Windows and 64-bit Linux, but not on AIX, Solaris, HP-UX and the other operating systems available for other editions. Support is via a free Oracle Discussion Forum [54] only.

As computers running Oracle often have many multi-core processors (resulting in many cores, all to be licensed), the software price can rise into the hundreds of thousands of dollars. The total cost of ownership often exceeds this, as large Oracle installations usually require experienced and trained database administrators to do the set-up properly. Furthermore, further components must be licensed and paid for, for instance the Enterprise Options used with the databases. Many licensing pitfalls let even rise the costs of ownership. Because of the product's large installed base and available training courses, Oracle specialists in some areas have become a more abundant resource than those for more exotic databases. Oracle frequently provides special training offers for database-administrators.

On Linux, Oracle's *certified configurations* include Oracle's own Oracle Linux and other commercial Linux distributions (Red Hat Enterprise Linux 3, 4 and 5, SuSE SLES 8, 9, 10 and 11, Asianux) which can cost in a range from a few hundred to a few thousand USD per year (depending on processor architecture and the support package purchased).

The Oracle database system can also install and run on freely available Linux distributions such as the Red Hat-based CentOS, or Debian-based systems.

Oracle Exadata

Oracle Exadata is a database appliance with support for both OLTP (transactional) and OLAP (analytical) database systems. It was initially designed in collaboration between Oracle Corporation and Hewlett Packard. Oracle designed the database, operating system (based on the Oracle Linux distribution), and storage software whereas HP designed the hardware for it. After Oracle's acquisition of Sun Microsystems, in 2010 Oracle announced the Exadata Version 2 with improved performance and Sun storage systems.

History

Exadata was announced by Larry Ellison at the 2009 Oracle OpenWorld conference in San Francisco for immediate delivery. The main headline was that Oracle was entering the hardware business with a pre-built database machine, engineered by Oracle. The hardware at this time was manufactured, delivered and supported by HP. Since the acquisition of Sun Microsystems by Oracle circa January 2010, Exadata used Sun-based hardware. In August 2011, Oracle announced that Exadata database machines would be orderable with Solaris 11 Express (in addition to Oracle Linux).[1]

Technical details

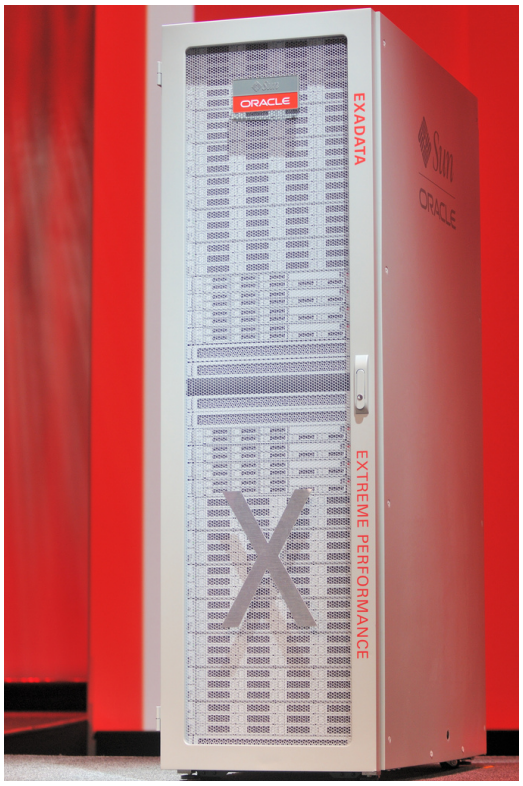
Database servers X3-2

A third generation was announced in 2012.[2] Each Database Server with

- 2 x Eight-Core Intel Xeon E5-2690 Processors (2.9 GHz)
- 128 GB Memory (expandable to 256GB)
- Disk Controller HBA with 512MB Battery Backed Write Cache
- 4 x 300 GB 10,000 RPM Disks
- 2 x QDR (40Gbit/s) Ports
- 4 x 1/10 Gb Ethernet Ports (copper)
- 2 x 10 Gb Ethernet Ports (optical)
- 1 x ILOM Ethernet Port
- 2 x Redundant Hot-Swappable Power Supplies

The Exadata X3-2 comes in 4 different sizes

- Eighth Rack - 2 Database Servers (half of the cores used in each server [8 cores per server]), 3 Storage Servers (half of the disks enabled, half of the Flash Cache enabled)
- Quarter Rack - 2 Database Servers, 3 Storage Servers
- Half Rack - 4 Database Servers, 7 Storage Servers
- Full Rack - 8 Database Servers, 14 Storage Servers



Exadata X2-2 at Oracle OpenWorld 2009

Database servers X3-8

2 Servers, each with

- 8 x Ten-Core Intel Xeon E7-8870 Processors (2.40 GHz)
- 2 TB Memory
- Disk Controller HBA with 512MB Battery Backed Write Cache
- 8 x 300 GB 10,000 RPM Disks
- 8 x InfiniBand QDR (40Gbit/s) Ports
- 8 x 10 Gb Ethernet Ports based on the Intel 82599 10GbE Controller
- 8 x 1 Gb Ethernet Ports
- 1 x ILOM Ethernet Port
- 4 x Redundant Hot-Swappable Power Supplies

Storage Servers X3-2

Each Storage Server has

- Processors: 2 x Six-Core Intel Xeon E5-2630L (2.0 GHz) Processors
- Exadata Smart Flash: Cache 1.6 TB (4 PCI cards)
- System Memory: 64 GB
- Disk Controller: Disk Controller HBA with 512MB Battery Backed Write Cache
- InfiniBand Connectivity: Dual-Port QDR (40Gbit/s) InfiniBand Host Channel Adapter
- Power Supplies: Dual-redundant, hot-swappable power supply
- Disk Drives:
  - 12 x 600 GB 15,000 RPM High Performance or
  - 12 x 3 TB 7,200 RPM High Capacity
  - For raw disk capacity, 1 GB = 1 billion bytes. Actual formatted capacity is less.
- Remote Management: Integrated Lights Out Manager (ILOM) Ethernet port

Database servers X2-2

Sun Fire X4170 M2[3]

- 2 × Six-Core Intel Xeon X5675 Processors (3.06 GHz)
- 96 GB Memory (expandable to 144 GB with optional memory expansion kit)
- Disk Controller HBA with 512MB Battery Backed Write Cache
- 4 × 300 GB 10,000 RPM SAS Disks
- 2 × QDR (40Gbit/s) Ports
- 2 × 10 Gb Ethernet Ports based on the Intel 82599 10GbE Controller
- 4 × 1 Gb Ethernet Ports
- 1 × ILOM Ethernet Port
- 2 × Redundant Hot-Swappable Power Supplies
- 3 × 36 port QDR (40 Gbit/s) InfiniBand Switches (2 x in Quarter Rack configuration)

Database servers X2-8

Sun Fire X4800[4]

- 8 × Ten-Core Intel Xeon E7-8870 Processors (2.40 GHz)
- 2 TB Memory.
- Disk Controller HBA with 512MB Battery Backed Write Cache.
- 8 × 300 GB 10,000 RPM SAS Disks
- 8 × QDR (40Gbit/s) Ports
- 8 × 10 Gb Ethernet Ports based on the Intel 82599 10GbE Controller
- 8 × 1 Gb Ethernet Ports
- 1 × ILOM Ethernet Port
- 4 × Redundant Hot-Swappable Power Supplies
- 3 × 36 port QDR (40 Gbit/s) InfiniBand Switches

Storage Servers X2-2

- 2 × Six-Core Intel Xeon L5640 (2.26 GHz) Processors
- Exadata Smart Flash Cache 384 GB
- System Memory 24 GB
- Disk Controller HBA with 512MB Battery Backed Write Cache
- InfiniBand Connectivity Dual-Port QDR (40Gbit/s) InfiniBand Host Channel Adapter
- Power Supplies Dual-redundant, hot-swappable power supply
- Remote Management Sun Embedded Integrated Lights Out Manager (ILOM)
- Disk Drives 12 × 600 GB 15,000 RPM High Performance SAS or
- 12 × 3 TB 7,200 RPM High Capacity SAS
- Integrated Lights Out Manager (ILOM) Ethernet port[5]

There was also an expansion rack.[6]

Software

Software caches database objects in flash memory, replacing slow, mechanical I/O operations to disk with rapid flash memory operations. Software also provides logging feature to speed database log I/O. Exadata storage cellsWikipedia:Please clarify determine which rows contain values that are being queried. Smart Scan only returns blocks that are relevant to the compute nodes. Storage cells can take over data intensive processing from compute nodes.

Storage cells keep track on maximum and minimum values stored in different areas and use those values to determine where predicates can not exist. This allows the storage cell to not have to read the area at all thus saving time and processing cycles.

InfiniBand switches

The 2010 version of the product used Sun Microsystems datacenter InfiniBand switches with 36 ports.

	Database Machine Full Rack	Database Machine Half Rack	Database Machine Quarter Rack
Database Servers	8	4	2
Exadata Storage Servers	14	7	3
InfiniBand Switches	3	3	2
Upgradability	Connect multiple Full Racks via the included InfiniBand fabric	Field upgrade to Full Rack	Field upgrade from Quarter Rack to Half Rack

Oracle Coherence

In computing, **Oracle Coherence** is a proprietary[1] Java-based in-memory data grid designed to improve reliability, scalability and performance compared to traditional relational database management systems.

Coherence provides several core services:

- Replicated and partitioned data management and caching services - At its core Oracle Coherence is a highly scalable and fault-tolerant distributed cache engine. Coherence uses a specialized scalable protocol and many inexpensive computers to create a cluster which can be seamlessly expanded to add more memory, processing power or both. As a result Coherence has no single point of failure and transparently fails over if a cluster member fails. When a Coherence server is added or removed the cluster automatically re-balances to share the workload. As a result Coherence provides a highly available and predictably horizontally scalable infrastructure for managing application data. [2]
- Replicated data processing engine - In addition to caching Coherence provides a rich data processing model so processing can be farmed out to where the data is, and results returned to the client. By moving the processing to the data, processing too is highly scalable. This is to some extent similar to a MapReduce framework, but lacks the option of parallel reductions. [3]
- Event model allowing developers to interact with data as it changes.
- Support for clients written in Java, C++, .NET as well as other languages using Representational State Transfer (REST).

In addition Coherence provides a variety of mechanisms to integrate with other services using TopLink, Java Persistence API, Oracle Golden Gate or almost any other platform using Coherence provided APIs.

Coherence can be used to manage HTTP sessions via Coherence*Web. With Coherence*Web, application services such as Oracle WebLogic Server, IBM WebSphere, Apache Tomcat and others can reap the same benefits of performance, fault tolerance, and scalability as data.

Some Coherence usage patterns are open source and are listed and supported through the Oracle Coherence incubator.[4] These patterns implement features such as messaging, work distribution and data replication across wide area networks with Coherence.

Tangosol Inc. developed the original Coherence product. Oracle Corporation acquired Tangosol in April 2007, when Coherence had about 120 direct customers.[5] It was also embedded in a few products from companies that included some of Oracle's competitors.[6]

NVL

In Oracle's dialect of SQL (and in PL/SQL), the **NVL** function lets you substitute a value when a null value is encountered.

The syntax for the NVL function is:

```
NVL( string1, replace_with_if_null )
```

string1 is the string to test for a null value. replace_with_if_null is the value returned if string1 is null.

If the first argument is a character type the function returns a varchar2 value. If the first argument is numeric the function returns a numeric value. You cannot use this function to replace a null integer by a string unless you call the TO_CHAR function on that value:

```
NVL(TO_CHAR(numeric_column), 'some string')
```

In comparison to COALESCE NVL evaluates all arguments before execution:

With NVL:

```
SQL> DECLARE
  2    a NUMBER;
  3
  4    FUNCTION err RETURN NUMBER IS
  5    BEGIN
  6      RAISE program_error;
  7    END err;
  8  BEGIN
  9    a := NVL(1, err);
 10  END;
 11  /
DECLARE
  a NUMBER;

  FUNCTION err RETURN NUMBER IS
  BEGIN
    RAISE program_error;
```

```
  END err;
BEGIN
  a := NVL(1, err);
END;
ORA-06501: PL/SQL: program error
ORA-06512: at line 6
ORA-06512: at line 9
```

With COALESCE:

```
SQL> DECLARE
  2    a NUMBER;
  3
  4    FUNCTION err RETURN NUMBER IS
  5    BEGIN
  6      RAISE program_error;
  7    END err;
  8  BEGIN
  9    a := COALESCE(1, err);
 10  END;
 11  /
PL/SQL procedure successfully completed
```

Pro*C

Pro*C (also known as **Pro*C/C++**) is an embedded SQL programming language used by Oracle Database database management systems. Pro*C uses either C or C++ as its host language. During compilation, the embedded SQL statements are interpreted by a precompiler and replaced by C or C++ function calls to their respective SQL library. The output from the Pro*C precompiler is standard C or C++ code that is then compiled by any one of several C or C++ compilers into an executable.

Tools

Toad Data Modeler

Toad Data Modeler is a database design tool allowing users to visually create, maintain and document new or existing database systems. It was previously called "CASE Studio 2" before it was acquired from Charonware by Quest Software in 2006. [1] Quest Software was acquired by Dell as of September 28, 2012.[2]

Visual creation of Entity Relationship Diagrams

Toad Data Modeler allows users to draw logical, physical and universal entity relationship diagrams (ERD). This tool supports various database specific items and therefore it is necessary to select a target database system for a physical ERD.

Physical ERD can be created for:

- DB2
- Ingres
- MS Access
- MS SQL Azure
- MS SQL Server
- MySQL
- Oracle
- PostgreSQL
- Sybase ASE
- Sybase SQL Anywhere

SQL Code Generation

Complex SQL/DDL code can be generated automatically for all above mentioned database systems. It is possible to select types of objects for SQL code generation as well as define options how to generate the output.

Reverse engineering and database visualization

Existing databases can be reverse engineered and displayed in form of a diagram. For all supported database systems it is possible to select particular connection method - native connection, ODBC etc. In addition, ER Diagrams can be created from SQL files for Oracle, Microsoft SQL Azure, Microsoft SQL Server, DB2 and MySQL databases.

Documentation

Toad Data Modeler users can generate reports in HTML, RTF or PDF format. It is also possible to generate output based on XSL transformations - XML, TXT, CSV etc. Pictures of ER Diagrams can be generated for HTML reports only.

Verification

Models can be verified and list of errors, warnings and hints can be displayed as a result of model verification process.

Advanced features

- Synchronization of models with physically existing database (using Alter Script Generation and Model Merge features)
- Version Manager
- Version Control System - Apache Subversion for TDM 4, integrated with Projects to achieve the best possible cooperative functionality
- Creation and maintenance of tasks related to a model or particular part of a model using To-Do list feature.
- Customization, including customization of forms
- Gallery of objects, which can be shared
- Refactoring Utility

Other features

- Support for unicode
- Undo/Redo
- Integration with Toad for Oracle

SQuirreL SQL Client

SQuirreL SQL Client

Developer(s)	Colin Bell, Gerd Wagner, Rob Manning and others
Stable release	3.5.0 / May 5, 2013
Operating system	Cross-platform
Platform	Java
Type	Database administration tool
License	LGPL
Website	www.squirrelsql.org [1]

The **SQuirreL SQL Client** is a database administration tool. It uses JDBC to allow users to explore and interact with databases via a JDBC driver. It provides an editor that offers code completion and syntax highlighting for standard SQL. It also provides a plugin architecture that allows plugin writers to modify much of the application's behavior to provide database-specific functionality or features that are database-independent. As this desktop application is written entirely in Java with Swing UI components, it should run on any platform that has a JVM.

SQuirreL SQL Client is free as open source software that is distributed under the GNU Lesser General Public License.

Feature Summary

- Object Tree allows for browsing database objects such as catalogs, schemas, tables, triggers, views, sequences, procedures, UDTs, etc.
- The SQL Editor is based on RSyntaxTextArea by fifesoft.com to provide syntax highlighting. It can be used to open, create, save and execute files containing SQL statements.
- Supports simultaneous sessions with multiple databases. This allows to compare data and share SQL statements between databases.
- It runs on any platform that has a JVM.
- Plugin architecture to facilitate database vendor-specific extensions (Information or actions not available using standard JDBC - see SQuirreL SQL Client Plugin API for more details)
- Translations for the user interface are available in: (Bulgarian, Brazilian Portuguese, Chinese, Czech, French, German, Italian, Japanese, Polish, Spanish, Russian).
- Graph capabilities to create charts showing table relationships.
- Bookmarks, which are user-defined code templates. SQuirreL comes with predefined example bookmarks for the most common SQL and DDL statements.

History

The SQuirreL SQL project was developed by a team of Java developers around the world and led by Colin Bell. It has been hosted as a SourceForge project since 2001, and is still being developed today.

Supported databases

- Axion Java RDBMS.
- Apache Derby
- Daffodil (One$DB)
- Fujitsu Siemens SESAM/SQL-Server with the SESAM/SQL JDBC driver
- Firebird with the JayBird JCA/JDBC Driver
- FrontBase
- Hypersonic SQL
- H2 (DBMS)
- IBM DB2 for Linux, OS/400 and Windows
- Informix
- Ingres (and OpenIngres)
- InstantDB
- InterBase
- Mckoi SQL Database
- Microsoft Access with the JDBC/ODBC bridge.
- Microsoft SQL Server
- Mimer SQL
- MySQL
- Netezza
- Oracle Database 8i, 9i, 10g, 11g
- Pointbase
- PostgreSQL 7.1.3 and higher
- SAPDB
- Sybase
- Sunopsis XML Driver (JDBC Edition)
- Teradata Warehouse
- ThinkSQL RDBMS
- Vertica Analytic Database

SQuirreL SQL Client Plugin API

Plugin Basics

Introduction

SQuirreL SQL Client uses the JDBC API to interact with a database, which for the most part makes it database implementation-agnostic. However, it can be extended to support implementation-specific features by writing a plugin that uses the Plugin API. For example, JDBC doesn't specify a generic way to obtain the source code that can be used to re-create database objects such as triggers, stored procedures, functions, views, etc. Yet this information is usually available in some data dictionary view that can be queried by object name. Although the SQL standard specifies a special optional schema (INFORMATION_SCHEMA) to store this information in, only a few database vendors have implemented this, while others have chosen a different schema to store this information in. A plugin can be written with the implementation-specific queries that are required to retrieve the source code for each type of database object. Additionally, other plugins that are not implementation-specific have been written using the Plugin API to implement features not available in the base SQuirreL software installation (for example, code completion, syntax highlighting, Look and Feel, query favorites, etc.)

Plugin Loading

A plugin is made available to SQuirreL as a set of classes that are packaged into a jar file which is located in the plugins directory in the installation directory. SQuirrel uses a custom classloader to find and load jars containing plugins. The PluginManager is responsible for reading prefs.xml (as an XML-Bean) and for each plugin found, noting whether or not to load it according to the attribute called "loadAtStartup". If a plugin is added to the plugins directory, SQuirreL must be restarted to pick up the new plugin (Updated plugin definitions require a restart as well).

Session Lifecycle

Plugins can register to listen for session start/end events by implementing the ISessionPlugin interface and/or DefaultSessionPlugin base class. Sessions can be started and stopped by the user at will. Therefore, it is important for plugins that implement the ISessionPlugin interface (including those that extend DefaultSessionPlugin) to use care when storing references to Sessions. Specifically, if a plugin stores a reference to an ISession instance that it received in a call to sessionStarted (ISession session), it should remove that reference when it's sessionEnding (ISession session) is called. Otherwise, the Session can not be garbage collected, which is a memory leak.

Structural Customizations

Providing Source Tabs

Source tabs can be added for specific node types by using the IObjectTreeAPI interface. What follows is example of an implementation of the ISessionPlugin interface method called sessionStarted (ISession session)

```
    public PluginSessionCallback sessionStarted(final ISession session)
 {
        IObjectTreeAPI treeApi =
session.getSessionInternalFrame().getObjectTreeAPI();
        _treeAPI.addDetailTab(DatabaseObjectType.VIEW, new
ViewSourceTab("Source");
    }
```

A reference to every newly created Session can be obtained by implementing the sessionStarted method in the ISessionPlugin interface. Notice that the "ViewSourceTab" is only installed for DatabaseObjectType.VIEW objects. This is so that our implementation of a "view" source tab can rely on the fact that it's always a view that the user has selected. In this way, different source tabs can be implemented for each type of object (table, view, trigger, UDT, sequence, procedure, function, etc.)

A source tab can then be implemented by extending the classes:

```
net.sourceforge.squirrel_sql.client.session.mainpanel.objecttree.tabs.BaseSourceTab

net.sourceforge.squirrel_sql.client.session.mainpanel.objecttree.tabs.BaseSourcePanel
```

In particular, BaseSourceTab has an abstract method called createStatement which is implemented to return a PreparedStatement by using BaseObjectTab.getSession() and BaseObjectTab.getDatabaseObjectInfo(). The method getDatabaseObjectInfo returns the node that is selected from which can be found the name, schema and catalog of the object to write an SQL statement that queries the data dictionary for the source for that object. The BaseSourcePanel.load method is then called with the ResultSet obtained by executing the PreparedStatement.

Custom data type implementations

Data Type classes are used by SQuirreL to read, render and display data stored in a column of a database table. Type codes are assigned (by JDBC as well as vendors) to represent standard and vendor-specific SQL types. The standard types are defined in the various SQL standards (SQL92, SQL:2003). These include types such as DATE, VARCHAR, CHAR, etc.

SQuirreL defines the IDataTypeComponent interface which encapsulates behavior necessary to read, write and render data of a given type. The SQuirreL framework module (located in sql12/fw/src) includes many implementations of this interface. Some examples are DataTypeBlob, DataTypeChar, DataTypeFloat and DataTypeDate. These implementations can be used as examples when a plugin writer wishes to support a data types that are only found in one database.

The CellComponentFactory class has a static method called registerDataType that allows plugin writers to install custom IDataTypeComponent implementations when the plugin is loaded.

Behavioral Customizations

Changing How SQuirreL Tokenizes a Script into Individual Statements

Native database tools that are used to run scripts must have a way of breaking a script into statements. Since statements can span lines, the end of line character (eol) normally isn't used for this purpose. For example, Oracle uses the semi-colon (;), whereas Sybase and MS SQL-Server use the word "GO" to distinguish multiple statements in a script. Users don't want to change their scripts to work with SQuirreL, so it is important for a plugin writer to consider customizing SQuirreL's default expectation of ";" if that is indeed not the statement separator used by the native database script interpreter. Other examples that require custom handling are:

- Stored Procedures (These can have embedded statement separators and may use other characters for delimiters - for example Oracle uses slash (/)
- References to external scripts (Oracle uses "@<script_location" to pull in the contents of another script during execution)

Plugins should implement the interface IQueryTokenizer and call the method ISession.setQuerytokenizer to add this capability to SQuirreL.

Formatting Vendor-Extended SQLExceptions

With some JDBC drivers, SQLException is extended to provide "enhanced" reporting of errors. In this case, the SQLException that is thrown by the driver may be cast to the vendor-specific class and non-standard methods may be called to get more specific information about the problem that caused the SQLException to be thrown. For example, the DB2 Universal Database Driver provides a DB2Diagnosable exception which extends SQLException. In some cases, the database will provide information that is only available using the DB2Diagnosable interface methods. According to the documentation [1] SQLException must be cast to a DB2Diagnosable, then call getSqlca() to get a DB2Sqlca object upon which a call to getMessage() will give the error message such as "Table foo does not exist" - when the exception results from selecting from a non-existent table.

In order for SQuirreL to facilitate this vendor-specific API, a new plugin API was introduced, known as the ExceptionFormatter. Each Session can have exactly one custom ExceptionFormatter (default and one custom ExceptionFormatter). The ExceptionFormatter is installed by calling ISession.setExceptionFormatter. The ExceptionFormatter interface looks as follows:

```
    /**
     * Returns a boolean indicating whether or not this formatter can
format the
     * specified exception.
     *
     * @param t the exception to determine formatting compatibility
     *
     * @return a boolean value to indicate whether format should be
called on the
     *         given throwable
     */
    boolean formatsException(Throwable t);

    /**
     *
     * @param t the exception to be formatted
     *
     * @return the message
     */
    String format(Throwable t);
```

A custom ExceptionFormatter implementation should be reflective in that it shouldn't reference any database vendor-specific classes directly, but indirectly using Class.forName(). This is required so that merely installing the plugin without the requisite driver classes won't cause the app to experience ClassNotFoundExceptions while loading the plugin. It is not required that the ExceptionFormatter handle all Throwables. Whichever Throwables aren't handled by the custom ExceptionFormatter, will be handled by the default ExceptionFormatter called DefaultExceptionFormatter.

Component Access

Getting the Currently Selected ResultTab

1. When a session starts, save off a reference to the SessionManager:

```
    IApplication application = ISession.getApplication();
    SessionManager sessionManager = application.getSessionManager();
```

2. At some later point to get a reference to the currently selected result tab do the following:

```
    ISession currentSession = sessionManager.getActiveSession();
    ISQLPanelAPI sqlPanelApi =
currentSession.getSQLPanelAPIOfActiveSessionWindow();
    ISQLResultExecuter executer = sqlPanelApi.getSQLResultExecuter();
    IResultTab selectedResultTab = executer .getSelectedResultTab();
```

SQLPro SQL Client

SQLPro

Original author(s)	Vive Corp.
Stable release	2.0 / November 26, 2013
Operating system	Windows
Type	SQL Programming Tool, Programming tool, Database administration and automation
Website	[1] [1]

SQLPro is a proprietary, visual database management and development tool for multiple databases. SQLPro comes with a three-pane interface and has integrated SQL editor with many useful SQL editing features. SQLPro connects directly (using native drivers) to most popular database servers using one single interface. It supports native data source connection for Oracle, PostgreSQL, MySQL, Microsoft SQL Server, Microsoft Access and SQLite. Provides quick view of the database schema, table schema and results of the query execution.

Amenities include color-coding of the SQL, drag-and-drop of objects into the SQL pane to save you from typing their name, retrieval of SQL for things like stored procedures and triggers from the underlying database, and one-click creation of SELECT and INSERT statements. You can save SQL files and print result sets.

Feature Summary

- SQLPro runs on all 32-bit Windows platforms, including Windows 95, 98, NT, 2000, XP, and Vista.
- No specific hardware requirements.
- Color coding of SQL keywords
- Retrieve stored procedures, triggers and functions
- No other software or third party drivers to install. SQLPro comes with full set of drivers.
- Multiple host/database connections.

Supported Databases

- Microsoft Access
- Microsoft SQL Server
- MySQL
- Oracle 8i, 9i, 10g and 11g
- PostgreSQL
- SQLite

Navicat

Navicat

Original author(s)	PremiumSoft CyberTech Ltd.
Developer(s)	PremiumSoft CyberTech Ltd.
Initial release	2002
Operating system	Cross-platform
Available in	Multilingual (8)
Type	SQL database management and development system
License	Proprietary / Shareware
Website	www.navicat.com [1]

Navicat is a series of graphical database management and development software produced by PremiumSoft CyberTech Ltd. for MySQL, MariaDB, Oracle, SQLite, PostgreSQL and Microsoft SQL Server. It has an Explorer-like graphical user interface and supports multiple database connections for local and remote databases. Its design is made to meet the needs of a variety of audiences, from database administrators and programmers to various businesses/companies that serve clients and share information with partners.[2][3]

History

The initial version of Navicat was developed in 2001. The main target of the initial version was to simplify the management of MySQL installations. In 2008, Navicat for MySQL was the winner of the Hong Kong ICT 2008 *Award of the Year*, *Best Business Grand Award* and *Best Business (Product) Gold Award*.[4]

Supported platforms and languages

Navicat is a cross-platform tool and works on Microsoft Windows, Mac OS X and Linux platforms. Upon purchase, users are able to select a language for the software from eight available languages: English, French, Spanish, Japanese, Korean, Polish, Simplified Chinese and Traditional Chinese.

Development

Navicat for MySQL

Officially released in March 2002, the Windows version of Navicat for MySQL became the first product offered to the public by PremiumSoft. Subsequently, the company released two additional versions of Navicat for MySQL on the Mac OS X and Linux operating system in June and October 2003 respectively. In November 2013, added the support of MariaDB.[5][6]

Navicat for PostgreSQL

PremiumSoft continued to expand their Navicat series by releasing Navicat for PostgreSQL for Windows in October 2005 and then for Mac OS X in June 2006. The Linux version of Navicat for PostgreSQL would not be released until 3 years later in August 2009.[7]

Navicat for Oracle

In August 2008 Navicat decided to further continue their product line and branch out into the Oracle community, creating Navicat for Oracle for Windows and Mac. In August of the following year they followed up with a version for the Linux Platform.[8] The Oracle version of Navicat supports most of the latest Oracle objects features including Directory, Tablespace, Synonym, Materialized View, Trigger, Sequence, and Type, etc.[9][10]

Navicat for SQLite

Navicat for SQLite was released for Windows and Mac OS X simultaneously in April 2009, and the Linux version soon followed two months later in June of the same year.[11] In April 2010, Navicat Premium began including Navicat for SQLite starting from version 9 to expand the usability of Navicat Premium.[12]

Navicat Premium

In 2009, PremiumSoft released Navicat Premium, a series of Navicat software that combines all previous Navicat versions into a single version and can connect to different database types including MySQL, Oracle, and PostgreSQL simultaneously, allowing users to do data migration between cross databases. Navicat Premium version also supports cross-platform administration, serving Windows, Mac OS X and Linux. In April 2010, version 9 of Navicat Premium was released, which added the connectivity of SQLite database to Navicat Premium, allowing Navicat Premium to connect to MySQL, Oracle, PostgreSQL and SQLite in a single application. In November 2010, support for Microsoft SQL Server was added. In January 2011, SQL Azure was included. In November 2013, added the support of MariaDB.[13]

Navicat for SQL Server

Navicat for SQL Server was released in November 2010 for the Windows platform and Mac OS X. Also at the release, the SQL server version was included in the Premium version of Navicat. In January 2011, support for SQL Azure was added.[14]

Navicat Essentials

Navicat Essentials was officially released in November 2011. This is a simple Navicat version for commercial use. The Essentials editions of Navicat lack several features found in the Standard/Enterprise editions, including form view, record filtering, visual query building, data modeling and options for import, export and backup of data, etc.[15]

Navicat Data Modeler

Navicat Data Modeler Windows version was officially released in March 2012. Then, Mac OS X and Linux version were released in May 2012 and June 2012. This is a standalone product for developers to create data models for MySQL, SQL Server, Oracle, PostgreSQL and SQLite databases. Navicat Data Modeler allows users to visually design database structures, perform reverse/forward engineer process, import table structures from ODBC data sources, generate SQL files and print models to files, etc.

Navicat for MariaDB

MariaDB is currently the newest addition to the list of database Navicat supports. The new line of product, called Navicat for MariaDB, was released in November 2013 for the Windows, Mac OS X and Linux. It provides a native environment for MariaDB database management and supports the extra features like new storage engines, microsecond, virtual columns. Also at the release, the MariaDB version was included in both Navicat Premium and Navicat for MySQL.

Features

Navicat's features include:

- visual query-builder
- SSH and HTTP tunneling
- data and structure migration and synchronization[16]
- import and export and backup of data[17]
- report builder
- task scheduling and wizards tool

There are differences in the features available across operating systems.[18]

Navicat also supports forks of MySQL such as Drizzle, OurDelta, and Percona

Version History

Version	Platforms & Release dates							Some notable features
	MySQL	PostgreSQL	Oracle	SQLite	SQL Server	MariaDB	Premium	
4.x	• Windows: March 2002 • Mac OS X: June 2003 • Linux: No release	N/A	N/A	N/A	N/A	N/A	N/A	• Analyze, check, and repair tables • Visual user manager to administer users and privilege • Schedule backup file • Import and Export data from MS Excel and MS Access
5.x	• Windows: January 2003 • Mac OS X: January 2004 • Linux: September 2004	N/A	N/A	N/A	N/A	N/A	N/A	• Back up database and tables to SQL scripts • Execute SQL script • Multiple SQL editors with syntax highlighted feature
6.x	• Windows: April 2004 • Mac OS X: November 2005 • Linux: October 2005	• Mac OS X: June 2006	N/A	N/A	N/A	N/A	N/A	• Import data from ODBC • Connection to MySQL Server through SSH • Able to set schedule on profiles

7.x	• Windows: November 2005 • Mac OS X: November 2007	• Windows: October 2005 • Mac OS X: December 2007	• Mac OS X: August 2008	N/A	N/A	N/A	• Data and structure Synchronization • Able to drag and drop tables • Create parameter queries
8.x	• Windows: January 2008 • Mac OS X: February 2009 • Linux: January 2008	• Windows: January 2008 • Mac OS X: April 2009 • Linux: August 2009	• Windows: August 2008 • Mac OS X: April 2009 • Linux: August 2009	N/A	N/A	N/A	• Windows: June 2009 • Mac OS X: June 2009 • Linux: August 2009	• Virtual grouping • Server Monitor to change system variables • Allows form view • Able to preview SQL before execution
9.x	• Windows: April 2010 • Mac OS X: April 2010 • Linux: June 2010	• Windows: April 2010 • Mac OS X: April 2010 • Linux: June 2010	• Windows: April 2010 • Mac OS X: April 2010 • Linux: June 2010	• Windows: April 2010 • Mac OS X: April 2010 • Linux: June 2010	• Windows: November 2010 • Mac OS X: November 2010 • Linux: N/A	N/A	• Windows: April 2010 • Mac OS X: April 2010 • Linux: June 2010	• History log viewer • Allows unicode character reports • Import and export connections • Word completion for SQL editors
10.0	• Windows: September 2011 • Mac OS X: September 2011 • Linux: September 2011	• Windows: September 2011 • Mac OS X: September 2011 • Linux: September 2011	• Windows: September 2011 • Mac OS X: September 2011 • Linux: September 2011	• Windows: September 2011 • Mac OS X: September 2011 • Linux: September 2011	• Windows: September 2011 • Mac OS X: September 2011 • Linux: N/A	N/A	• Windows: September 2011 • Mac OS X: September 2011 • Linux: September 2011	• Data Modeling Tool • ER Diagram view • Database wide search • Minify SQL

10.1	• Windows: June 2012 • Mac OS X: June 2012 • Linux: June 2012	• Windows: June 2012 • Mac OS X: June 2012 • Linux: June 2012	• Windows: June 2012 • Mac OS X: June 2012 • Linux: June 2012	• Windows: June 2012 • Mac OS X: June 2012 • Linux: June 2012	• Windows: June 2012 • Mac OS X: June 2012 • Linux: N/A	N/A	• Windows: June 2012 • Mac OS X: June 2012 • Linux: June 2012	• Multiple schemas in one model • Enhanced Import from Database Wizard • Enhanced Synchronize to Database Wizard • Align/Distribute Diagram Objects • Search table in Model Designer
11.0	• Windows: April 2013 • Mac OS X: April 2013 • Linux: April 2013	• Windows: April 2013 • Mac OS X: April 2013 • Linux: April 2013	• Windows: April 2013 • Mac OS X: April 2013 • Linux: April 2013	• Windows: April 2013 • Mac OS X: April 2013 • Linux: April 2013	• Windows: April 2013 • Mac OS X: April 2013 • Linux: N/A	• Windows: November 2013 • Mac OS X: November 2013 • Linux: November 2013	• Windows: April 2013 • Mac OS X: April 2013 • Linux: April 2013	• New SSH Manager • Connection Tree Filter • Find and Replace data • Search Columns • Enhanced Import and Export Wizard • Native Windows and Mac 64-bit version

Navicat Community

Navicat Community provides a flexible environment for Navicat users to post questions, share experiences and solutions. It includes forum discussions, blog articles, tutorial videos and Wiki FAQ.

ModelRight

ModelRight is a database design and data modeling tool developed by ModelRight Inc. It is used by data modelers, database developers and database architects to create, visualize, and document their databases as an Entity Relationship Diagram (ERD).

Features

- Reverse Engineer an existing database
- Generate SQL DDL to create a database
- Compare a data model and a database
- Compare a data model with another data model
- Document a database with notes, definitions, and revision notes
- Automation and scripting support
- Model subset management
- Generate HTML reports
- Supports large, complex data modeling and data warehousing projects
- Generate model contents as XML

Support

- IDEF1X
- Information Engineering (IE)/Crow's Foot Notation
- UML Class Diagrams
- Barker Notation

MySQL

MySQL

Screenshot of the default MySQL command line

Original author(s)	MySQL AB
Developer(s)	Oracle Corporation
Initial release	23 May 1995
Stable release	5.6.16 / 31 January 2014
Preview release	5.7.3 / 3 December 2013
Development status	Active
Written in	C, C++
Operating system	Windows, Linux, Solaris, OS X, FreeBSD
Available in	English
Type	RDBMS
License	GPL (version 2) or commercial[1]
Website	www.mysql.com [2]

MySQL (/maɪHelp:IPA for English#Key ˌɛskjuːˈɛl/ "My S-Q-L", officially, but also called /maɪHelp:IPA for English#Key ˈsiːkwəl/ "My Sequel") is (as of July 2013) the world's second most[3] In the second quarter of 2013 alone, 213 million smartphones shipped, of which 200 million were Android and iOS.</ref> widely used open-source relational database management system (RDBMS). It is named after co-founder Michael Widenius's daughter, My. The SQL phrase stands for Structured Query Language.

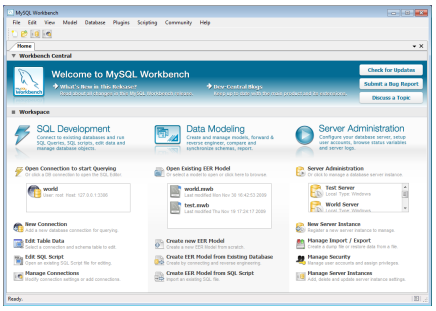
The MySQL development project has made its source code available under the terms of the GNU General Public License, as well as under a variety of proprietary agreements. MySQL was owned and sponsored by a single for-profit firm, the Swedish company MySQL AB, now owned by Oracle Corporation.

MySQL is a popular choice of database for use in web applications, and is a central component of the widely used LAMP open source web application software stack (and other 'AMP' stacks). LAMP is an acronym for "Linux, Apache, MySQL, Perl/PHP/Python." Free-software-open source projects that require a full-featured database management system often use MySQL.

For commercial use, several paid editions are available, and offer additional functionality. Applications which use MySQL databases include: TYPO3, MODx, Joomla, WordPress, phpBB, MyBB, Drupal and other software. MySQL is also used in many high-profile, large-scale websites, including Wikipedia, Google (though not for searches), Facebook, Twitter, Flickr, and YouTube.

Interfaces

MySQL is a relational database management system (RDBMS), and ships with no GUI tools to administer MySQL databases or manage data contained within the databases. Users may use the included command line tools,[4][5] or use MySQL "front-ends", desktop software and web applications that create and manage MySQL databases, build database structures, back up data, inspect status, and work with data records.[6][7][8][9] The official set of MySQL front-end tools, MySQL Workbench is actively developed by Oracle, and is freely available for use.[10]



MySQL Workbench in Windows

Graphical

The official MySQL Workbench is a free integrated environment developed by MySQL AB, that enables users to graphically administer MySQL databases and visually design database structures. MySQL Workbench replaces the previous package of software, MySQL GUI Tools. Similar to other third-party packages, but still considered the authoritative MySQL front end, MySQL Workbench lets users manage database design & modeling, SQL development (replacing MySQL Query Browser) and Database administration (replacing MySQL Administrator).

MySQL Workbench is available in two editions, the regular free and open source *Community Edition* which may be downloaded from the MySQL website, and the proprietary *Standard Edition* which extends and improves the feature set of the Community Edition.

Third-party proprietary and free graphical administration applications (or "front ends") are available that integrate with MySQL and enable users to work with database structure and data visually. Some well-known front ends, in alphabetical order, are:

- Adminer – a free MySQL front end written in one PHP script, capable of managing multiple databases, with many CSS skins available.
- DaDaBIK – a customizable CRUD front-end to MySQL. Written in PHP. Commercial.
- DBEdit – a free front end for MySQL and other databases.
- HeidiSQL – a full featured free front end that runs on Windows, and can connect to local or remote MySQL servers to manage databases, tables, column structure, and individual data records. Also supports specialised GUI features for date/time fields and enumerated multiple-value fields.
- LibreOffice Base – LibreOffice Base allows the creation and management of databases, preparation of forms and reports that provide end users easy access to data. Like Microsoft Access, it can be used as a front-end for various database systems, including Access databases (JET), ODBC data sources, and MySQL or PostgreSQL.
- Navicat – a series of proprietary graphical database management applications, developed for Windows, Macintosh and Linux.
- OpenOffice.org – OpenOffice.org Base can manage MySQL databases if the entire suite is installed. Free and open-source.
- phpMyAdmin – a free Web-based front end widely installed[*citation needed*] by web hosts, since it is developed in PHP and is included in the LAMP stack, MAMP, XAMPP and WAMP software bundle installers.
- SQLBuddy – a free Web-based front end, developed in PHP.
- SQLyog – commercial, but there is also a free 'community' edition available.
- Toad for MySQL – a free development and administration front end for MySQL from Quest Software

Other available proprietary MySQL front ends include dbForge Studio for MySQL, DBStudio, Epictetus, Microsoft Access, Oracle SQL Developer, SchemaBank, SQLPro SQL Client, Toad Data Modeler.

Command line

MySQL ships with many command line tools, from which the main interface is 'mysql' client. Third-parties have also developed tools to manage, optimize, monitor and backup a MySQL server, some listed below. All these tools work on *NIX type operating systems, and some of them also on Windows.

- Maatkit – a cross-platform toolkit for MySQL, PostgreSQL and Memcached, developed in Perl. Maatkit can be used to prove replication is working correctly, fix corrupted data, automate repetitive tasks, and speed up servers. Maatkit is included with several Linux distributions such as CentOS and Debian and packages are available for Fedora and Ubuntu as well. As of late 2011, Maatkit is no longer developed, but Percona has continued development under the Percona Toolkit brand.[11]
- XtraBackup – Open Source MySQL hot backup software. Some notable features include hot, non-locking backups for InnoDB storage, incremental backups, streaming, parallel-compressed backups, throttling based on the number of IO operations per second, etc.
- MySQL::Replication – a replacement for MySQL's built-in replication, developed in Perl. MySQL::Replication can be used to create a peer-to-peer, multi-master MySQL replication network.
- SymmetricDS – asynchronous MySQL multi-master replication capable of multi-tier replication and designed for a large number of databases across low-bandwidth connections. Licensed as open source (GPL) with commercial options from JumpMind.

Programming

MySQL works on many system platforms, including AIX, BSDi, FreeBSD, HP-UX, eComStation, i5/OS, IRIX, Linux, OS X, Microsoft Windows, NetBSD, Novell NetWare, OpenBSD, OpenSolaris, OS/2 Warp, QNX, Solaris, Symbian, SunOS, SCO OpenServer, SCO UnixWare, Sanos and Tru64. A port of MySQL to OpenVMS also exists.

MySQL is written in C and C++. Its SQL parser is written in yacc, but it uses a home-brewed lexical analyzer. Many programming languages with language-specific APIs include libraries for accessing MySQL databases. These include MySQL Connector/Net for integration with Microsoft's Visual Studio (languages such as C# and VB are most commonly used) and the JDBC driver for Java. In addition, an ODBC interface called MyODBC allows additional programming languages that support the ODBC interface to communicate with a MySQL database, such as ASP or ColdFusion. The HTSQL – URL-based query method also ships with a MySQL adapter, allowing direct interaction between a MySQL database and any web client via structured URLs.

Features

As of April 2009[12], MySQL offered MySQL 5.1 in two different variants: the open source MySQL Community Server and the commercial Enterprise Server. MySQL 5.5 is offered under the same licenses. They have a common code base and include the following features:

- A broad subset of ANSI SQL 99, as well as extensions
- Cross-platform support
- Stored procedures, using a procedural language that closely adheres to SQL/PSM
- Triggers
- Cursors
- Updatable views
- Information schema
- Strict mode (ensures MySQL does not truncate or otherwise modify data to conform to an underlying data type, when an incompatible value is inserted into that type)
- X/Open XA distributed transaction processing (DTP) support; two phase commit as part of this, using Oracle's InnoDB engine

- Independent storage engines (MyISAM for read speed, InnoDB for transactions and referential integrity, MySQL Archive for storing historical data in little space)
- Transactions with the InnoDB and NDB Cluster storage engines; savepoints with InnoDB
- SSL support
- Query caching
- Sub-SELECTs (i.e. nested SELECTs)
- Replication support (i.e. Master-Master Replication & Master-Slave Replication) with one master per slave, many slaves per master. Multi-master replication is provided in MySQL Cluster, and multi-master support can be added to unclustered configurations using Galera Cluster.
- Full-text indexing and searching using MyISAM engine
- Embedded database library
- Unicode support (however prior to 5.5.3 UTF-8 and UCS-2 encoded strings are limited to the BMP, in 5.5.3 and later use utf8mb4 for full unicode support)
- ACID compliance when using transaction capable storage engines (InnoDB and Cluster)
- Partitioned tables with pruning of partitions in optimizer
- Shared-nothing clustering through MySQL Cluster
- Hot backup (via `mysqlhotcopy`) under certain conditions
- Multiple storage engines, allowing one to choose the one that is most effective for each table in the application (in MySQL 5.0, storage engines must be compiled in; in MySQL 5.1, storage engines can be dynamically loaded at run time):
  - Native storage engines (MyISAM, Falcon, Merge, Memory (heap), Federated, Archive, CSV, Blackhole, Cluster, EXAMPLE, Aria, and InnoDB, which was made the default as of 5.5)
  - Partner-developed storage engines (solidDB, Infobright (formerly Brighthouse), Kickfire, XtraDB, IBM DB2). InnoDB used to be a partner-developed storage engine, but with recent acquisitions, Oracle now owns both MySQL core and InnoDB.
  - Community-developed storage engines (memcache engine, httpd, PBXT, Revision Engine)
  - Custom storage engines
- Commit grouping, gathering multiple transactions from multiple connections together to increase the number of commits per second. (PostgreSQL has an advanced form of this functionality)

The developers release monthly versions of the MySQL Server. The sources can be obtained from MySQL's website or from MySQL's Bazaar repository, both under the GPL license.

Limitations

Like other SQL databases, MySQL does not currently comply with the full SQL standard for some of the implemented functionality, including foreign key references when using some storage engines other than the 'standard' InnoDB (or third-party engines which supports foreign keys).

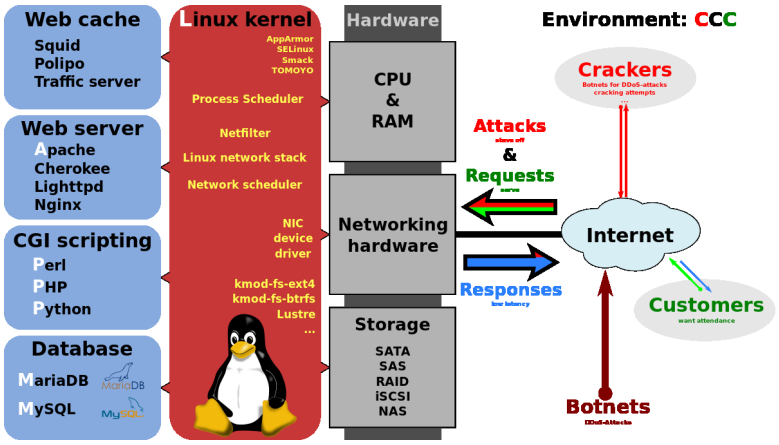
Triggers are currently limited to one per action / timing, i.e. maximum one after insert and one before insert on the same table. There are no triggers on views.

MySQL, like most other transactional relational databases, is strongly limited by hard disk performance. This is especially true in terms of write latency. Given the recent appearance of very affordable consumer grade SATA interface solid-state drives that offer zero mechanical latency, a fivefold speedup over even an eight drive RAID array can be had for a smaller investment.[13]

MySQL database's inbuilt functions like UNIX_TIMESTAMP() will return 0 after 03:14:07 UTC on 19 January 2038.

Deployment

MySQL can be built and installed manually from source code, but this can be tedious so it is more commonly installed from a binary package unless special customizations are required. On most Linux distributions the package management system can download and install MySQL with minimal effort, though further configuration is often required to adjust security and optimization settings.



The LAMP software bundle (here additionally with Squid). A high performance and high-availability solution for a hostile environment

Though MySQL began as a low-end alternative to more powerful proprietary databases, it has gradually evolved to support higher-scale needs as well. It is still most commonly used in small to medium scale single-server deployments, either as a component in a LAMP-based web application or as a standalone database server. Much of MySQL's appeal originates in its relative simplicity and ease of use, which is enabled by an ecosystem of open source tools such as phpMyAdmin. In the medium range, MySQL can be scaled by deploying it on more powerful hardware, such as a multi-processor server with gigabytes of memory.

There are however limits to how far performance can scale on a single server ('scaling up'), so on larger scales, multi-server MySQL ('scaling out') deployments are required to provide improved performance and reliability. A typical high-end configuration can include a powerful master database which handles data write operations and is replicated to multiple slaves that handle all read operations. The master server synchronizes continually with its slaves so in the event of failure a slave can be promoted to become the new master, minimizing downtime. Further improvements in performance can be achieved by caching the results from database queries in memory using memcached, or breaking down a database into smaller chunks called shards which can be spread across a number of distributed server clusters.

High availability

Ensuring high availability requires a certain amount of redundancy in the system. For database systems, the redundancy traditionally takes the form of having a primary server acting as a master, and using replication to keep secondaries available to take over in case the primary fails. This means that the "server" that the application connects to is in reality a collection of servers, not a single server. In a similar manner, if the application is using a sharded database, it is in reality working with a collection of servers, not a single server. In this case, a collection of servers is usually referred to as a *farm*.

One of the projects aiming to provide high availability for MySQL is *MySQL Fabric*, an integrated system for managing a collection of MySQL servers, and a framework on top of which high availability and database sharding is built. MySQL Fabric is open-source and is intended to be extensible, easy to use, and to support procedure execution even in the presence of failure, providing an execution model usually called *resilient execution*. MySQL client libraries are extended so they are hiding the complexities of handling failover in the event of a server failure, as well as correctly dispatching transactions to the shards. As of September 2013, there is currently support for Fabric-aware versions of Connector/J, Connector/PHP, Connector/Python, as well as some rudimentary support for Hibernate and Doctrine. As of March 2014, MySQL Fabric is in a beta stage of development.

Cloud deployment

MySQL can also be run on cloud computing platforms such as Amazon EC2. Listed below are some common deployment models for MySQL on the cloud:

- Virtual Machine Image – cloud users can upload a machine image of their own with MySQL installed, or use a ready-made machine image with an optimized installation of MySQL on it, such as the one provided by Amazon EC2.
- MySQL as a Service – some cloud platforms offer MySQL "as a service". In this configuration, application owners do not have to install and maintain the MySQL database on their own. Instead, the database service provider takes responsibility for installing and maintaining the database, and application owners pay according to their usage. Notable cloud-based MySQL services are the Amazon Relational Database Service; the Xeround Cloud Database, which runs on EC2; Rackspace; HP Converged Cloud; Heroku and Jelastic.
- Managed MySQL cloud hosting – the database is not offered as a service, but the cloud provider hosts the database and manages it on the application owner's behalf. As of 2011, of the major cloud providers, only Terremark and Rackspace offer managed hosting for MySQL databases.

Community

The MySQL server software itself and the client libraries use dual-licensing distribution. They are offered under GPL version 2, beginning from 28 June 2000 (which in 2009 has been extended with a FLOSS License Exception) or to use a proprietary license. In 2013, the Linux man pages for MySQL switched to a proprietary license temporarily due to a build system bug. The original GPL license has since been restored.

Support can be obtained from the official manual.[14] Free support additionally is available in different IRC channels and forums. Oracle offers paid support via its MySQL Enterprise products. They differ in the scope of services and in price. Additionally, a number of third party organisations exist to provide support and services, including SkySQL Ab and Percona.

MySQL has received positive reviews, and reviewers noticed it "performs extremely well in the average case." and that the "developer interfaces are there, and the documentation (not to mention feedback in the real world via Web sites and the like) is very, very good".[15] It has also been tested to be a "fast, stable and true multi-user, multi-threaded sql database server".[16]

Related projects

- Drizzle – a fork targeted at the web-infrastructure and cloud computing markets. The developers of the product describe it as a "smaller, slimmer and (hopefully) faster version of MySQL". As a result, many common MySQL features will be stripped out, including stored procedures, query cache, prepared statements, views, and triggers. This is a partial rewrite of the server that does not maintain compatibility with MySQL.
- MariaDB – a community-developed fork of the MySQL database source code, the impetus being the community maintenance of its free status under GPL as opposed to any uncertainty of MySQL license status under its current ownership by Oracle. The intent also being to maintain high fidelity with MySQL, ensuring a "drop-in" replacement capability with library binary equivalency and exact matching with MySQL APIs and commands. It includes the XtraDB storage engine as a replacement for InnoDB.
- Percona Server – a fork of MySQL that includes the XtraDB storage engine. Its policy is to deviate as little as possible from MySQL and remain fully compatible, while providing new features, better performance, and additional instrumentation for analysis of performance and usage.
- OurDelta – No longer maintained. It was a fork compiled with various patches, including patches from MariaDB, Percona, and Google, and a storage engine called OQGRAPH.

History

MySQL was created by a Swedish company, MySQL AB, founded by David Axmark, Allan Larsson and Michael "Monty" Widenius. The first version of MySQL appeared on 23 May 1995. It was initially created for personal usage from mSQL based on the low-level language ISAM, which the creators considered too slow and inflexible. They created a new SQL interface, while keeping the same API as mSQL. By keeping the API consistent with the mSQL system, many developers were able to use MySQL instead of the (commercially licensed) mSQL antecedent.[*citation needed*]Wikipedia:Disputed statement

Legal and acquisition impacts

On 15 June 2001, NuSphere sued MySQL AB, TcX DataKonsult AB and its original authors Michael ("Monty") Widenius and David Axmark in U.S District Court in Boston for "breach of contract, tortious interference with third party contracts and relationships and unfair competition".

In 2002, MySQL AB sued Progress NuSphere for copyright and trademark infringement in United States district court. NuSphere had allegedly violated MySQL's copyright by linking MySQL's GPL'ed code with NuSphere Gemini table without being in compliance with the license. After a preliminary hearing before Judge Patti Saris on 27 February 2002, the parties entered settlement talks and eventually settled. After the hearing, FSF commented that "Judge Saris made clear that she sees the GNU GPL to be an enforceable and binding license."

In October 2005, Oracle Corporation acquired Innobase OY, the Finnish company that developed the third-party InnoDB storage engine that allows MySQL to provide such functionality as transactions and foreign keys. After the acquisition, an Oracle press release mentioned that the contracts that make the company's software available to MySQL AB would be due for renewal (and presumably renegotiation) some time in 2006. During the MySQL Users Conference in April 2006, MySQL issued a press release that confirmed that MySQL and Innobase OY agreed to a "multi-year" extension of their licensing agreement.

In February 2006, Oracle Corporation acquired Sleepycat Software, makers of the Berkeley DB, a database engine providing the basis for another MySQL storage engine. This had little effect, as Berkeley DB was not widely used, and was dropped (due to lack of use) in MySQL 5.1.12, a pre-GA release of MySQL 5.1 released in October 2006.

In January 2008, Sun Microsystems bought MySQL for $1 billion.

In April 2009, Oracle Corporation entered into an agreement to purchase Sun Microsystems, then owners of MySQL copyright and trademark. Sun's board of directors unanimously approved the deal, it was also approved by Sun's shareholders, and by the U.S. government on 20 August 2009. On 14 December 2009, Oracle pledged to continue to enhance MySQL as it had done for the previous four years.

A movement against Oracle's acquisition of MySQL, to "Save MySQL" from Oracle was started by one of the MySQL founders, Monty Widenius. The petition of 50,000+ developers and users called upon the European Commission to block approval of the acquisition. At the same time, several Free Software opinion leaders (including Eben Moglen, Pamela Jones of Groklaw, Jan Wildeboer and Carlo Piana, who also acted as co-counsel in the merger regulation procedure) advocated for the unconditional approval of the merger.[*citation needed*] As part of the negotiations with the European Commission, Oracle committed that MySQL server will continue until at least 2015 to use the dual-licensing strategy long used by MySQL AB, with commercial and GPL versions available. The antitrust of the EU had been "pressuring it to divest MySQL as a condition for approval of the merger". But, as revealed by Wikileaks, the US Department of Justice and Antitrust, at the request of Oracle, pressured the EU to unconditionally approve the merger. The European Commission eventually unconditionally approved Oracle's acquisition of MySQL on 21 January 2010.

In January 2009, prior to Oracle's acquisition of MySQL, Monty Widenius started a GPL-only fork, MariaDB. MariaDB is based on the same code base as MySQL server 5.1 and strives to maintain compatibility with Oracle-provided versions.

In August 2012, TechCrunch's Alex Williams reported that Oracle was holding back MySQL Server test cases, a move that he concluded indicated that Oracle is attempting to kill the product. Percona also reported that Oracle is no longer synchronizing their changes with the public source repositories. Widenius called this a breach of the agreement that Oracle entered into with the EU as a condition of their acquisition of Sun.

Since the final quarter of 2012, several Linux distributions and some important users (like Wikipedia[17] and Google[18]) started to replace MySQL with MariaDB.[19][20][21]Wikipedia:Disputed statement

Milestones

Notable milestones in MySQL development include:

- Original development of MySQL by Michael Widenius and David Axmark beginning in 1994
- First internal release on 23 May 1995
- Version 3.19: End of 1996, from www.tcx.se
- Version 3.20: January 1997
- Windows version was released on 8 January 1998 for Windows 95 and NT
- Version 3.21: production release 1998, from www.mysql.com
- Version 3.22: alpha, beta from 1998
- Version 3.23: beta from June 2000, production release 22 January 2001
- Version 4.0: beta from August 2002, production release March 2003 (unions)
- Version 4.01: beta from August 2003, JyotiWikipedia:Please clarify[*citation needed*] adopts MySQL for database tracking
- Version 4.1: beta from June 2004, production release October 2004 (R-trees and B-trees, subqueries, prepared statements)
- Version 5.0: beta from March 2005, production release October 2005 (cursors, stored procedures, triggers, views, XA transactions)

  The developer of the Federated Storage Engine states that "The Federated Storage Engine is a proof-of-concept storage engine", but the main distributions of MySQL version 5.0 included it and turned it on by default. Documentation of some of the short-comings appears in "MySQL Federated Tables: The Missing Manual".
- Sun Microsystems acquired MySQL AB in 2008.
- Version 5.1: production release 27 November 2008 (event scheduler, partitioning, plugin API, row-based replication, server log tables)

  Version 5.1 contained 20 known crashing and wrong result bugs in addition to the 35 present in version 5.0 *(almost all fixed as of release 5.1.51)*.

  MySQL 5.1 and 6.0 showed poor performance when used for data warehousing — partly due to its inability to utilize multiple CPU cores for processing a single query.
- Oracle acquired Sun Microsystems on 27 January 2010.
- MySQL Server 5.5 is currently generally available (as of December 2010[12]). Enhancements and features include:
  - The default storage engine is InnoDB, which supports transactions and referential integrity constraints.
  - Improved InnoDB I/O subsystem
  - Improved SMP support
  - Semisynchronous replication.
  - SIGNAL and RESIGNAL statement in compliance with the SQL standard.
  - Support for supplementary Unicode character sets utf16, utf32, and utf8mb4.
  - New options for user-defined partitioning.

MySQL Server 6.0.11-alpha was announced on 22 May 2009 as the last release of the 6.0 line. Future MySQL Server development uses a New Release Model. Features developed for 6.0 are being incorporated into future releases.

MySQL 5.6, a development milestone release, was announced at the MySQL users conference 2011. New features include performance improvements to the query optimizer, higher transactional throughput in InnoDB, new NoSQL-style memcached APIs, improvements to partitioning for querying and managing very large tables, improvements to replication and better performance monitoring by expanding the data available through the PERFORMANCE_SCHEMA. In July further previews with a BINLOG API, group commit, and InnoDB full text searching were released.

SQL Anywhere

SAP SQL Anywhere is a relational database management system (RDBMS) product from SAP. SQL Anywhere was known as Sybase SQL Anywhere prior to the acquisition of Sybase by SAP.

Features

SQL Anywhere can be run on Windows, Windows CE, Mac OS X, and various UNIX platforms, including Linux, AIX, HP-UX and Solaris. Database files are independent of the operating system, allowing them to be copied between supported platforms. The product provides several standard interfaces (ODBC, JDBC, and ADO.NET) and a number of special interfaces such as PHP and Perl. The engine supports stored procedures, user functions (using Watcom SQL, T-SQL, Java, or C/C++), triggers, referential integrity, row-level locking, replication, high availability, proxy tables, and events (scheduled and system events). Strong encryption is supported for both database files and client-server communication.

Uses

SQL Anywhere is used in several contexts, including as an embedded database, particularly as an application data store. For example, it is used in Intuit QuickBooks, in network management products, and in backup products. Its ability to be used with minimal administration is a distinguishing feature in this role. It can be used as a database server for work groups or for small or medium-sized businesses. It can also function as a mobile database. It includes scalable data synchronization technology that provides change-based replication between separate databases, including large server-based RDBMS systems.

Technologies

SQL Anywhere Server is a high performing and embeddable relational database-management system (RDBMS) that scales from thousands of users in server environments down to desktop and mobile applications used in widely deployed, zero-administration environments.

Ultralite: UltraLite is a database-management system designed for small-footprint mobile devices such as PDAs and smart phones.

Mobilink: MobiLink is a highly-scalable, session-based synchronization technology for exchanging data among relational databases and other non-relational data sources.

QAnywhere: QAnywhere facilitates the development of robust and secure store-and-forward mobile messaging applications.

SQL Remote: SQL Remote technology is based on a store and forward architecture that allows occasionally connected users to synchronize data between SQL Anywhere databases using a file or message transfer mechanism.

History

- Initially created by Watcom as Watcom SQL.
- Version 3: 1992
- Watcom acquired by Powersoft in 1993; Watcom SQL shipped with their visual programming environment PowerBuilder
- Version 4: 1994 (Stored procedures, triggers)
- PowerSoft and Sybase merged in 1995: Watcom SQL was renamed **SQL Anywhere**.
- Version 5: 1995 (SQL Remote data replication; graphical administration tools)
- Version 6: 1998. Renamed **Adaptive Server Anywhere**. (multi-processor support, Java objects in the database)
- Version 6.0.2: 1999 (MobiLink data synchronization, UltraLite mobile database for Palm OS and Windows CE)
- Version 7: 2000 (dynamic cache, task scheduling and event handling, cross-platform administration tools)
- Version 8: 2001 (Volcano query optimizer, encrypted data storage and transmission)
- Version 9: 2003 (Index consultant, embedded HTTP server)
- Version 10: 2006 - renamed **SQL Anywhere** (high availability, intra-query parallelism, materialized views)
- Version 11: 2008 (full text search, BlackBerry support)
- Version 12: 2010 (support for spatial data)[1]
- Version 16: April 18, 2013 - (faster synchronization and improved security) [2]

SQLite

SQLite

Developer(s)	D. Richard Hipp
Initial release	August 2000
Stable release	3.8.4 (March 10, 2014) [±] [1]
Written in	C
Operating system	Cross-platform
Size	658 KiB
Type	RDBMS (embedded)
License	Public domain
Website	sqlite.org [2]

SQLite (/ˌɛskjuːɛlˈlaɪt/ or /ˈsiːkwəl.laɪt/) is a relational database management system contained in a C programming library. In contrast to other database management systems, SQLite is not a separate process that is accessed from the client application, but an integral part of it.

SQLite is ACID-compliant and implements most of the SQL standard, using a dynamically and weakly typed SQL syntax that does not guarantee the domain integrity.

SQLite is a popular choice as embedded database for local/client storage in application software such as web browsers. It is arguably the most widely deployed database engine, as it is used today by several widespread browsers, operating systems, and embedded systems, among others. SQLite has many bindings to programming languages.

The source code for SQLite is in the public domain.

Design

Unlike client–server database management systems, the SQLite engine has no standalone processes with which the application program communicates. Instead, the SQLite library is linked in and thus becomes an integral part of the application program. (In this, SQLite follows the precedent of Informix SE of c. 1984 [3]) The library can also be called dynamically. The application program uses SQLite's functionality through simple function calls, which reduce latency in database access: function calls within a single process are more efficient than inter-process communication. SQLite stores the entire database (definitions, tables, indices, and the data itself) as a single cross-platform file on a host machine. It implements this simple design by locking the entire database file during writing. SQLite read operations can be multitasked, though writes can only be performed sequentially.

History

D. Richard Hipp designed SQLite in the spring of 2000 while working for General Dynamics on contract with the United States Navy. Hipp was designing software used on board guided missile destroyers, which were originally based on HP-UX with an IBM Informix database back-end. The design goals of SQLite were to allow the program to be operated without installing a database management system or requiring a database administrator. In August 2000, version 1.0 of SQLite was released, based on gdbm (GNU Database Manager). SQLite 2.0 replaced gdbm with a custom B-tree implementation, adding support for transactions. SQLite 3.0, partially funded by America Online, added internationalization, manifest typing, and other major improvements.

In 2011 Hipp announced his plans to add an UnQL interface to SQLite databases and to develop *UnQLite*, an embeddable document-oriented database. Howard Chu ported SQLite 3.7.7.1 to use Openldap MDB instead of the original Btree code and called it sqlightning. One cited insert test of 1000 records was 20 times faster.[4][5]

Features

SQLite implements most of the SQL-92 standard for SQL but it lacks some features. For example it has partial support for triggers, and it can't write to views (however it supports INSTEAD OF triggers that provide this functionality). While it supports complex queries, it still has limited ALTER TABLE support, as it can't modify or delete columns.

SQLite uses an unusual type system for an SQL-compatible DBMS; instead of assigning a type to a column as in most SQL database systems, types are assigned to individual values; in language terms it is *dynamically typed*. Moreover, it is *weakly typed* in some of the same ways that Perl is: one can insert a string into an integer column (although SQLite will try to convert the string to an integer first, if the column's preferred type is integer). This adds flexibility to columns, especially when bound to a dynamically typed scripting language. However, the technique is not portable to other SQL products. A common criticism is that SQLite's type system lacks the data integrity mechanism provided by statically typed columns in other products. The SQLite web site describes a "strict affinity" mode, but this feature has not yet been added. However, it can be implemented with constraints like `CHECK(typeof(x)='integer')`.

Several computer processes or threads may access the same database concurrently. Several read accesses can be satisfied in parallel. A write access can only be satisfied if no other accesses are currently being serviced. Otherwise, the write access fails with an error code (or can automatically be retried until a configurable timeout expires). This concurrent access situation would change when dealing with temporary tables. This restriction is relaxed in version 3.7 when WAL is turned on enabling concurrent reads and writes.

A standalone program called `sqlite3` is provided that can be used to create a database, define tables within it, insert and change rows, run queries and manage an SQLite database file. This program is a single executable file on the host machine. It also serves as an example for writing applications that use the SQLite library.

SQLite full Unicode support is optional.

SQLite has automated regression testing prior to each release. Over 2 million tests are run as part of a release's verification. Starting with the August 10, 2009 release of SQLite 3.6.17, SQLite releases have 100% branch test coverage, one of the components of code coverage.

As of version 3.8.2 it's possible to create tables without rowid.[6]

Development

SQLite development stores revisions of its source code in Fossil, a distributed version control system that is itself built upon an SQLite database.

Adoption

Programming languages

SQLite has bindings for a large number of programming languages, including :

• BASIC	• Haskell	• PureBasic
• Delphi	• Java	• Python[7]
• C	• JavaScript[8]	• R
• C#	• Livecode	• REALbasic
• C++	• Lua	• REBOL
• Clipper//Harbour	• newLisp	• Ruby[9]
• Common Lisp	• Objective-C (on OS X and iOS)	• Scheme
• Curl	• OCaml	• Smalltalk
• D	• Perl[10]	• Tcl
• Free Pascal	• PHP	• Visual Basic
	• Pike	

Middleware

- ADO.NET adapter, initially developed by Robert Simpson, is maintained jointly with the SQLite developers since April 2010.[11]
- ODBC driver has been developed and is maintained separately by Christian Werner.[12] Werner's ODBC driver is the recommended connection method for accessing SQLite from OpenOffice.org.[13]
- COM (ActiveX) wrapper making SQLite accessible on Windows to scripted languages such as JScript and VBScript. This adds database capabilities to HTML Applications (HTA).

Web browsers

- Mozilla Firefox and Mozilla Thunderbird store a variety of configuration data (bookmarks, cookies, contacts etc.) in internally managed SQLite databases, and even offer an add-on to manage SQLite databases.
- Google's Chrome browser
- The Opera Internet suite and browser uses SQLite 3.7.9 for managing WebSQL databases. This is noted in `opera:about`, although without the mention of WebSQL (databases can be managed through `opera:webdatabases`).

Web application frameworks

- Django, a Python web framework, supports SQLite3 by default.
- As of version 7, Drupal, a PHP-based content management system for making websites and blogs, has an option to install using SQLite.
- Ruby on Rails' default database management system is also SQLite.
- web2py, a Python web framework, default database management system is also SQLite.

Various

- Skype is a widely deployed application that uses SQLite.
- Adobe Systems uses SQLite as its file format in Adobe Photoshop Lightroom, a standard database in Adobe AIR, and internally within Adobe Reader.
- The Service Management Facility, used for service management within the Solaris and OpenSolaris operating systems, uses SQLite internally.
- Flame, a malware program used for cyberespionage, used SQLite to store the data it collects.
- The Xojo Programming Language has SQLite support built in to both the desktop and web frameworks.

Operating systems

Because of its small size, SQLite is well suited to embedded systems, and is also included in:

- Blackberry's BlackBerry 10 OS
- Microsoft's Windows Phone 8
- Apple's iOS
- Symbian OS
- Nokia's Maemo
- Google's Android
- Linux Foundation's MeeGo
- LG's webOS
- NetBSD
- OpenBSD
- FreeBSD where starting with 10-RELEASE version it is the core package management system.

However, it is also suitable for desktop operating systems; Apple adopted it as an option in OS X's Core Data API from the original implementation in Mac OS X 10.4 onwards, and also for administration of videos and songs on the iPhone.

SESAM (database)

SESAM / SQL Server is a relational database system developed by Fujitsu Technology Solutions. It runs on the BS2000/OSD mainframe. Endpoint clients running on BS2000/OSD, UNIX systems, Solaris, Linux and Microsoft Windows are possible.

Features

- Support for SQL3
- Data can be stored in EBCDIC and Unicode
- Cost-based optimizer
- Maintenance is possible during operation
- Table partitioning
- Multi-platform support
- Apache web-server integration

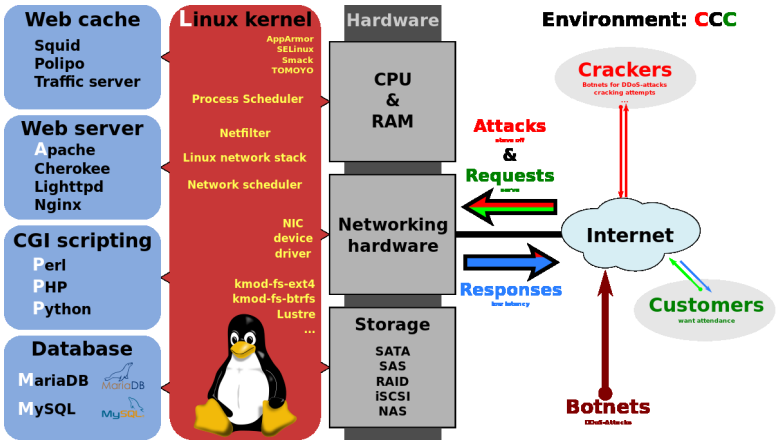
LAMP

The acronym **LAMP** refers to first letters of the four components of a solution stack, composed entirely of free and open-source software, suitable for building high-availability heavy-duty dynamic web sites, and capable of serving tens of thousands of requests simultaneously.



The LAMP, LYME and LYCE software bundles, displayed here together with Squid. High-performance and high-availability web server solutions providing security in hostile environments.

The meaning of the LAMP acronym depends on which specific components are used as part of the actual bundle:

- **L**inux, the operating system (i.e. not just the Linux kernel, but also glibc and some other essential components of an operating system)
- **A**pache HTTP Server, the web server
- **M**ySQL, **M**ariaDB or **M**ongoDB, the database management system
- **P**HP, **P**erl, or **P**ython, the scripting languages (respectively programming languages) used for dynamic web pages and web development.

The exact combination of the software included in a LAMP stack is prone to variation, for example Apache web server can be replaced by some other web server software. Though the original authors of these programs did not design them to work as a component of the LAMP stack, the development philosophy and tool sets are shared and were developed in close conjunction, so they work and scale very well together. The software combination has become popular because it is entirely free and open-source software, which means that each component can be adapted to the underlying hardware and customized to meet the specification as exactly as possible, without the slightest vendor lock-in. The complete software stack is also free of cost, maximizing the available budget for tailoring the hardware and software.

Due to the nature of free and open-source software and the ubiquity of its components, each component of the LAMP stack is very well tested regarding performance and security. At the same time, there is an abundance of experienced contractors to do the tailoring required for various customizations, or for complex setups. There is also constant development going on.

The components of the LAMP stack are present in the software repositories of most (if not all) Linux distributions, giving any end-user a simple way to install, set up and operate an initial LAMP stack out of the box. The web presence of a small company that does not have a high hit count and is not prone to frequent attacks, can therefore be administered by another small company, by a one man company or even by a student.

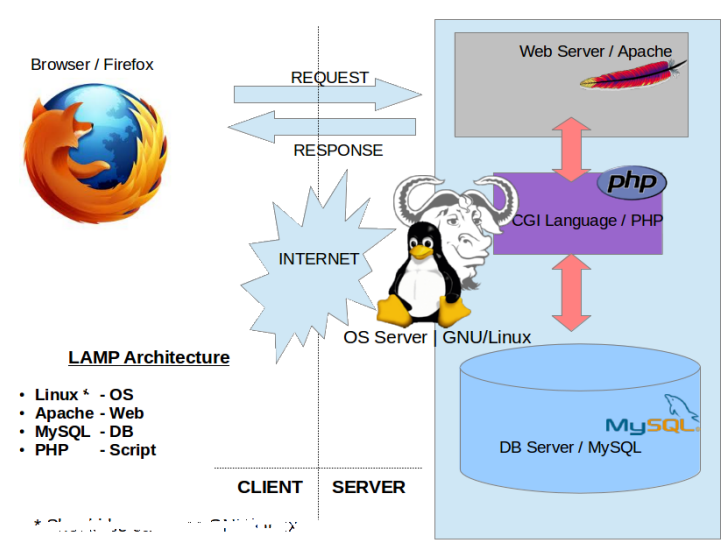
The LAMP bundle can be and often is combined with many other free and open-source software packages such as, for example:

- netsniff-ng for security testing and hardening
- Snort, an intrusion detection (IDS) and intrusion prevention system (IPS)
- RRDtool for diagrams
- Nagios, Collectd or Cacti, for monitoring.

Software components

Linux

Linux is a Unix-like and POSIX-compliant computer operating system assembled under the model of free and open source software development and distribution. The main form of distribution are Linux distributions, usually providing complete LAMP setups out of the box through their package management systems. Of the most widespread Linux distributions, as of 1 October 2013, 58.5% of web server market share is shared between Debian and Ubuntu, while RHEL, Fedora and CentOS together share 37.3%.



High-level overview of LAMP components

Many options are available for customizing and securing Linux installations, for example by using SELinux, or by employing chroot environments.

Apache

Apache is a web server, the most popular in use. As of June 2013[1], Apache was estimated to serve 54.2% of all active websites and 53.3% of the top servers across all domains.

Apache is developed and maintained by an open community of developers under the auspices of the Apache Software Foundation. Released under the Apache License, Apache is open-source software. A wide variety of features is supported, and many of them are implemented as compiled modules which extend the core functionality of Apache. These can range from server-side programming language support to authentication schemes.

MySQL, MariaDB, MongoDB

MySQL is a multithreaded, multi-user, SQL database management system (DBMS) now owned by Oracle Corporation.[2] MySQL has been owned by Oracle Corporation since January 27, 2010 through the purchase of Sun Microsystems.[3][4] Sun had originally acquired MySQL on February 26, 2008. The MySQL development project has made its source code available under the terms of the GNU General Public License, as well as under a variety of proprietary agreements.

MariaDB is a fork of MySQL. MongoDB is a widely used open-source NoSQL database. MongoDB eschews the traditional table-based relational database structure in favor of JSON-like documents with dynamic schemas (calling the format BSON), making the integration of data in certain types of applications easier and faster.

Other RDBM systems such as PostgreSQL (forming up the LAPP bundle) are also viable.[5]

PHP, Perl, Python

PHP is a server-side scripting language designed for web development but also used as a general-purpose programming language. PHP code is interpreted by a web server with a PHP processor module, which generates the resulting web page: PHP commands can be embedded directly into an HTML source document rather than calling an external file to process data. It has also evolved to include a command-line interface capability and can be used in standalone graphical applications.

PHP is free software released under the PHP License, which is incompatible with the GNU General Public License (GPL) due to restrictions on the usage of the term *PHP*.

Perl is a family of high-level, general-purpose, interpreted, dynamic programming languages. The languages in this family include Perl 5 and Perl 6. The Perl languages borrow features from other programming languages including C, shell scripting (sh), AWK, and sed. They provide powerful text processing facilities without the arbitrary data-length limits of many contemporary Unix commandline tools, facilitating easy manipulation of text files. Perl 5 gained widespread popularity in the late 1990s as a CGI scripting language, in part due to its parsing abilities.

Python is a widely used general-purpose, high-level programming language. Python supports multiple programming paradigms, including object-oriented, imperative and functional programming or procedural styles. It features a dynamic type system and automatic memory management and has a large and comprehensive standard library.[6] Like other dynamic languages, Python is often used as a scripting language, but is also used in a wide range of non-scripting contexts.

Variants and equivalents on other platforms

With the growing use of LAMP, variations and retronyms appeared for other combinations of operating system, web server, database, and software language. For example the equivalent installation on a Microsoft Windows operating system is known as WAMP. An alternative running IIS in place of Apache called WIMP. Variants involving other operating systems include MAMP (Macintosh), SAMP (Solaris), FAMP (FreeBSD) and iAMP (iSeries).

The web server or database management system also vary. LEMP is a version where Apache has been replaced with the more lightweight web server Nginx. A version where MySQL has been replaced by PostgreSQL is called LAPP, or sometimes by keeping the original acronym, LAMP (Linux / Apache / Middleware (Perl, PHP, Python, Ruby) / PostgreSQL).

A server running LAMP may be colloquially known as a lamp box, punning on the type of post box. The GNU project is advocating people to use the term "GLAMP" since many distributions of what is known as "Linux" include the GNU tools as well as the Linux kernel.

High availability and load balancing

Specific solutions are required for web sites serving large numbers of requests, or providing services demanding no downtimes. Usual approach for the LAMP stack involves multiple web and database servers, with additional components providing logical aggregation of resources provided by each of the servers, and distribution of the workload across multiple servers. Such aggregation for web servers is usually provided by a form of load balancer placed in front of them, such as Linux Virtual Server (LVS). For the database servers, MySQL provides internal replication mechanisms, implementing a master/slave relationship between the original database (master) and its copies (slaves).

Such setups are improving the availability of LAMP instances by providing various forms of redundancy, making it possible for a certain number of instance's components (separate servers) to go down without causing interruptions to provided services. Also, such redundant setups allow for hardware failures resulting in data loss on separate servers, without the stored data actually becoming lost. Besides higher availability, such LAMP setups are providing almost linear improvements in performance for services where the number of internal database read operations is much higher than the number of write/update operations.

Watcom SQL

Watcom SQL was a relational database for PC platforms released by Watcom in 1992. It was renamed to SQL Anywhere Studio after Watcom joined Powersoft which was subsequently acquired by Sybase.

The Watcom SQL 4.0 family of databases are based on scalable technology that combines a full-featured SQL database engine with unparalleled simplicity, economy and performance. Watcom SQL version 4.0 is designed for environments ranging from large departmental networks with a diverse range of PC client systems to peer-to-peer workgroups to standalone PCs. Watcom SQL Version 4.0 is available immediately in standalone versions for Windows and multi-user network server versions for NetWare. Standalone and multi-user versions for OS/2, Windows NT (Windows New Technology) A 32-bit operating system from Microsoft for Intel x86 CPUs. NT is the core technology in Windows 2000 and Windows XP (see Windows). Available in separate client and server versions, it includes built-in networking and preemptive multitasking. and DOS will be available within sixty days.

"To meet the needs of the 'shrink-wrapped' server marketplace, Watcom SQL was designed with a small 'footprint' for the desktop PC and LAN server environments," said Ian McPhee, president of Watcom. "Watcom SQL requires minimal database administration, takes only a few minutes to install and offers excellent performance out of the box without tuning."

"The addition of stored procedures and triggers to Watcom SQL 4.0 brings industrial-strength features to the workgroup database market," said Herb Edelstein, principal and founder of Euclid Associates, a Maryland-based database and image management consulting firm. "Workgroup users will appreciate the functionality added to Watcom SQL, a database that remains easy to set up and run."

"The Watcom SQL database fits perfectly into our plans," said Jim Braun, project manager at Kansas State University, main campus at Manhattan; coeducational; land-grant and state supported; chartered and opened 1863. There is an additional campus at Salina. Among the university's research facilities are the J. R. . "We needed a database that could distribute key systems across our organization, and Watcom SQL 4.0 gave us this, in addition to stored procedures and triggers. Watcom SQL is an impressive, economical package of performance and functionality."

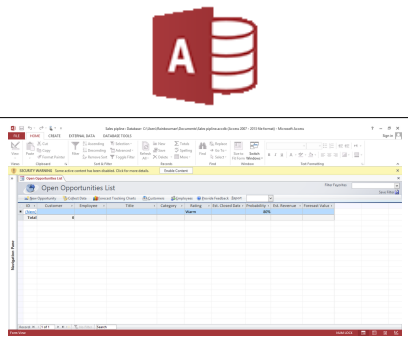
Microsoft Access

Microsoft Access



Microsoft Office Access 2013 running on Windows 8

Developer(s)	Microsoft Corporation
Initial release	November 1992
Stable release	2013 (15.0.4420.1017) / October 2, 2012
Development status	Active
Operating system	Microsoft Windows
Type	DBMS
License	Trialware
Website	office.microsoft.com/access [1]

Microsoft Access, also known as **Microsoft Office Access**, is a database management system from Microsoft that combines the relational Microsoft Jet Database Engine with a graphical user interface and software-development tools. It is a member of the Microsoft Office suite of applications, included in the Professional and higher editions or sold separately.

Microsoft Access stores data in its own format based on the Access Jet Database Engine. It can also import or link directly to data stored in other applications and databases.

Software developers and data architects can use Microsoft Access to develop application software, and "power users" can use it to build software applications. Like other Office applications, Access is supported by Visual Basic for Applications, an object-oriented programming language that can reference a variety of objects including DAO (Data Access Objects), ActiveX Data Objects, and many other ActiveX components. Visual objects used in forms and reports expose their methods and properties in the VBA programming environment, and VBA code modules may declare and call Windows operating-system functions.

History

Project Omega

Microsoft's first attempt to sell a relational database product was during the mid-1980s, when Microsoft obtained a license to sell R:Base. In the late 1980s Microsoft developed its own solution codenamed Omega. It was confirmed in 1988 that a database product for Windows and OS/2 was in development. It was going to include "EB" Embedded Basic language, which was going to be the language for writing macros in all Microsoft applications, but the unification of macro languages did not happen until the introduction of VBA. Omega was also expected to provide a front end to the Microsoft SQL Server. The application was very resource-hungry, and there were reports that it was working slowly on the 386 processors that were available at the time. It was scheduled to be released in the 1st quarter of 1990, but in 1989 the development of the product was reset and it was rescheduled to be delivered no sooner than in January 1991. Parts of the project were later used for other Microsoft projects: Cirrus (codename for Access) and Thunder (codename for Visual Basic, where the Embedded Basic engine was used). After Access's premiere, the Omega project was demonstrated in 1992 to several journalists and included features that were not available in Access.

Project Cirrus

After the Omega project was scrapped, some of its developers were assigned to the Cirrus project (most were assigned to the team which created Visual Basic). Its goal was to create a competitor for applications like Paradox or dBase that would work on Windows. After Microsoft acquired FoxPro, there were rumors that the Microsoft project might get replaced with it, but the company decided to develop them in parallel. It was assumed that the project would make use of Extensible Storage Engine (Jet Blue) but, in the end, only support for Microsoft Jet Database Engine (Jet Red) was provided. The project used some of the code from both the Omega project and a pre-release version of Visual Basic. In July 1992, betas of Cirrus shipped to developers and the name Access became the official name of the product.

Timeline

1992: Microsoft released Access version 1.0 on 13 November 1992, and an Access 1.1 release in May 1993 to improve compatibility with other Microsoft products and to include the Access Basic programming language.

1994: Microsoft specified the minimum hardware requirements for Access v2.0 as: Microsoft Windows v3.1 with 4 MB of RAM required, 6 MB RAM recommended; 8 MB of available hard disk space required, 14 MB hard disk space recommended. The product shipped on seven 1.44 MB diskettes. The manual shows a 1994 copyright date.

Originally, the software worked well with relatively small databases but testing showed that some circumstances caused data corruption. For example, file sizes over 10 MB proved problematic (note that most hard disks held less than 500 MB at the time this was in wide use), and the *Getting Started* manual warns about a number of circumstances where obsolete device drivers or incorrect configurations can cause data loss. With the phasing out of Windows 95, 98 and ME, improved network reliability, and Microsoft having released 8 service packs for the Jet Database Engine, the reliability of Access databases has improvedWikipedia:Manual of Style/Dates and numbers#Chronological items and it supports both more data and a larger number of users.

With Office 95, Microsoft Access 7.0 (a.k.a. "Access 95") became part of the Microsoft Office Professional Suite, joining Microsoft Excel, Word, and PowerPoint and transitioning from Access Basic to Visual Basic for Applications (VBA). Since then, Microsoft has released new versions of Microsoft Access with each release of Microsoft Office. This includes Access 97 (version 8.0), Access 2000 (version 9.0), Access 2002 (version 10.0), Access 2003 (version 11.5), Access 2007 (version 12.0), and Access 2010 (version 14.0).

Versions 3.0 and 3.5 of Microsoft Jet database engine (used by Access 7.0 and the later-released Access 97 respectively) had a critical issue which made these versions of Access unusable on a computer with more than 1 GB

of memory.[2] While Microsoft fixed this problem for Jet 3.5/Access 97 post-release, it never fixed the issue with Jet 3.0/Access 95.

The native Access database format (the Jet MDB Database) has also evolved over the years. Formats include Access 1.0, 1.1, 2.0, 7.0, 97, 2000, 2002, 2007, and 2010. The most significant transition was from the Access 97 to the Access 2000 format; which is not backward compatible with earlier versions of Access. As of 2011[3] all newer versions of Access support the Access 2000 format. New features were added to the Access 2002 format which can be used by Access 2002, 2003, 2007, and 2010.

Microsoft Access 2000 increased the maximum database size to 2GB from 1GB in Access 97.

Microsoft Access 2007 introduced a new database format: ACCDB. ACCDB supports links to SharePoint lists and complex data types such as multivalue and attachment fields. These new field types are essentially recordsets in fields and allow the storage of multiple values or files in one field. Microsoft Access 2007 also introduced File Attachment field, which stored data more efficiently than the OLE (Object Linking and Embedding) field.

Microsoft Access 2010 introduced a new version of the ACCDB format supported hosting Access Web solutions on a SharePoint 2010 server. For the first time, this allowed Access solutions to be run without having to install Access on their PC and was the first support of Mac users. Any user on the SharePoint site with sufficient rights could use the Access Web solution. A copy of Access was still required for the developer to create the Access Web solution, and the desktop version of Access remained part of Access 2010. The Access Web solutions were not the same as the desktop solutions. Automation was only through the macro language (not VBA) which Access automatically converted to JavaScript. The data was no longer in an Access database but SharePoint lists. An Access desktop database could link to the SharePoint data, so hybrid applications were possible so that SharePoint users needing basic views and edits could be supported while the more sophisticated, traditional solutions could remain in the desktop Access database.

Microsoft Access 2013 offers traditional Access desktop solutions plus a significantly updated SharePoint 2013 web solution.[4] The Access Web model in Access 2010 was replaced by a new architecture that stores its data in actual SQL Server databases. Unlike SharePoint lists, this offers true relational database design with referential integrity, scalability, extensibility and performance one would expect from SQL Server.[5] The database solutions that can be created on SharePoint 2013 offer a modern user interface designed to display multiple levels of relationships that can be viewed and edited, along with resizing for different devices and support for touch. The Access 2013 desktop is similar to Access 2010 but several features were discontinued including support for Access Data Projects (ADPs), pivot tables, pivot charts, Access data collections, source code control, replication, and other legacy features.[6] Access desktop database maximum size remained 2GB (as it has been since the 2000 version).

Prior to the introduction of Access, Borland (with Paradox and dBase) and Fox (with FoxPro) dominated the desktop database market. Microsoft Access was the first mass-market database program for Windows. With Microsoft's purchase of FoxPro in 1992 and the incorporation of Fox's Rushmore query optimization routines into Access, Microsoft Access quickly became the dominant database for Windows - effectively eliminating the competition which failed to transition from the MS-DOS world.[7]

Access's initial codename was Cirrus; the forms engine was called Ruby. This was before Visual Basic. Bill Gates saw the prototypes and decided that the BASIC language component should be co-developed as a separate expandable application, a project called Thunder. The two projects were developed separately.

Access was also the name of a communications program from Microsoft, meant to compete with ProComm and other programs. This proved a failure and was dropped.[8] Years later, Microsoft reused the name for its database software.

Uses

In addition to using its own database storage file, Microsoft Access also may be used as the 'front-end' with other products as the 'back-end' tables, such as Microsoft SQL Server and non-Microsoft products such as Oracle and Sybase. Multiple backend sources can be used by a Microsoft Access Jet Database (accdb and mdb formats). Similarly, some applications such as Visual Basic, ASP.NET, or Visual Studio .NET will use the Microsoft Access database format for its tables and queries. Microsoft Access may also be part of a more complex solution, where it may be integrated with other technologies such as Microsoft Excel, Microsoft Outlook, Microsoft Word, Microsoft PowerPoint and ActiveX Controls.

Access tables support a variety of standard field types, indices, and referential integrity including cascading updates and deletes. Access also includes a query interface, forms to display and enter data, and reports for printing. The underlying Jet database, which contains these objects, is multiuser-aware and handles record-locking.

Repetitive tasks can be automated through macros with point-and-click options. It is also easy to place a database on a network and have multiple users share and update data without overwriting each other's work. Data is locked at the record level which is significantly different from Excel which locks the entire spreadsheet.

There are template databases within the program and for download from their website [9]. These options are available upon starting Access and allow users to enhance a database with predefined tables, queries, forms, reports, and macros. Database templates support VBA code but Microsoft's templates do not include VBA code.

Programmers can create solutions using the programming language Visual Basic for Applications (VBA), which is similar to Visual Basic 6.0 (VB6) and used throughout the Microsoft Office programs such as Excel, Word, Outlook and PowerPoint. Most VB6 code, including the use of Windows API calls, can be used in VBA. Power users and developers can extend basic end-user solutions to a professional solution with advanced automation, data validation, error trapping, and multi-user support.

The number of simultaneous users that can be supported depends on the amount of data, the tasks being performed, level of use, and application design. Generally accepted limits are solutions with 1 GB or less of data (Access supports up to 2 GB) and performs quite well with 100 or fewer simultaneous connections (255 concurrent users are supported). This capability is often a good fit for department solutions. If using an Access database solution in a multi-user scenario, the application should be "split". This means that the tables are in one file called the back end (typically stored on a shared network folder) and the application components (forms, reports, queries, code, macros, linked tables) are in another file called the front end. The linked tables in the front end point to the back end file. Each user of the Access application would then receive his or her own copy of the front end file.

Applications that run complex queries or analysis across large datasets would naturally require greater bandwidth and memory. Microsoft Access is designed to scale to support more data and users by linking to multiple Access databases or using a back-end database like Microsoft SQL Server. With the latter design, the amount of data and users can scale to enterprise-level solutions.

Microsoft Access's role in web development prior to version 2010 is limited. User interface features of Access, such as forms and reports, only work in Windows. In versions 2000 through 2003 an Access object type called Data Access Pages created publishable web pages. Data Access Pages are no longer supported. The Microsoft Jet Database Engine, core to Access, can be accessed through technologies such as ODBC or OLE DB. The data (i.e., tables and queries) can be accessed by web-based applications developed in ASP.NET, PHP, or Java. With the use of Microsoft's Terminal Services and Remote Desktop Application in Windows Server 2008 R2, organizations can host Access applications so they can be run over the web.[10] This technique does not scale the way a web application would but is appropriate for a limited number of users depending on the configuration of the host.

Access 2010 allows databases to be published to SharePoint 2010 web sites running Access Services. These web-based forms and reports run in any modern web browser. The resulting web forms and reports, when accessed via a web browser, don't require any add-ins or extensions (e.g. ActiveX, Silverlight).

Access 2013 can create web applications directly in SharePoint 2013 sites running Access Services. Access 2013 web solutions store its data in an underlying SQL Server database which is much more scalable and robust than the Access 2010 version which used SharePoint lists to store its data.

A compiled version of an Access database (File extensions: .MDE /ACCDE or .ADE; ACCDE only works with Access 2007 or later) can be created to prevent user from accessing the design surfaces to modify module code, forms, and reports. An MDE/ACCDE file is a Microsoft Access database file with all modules compiled and all editable source code removed. An ADE file is an Access project file with all modules compiled and all editable source code removed. Both the .MDE/ACCDE and .ADE versions of an Access database are used when end-user modifications are not allowed or when the application's source code should be kept confidential.

Microsoft also offers developer extensions [11] for download to help distribute Access 2007 applications, create database templates, and integrate source code control with Microsoft Visual SourceSafe.

Features

Users can create tables, queries, forms and reports, and connect them together with macros. Advanced users can use VBA to write rich solutions with advanced data manipulation and user control. Access also has report creation features that can work with any data source that Access can "access".

The original concept of Access was for end users to be able to "access" data from any source. Other features include: the import and export of data to many formats including Excel, Outlook, ASCII, dBase, Paradox, FoxPro, SQL Server, Oracle, ODBC, etc. It also has the ability to link to data in its existing location and use it for viewing, querying, editing, and reporting. This allows the existing data to change while ensuring that Access uses the latest data. It can perform heterogeneous joins between data sets stored across different platforms. Access is often used by people downloading data from enterprise level databases for manipulation, analysis, and reporting locally.

There is also the Jet Database format (MDB or ACCDB in Access 2007) which can contain the application and data in one file. This makes it very convenient to distribute the entire application to another user, who can run it in disconnected environments.

One of the benefits of Access from a programmer's perspective is its relative compatibility with SQL (structured query language) — queries can be viewed graphically or edited as SQL statements, and SQL statements can be used directly in Macros and VBA Modules to manipulate Access tables. Users can mix and use both VBA and "Macros" for programming forms and logic and offers object-oriented possibilities. VBA can also be included in queries.

Microsoft Access offers parameterized queries. These queries and Access tables can be referenced from other programs like VB6 and .NET through DAO or ADO. From Microsoft Access, VBA can reference parameterized stored procedures via ADO.

The desktop editions of Microsoft SQL Server can be used with Access as an alternative to the Jet Database Engine. This support started with MSDE (Microsoft SQL Server Desktop Engine), a scaled down version of Microsoft SQL Server 2000, and continues with the SQL Server Express versions of SQL Server 2005 and 2008.

Microsoft Access is a file server-based database. Unlike client–server relational database management systems (RDBMS), Microsoft Access does not implement database triggers, stored procedures, or transaction logging. Access 2010 includes table-level triggers and stored procedures built into the ACE data engine. Thus a Client-server database system is not a requirement for using stored procedures or table triggers with Access 2010. Tables, queries, forms, reports and macros can now be developed specifically for web base application in Access 2010. Integration with Microsoft SharePoint 2010 is also highly improved.

Access Services and Web database

ASP.NET web forms can query a Microsoft Access database, retrieve records and display them on the browser.

SharePoint Server 2010 via Access Services allows for Access 2010 databases to be published to SharePoint, thus enabling multiple users to interact with the database application from any standards-compliant Web browser. Access Web databases published to SharePoint Server can use standard objects such as tables, queries, forms, macros, and reports. Access Services stores those objects in SharePoint.

Access 2013 offers the ability to publish Access web solutions on SharePoint 2013. Rather than using SharePoint lists as its data source, Access 2013 uses an actual SQL Server database hosted by SharePoint or SQL Azure. This offers a true relational database with referential integrity, scalability, maintainability, and extensibility compared to the SharePoint views Access 2010 used.. The macro language is enhanced to support more sophisticated programming logic and database level automation.[12]

Import or Link sources

Microsoft Access can also import or link directly to data stored in other applications and databases. Microsoft Office Access 2007 and newer can import from or link to:

- Microsoft Access
- Excel
- SharePoint lists
- Plain text
- XML
- Outlook
- HTML
- dBase (dropped in Access 2013)
- Paradox (with Access 2007; dropped in Access 2010)
- Lotus 1-2-3 (dropped in Access 2010)
- ODBC-compliant data containers, including:
  - Microsoft SQL Server
  - Oracle
  - MySQL
  - PostgreSQL
  - IBM Lotus Notes
  - AS 400 DB2

Microsoft Access Runtime

Microsoft offers free runtime versions of Microsoft Access: Access 2013 Runtime [13], Access 2010 Runtime [14], Access 2007 Runtime [15], which allow users to run an Access desktop application without needing to purchase or install a full version of Microsoft Access. This allows Access developers to create databases that can be freely distributed to an unlimited number of end-users. The runtime version allows users to view, edit and delete data, along with running queries, forms, reports, macros and VBA module code. But the runtime version does not allow users to change the design of Microsoft Access objects or code. The runtime versions are similar to their corresponding full version of Access and usually compatible with earlier versions; for example Access Runtime 2010 allows a user to run an Access application made with the 2010 version as well as 2007 through 2000. Due to deprecated features in Access 2013, its runtime version is also unable to support those older features.

Development

Access stores all database tables, queries, forms, reports, macros, and modules in the Access Jet database as a single file.

For query development, Access offers a "Query Designer", a graphical user interface that allows users to build queries without knowledge of structured query language. In the Query Designer, users can "show" the datasources of the query (which can be tables or queries) and select the fields they want returned by clicking and dragging them into the grid. One can set up joins by clicking and dragging fields in tables to fields in other tables. Access allows users to view and manipulate the SQL code if desired. Any Access table, including linked tables from different data sources, can be used in a query.

Access also supports the creation of "pass-through queries". These snippets of SQL code can address external data sources through the use of ODBC connections on the local machine. This enables users to interact with data stored outside the Access program without using linked tables or Jet. Users construct the pass-through queries using the SQL syntax supported by the external data source.

When developing reports (in "Design View") additions or changes to controls cause any linked queries to execute in the background and the designer is forced to wait for records to be returned before being able to make another change. This feature cannot be turned off.

Non-programmers can use the macro feature to automate simple tasks through a series of drop-down selections. Macros allow users to easily chain commands together such as running queries, importing or exporting data, opening and closing forms, previewing and printing reports, etc. Macros support basic logic (IF-conditions) and the ability to call other macros. Macros can also contain sub-macros which are similar to subroutines. In Access 2007, enhanced macros included error-handling and support for temporary variables. Access 2007 also introduced embedded macros that are essentially properties of an object's event. This eliminated the need to store macros as individual objects. However, macros were limited in their functionality by a lack of programming loops and advanced coding logic until Access 2013. With significant further enhancements introduced in Access 2013, the capabilities of macros became fully comparable to VBA. They made feature rich web-based application deployments practical, via a greatly enhanced Microsoft SharePoint interface and tools, as well as on traditional Windows desktops.

In common with other products in the Microsoft Office suite, the other programming language used in Access is Microsoft VBA Visual Basic for Applications. VBA is similar to Visual Basic 6.0 (VB6) and code can be stored in modules, classes, and code behind forms and reports. To create a richer, more efficient and maintainable finished product with good error handling, most professional Access applications are developed using the VBA programming language rather than macros, except where web deployment is a business requirement.

To manipulate data in tables and queries in VBA or macros, Microsoft provides two database access libraries of COM components:

1. Data Access Objects (DAO) (32-bit only), which is included in Access and Windows and evolved to ACE in Microsoft Access 2007 for the ACCDE database format
2. ActiveX Data Objects ActiveX Data Objects (ADO) (both 32-bit and 64-bit versions)

As well as DAO and ADO, developers can also use OLE DB and ODBC for developing native C/C++ programs for Access. For ADPs and the direct manipulation of SQL Server data, ADO is required. DAO is most appropriate for managing data in Access/Jet databases, and the only way to manipulate the complex field types in ACCDB tables.

In the database container or navigation pane in Access 2007 and later versions, the system automatically categorizes each object by type (e.g., table, query, macro). Many Access developers use the Leszynski naming convention, though this is not universal; it is a programming convention, not a DBMS-enforced rule.[16][17] It is particularly helpful in VBA where references to object names may not indicate its data type (e.g. tbl for tables, qry for queries).

Developers deploy Microsoft Access most often for individual and workgroup projects (the Access 97 speed characterization was done for 32 users).[18] Since Access 97, and with Access 2003 and 2007, Microsoft Access and

hardware have evolved significantly. Databases under 1 GB in size (which can now fit entirely in RAM) and 50 simultaneous users are well within the capabilities of Microsoft Access. Of course, performance depends on the database design and tasks. Disk-intensive work such as complex searching and querying take the most time.

As data from a Microsoft Access database can be cached in RAM, processing speed may substantially improve when there is only a single user or if the data are not changing. In the past, the effect of packet latency on the record-locking system caused Access databases to run slowly on a Virtual Private Network (VPN) or a Wide Area Network (WAN) against a Jet database. As of 2010[3] broadband connections have mitigated this issue. Performance can also be enhanced if a continuous connection [19] is maintained to the back-end database throughout the session rather than opening and closing it for each table access. If Access database performance over VPN or WAN suffers, then a client using Remote Desktop Protocol (such as Microsoft Terminal Services) can provide an effective solution. Access databases linked to SQL Server or to Access Data Projects work well[*citation needed*] over VPNs and WANs.

In July 2011, Microsoft acknowledged an intermittent query performance problem with all versions of Access and Windows 7 and Windows Server 2008 R2 due to the nature of resource management being vastly different in newer operating systems.[20] This issue severely affects query performance on both Access 2003 and earlier with the Jet Database Engine code, as well as Access 2007 and later with the Access Database Engine (ACE). Microsoft has issued hotfixes KB2553029 [21] for Access 2007 and KB2553116 [22] for Access 2010, but will not fix the issue with Jet 4.0 as it is out of mainstream support.

In previous versions of Microsoft Access the ability to distribute applications required the purchase of the Developer Toolkit; in Access 2010 and Access 2013 the "Runtime Only" version is offered as a free download, making the distribution of royalty-free applications possible on Windows 7 and Windows 8.x.[23]

Split Database Architecture

Microsoft Access applications can adopt a split-database architecture. The single database can be divided into a separate "back-end" file that contains the data tables (shared on a file server) and a "front-end" (containing the application's objects such as queries, forms, reports, macros, and modules). The "front-end" Access application is distributed to each user's desktop and linked to the shared database. Using this approach, each user has a copy of Microsoft Access (or the runtime version) installed on their machine along with their application database. This reduces network traffic since the application is not retrieved for each use. The "front-end" database can still contain local tables for storing a user's settings or temporary data. This split-database design also allows development of the application independent of the data. One disadvantage is that users may make various changes to their own local copy of the application and this makes it hard to manage version control. When a new version is ready, the front-end database is replaced without impacting the data database. Microsoft Access has two built-in utilities, Database Splitter and Linked Table Manager, to facilitate this architecture.

Linked tables in Access use absolute paths rather than relative paths, so the development environment either has to have the same path as the production environment or a "dynamic-linker" routine can be written in VBA.

For very large Access databases, this may have performance issues and a SQL backend should be considered in these circumstances. This is less of an issue if the entire database can fit in the PC's RAM since Access caches data and indexes.

Access to SQL Server Upsizing (Upgrading) (SQL as a backend)

To scale Access applications to enterprise or web solutions, one possible technique involves migrating to Microsoft SQL Server or equivalent server database. A client–server design significantly reduces maintenance and increases security, availability, stability, and transaction logging.

Access 2010 included a feature called the Upsizing Wizard that allowed users to upgrade their databases to Microsoft SQL Server, an ODBC client–server database. This feature was removed from Access 2013. An additional solution, the SQL Server Migration Assistant for Access (SSMA), continues to be available for free download from Microsoft.

A variety of upgrading options are available.[24] After migrating the data and queries to SQL Server, the MDB/ACCDB Access database can be linked to the database. However, certain data types are problematic, most notably "Yes/No". In MS Access there are three states for the Yes/No (True/False) data type: empty, No/False (zero) and Yes/True (-1). The corresponding SQL Server data type is binary, with only two states, permissible values, zero and 1. Regardless, SQL Server is still the easiest migration, and most appropriate especially if the user does not have rights to create objects such as stored procedures on SQL Server. Retrieving data from linked tables is optimized to just the records needed, but this scenario may operate less efficiently than what would otherwise be optimal for SQL Server. For example, in instances where multi-table joins still require copying the whole table across the network.

In previous versions of Access, including Access 2010, databases can also be converted to Access Data Projects (ADP) which are tied directly to one SQL Server database. This feature was removed from Access 2013. ADP's support the ability to directly create and modify SQL Server objects such as tables, views, stored procedures, and SQL Server constraints. The views and stored procedures can significantly reduce the network traffic for multi-table joins. Fortunately, SQL Server supports temporary tables and links to other data sources beyond the single SQL Server database.

Finally, some Access databases are completely replaced by another technology such as ASP.NET or Java once the data is converted. However any migration may dictate major effort since the Access SQL language is a more powerful superset of standard SQL. Further, Access application procedures, whether VBA and macros, are written at a relatively higher level versus the currently available alternatives that are both robust and comprehensive. Note that the Access macro language, allowing an even higher level of abstraction than VBA, was significantly enhanced in Access 2010 and again in Access 2013.

In many cases, developers build direct web-to-data interfaces using ASP.NET, while keeping major business automation processes, administrative and reporting functions that don't need to be distributed to everyone in Access for information workers to maintain.

While all most Access data can migrate to SQL Server directly, some queries cannot migrate successfully. In some situations, you may need to translate VBA functions and user defined functions into T–SQL or .NET functions / procedures. Crosstab queries can be migrated to SQL Server using the PIVOT command.

Protection

Microsoft Access offers several ways to secure the application while allowing users to remain productive.

The most basic is a database password. Once entered, the user has full control of all the database objects. This is a relatively weak form of protection which can be easily cracked.

A higher level of protection is the use of workgroup security requiring a user name and password. Users and groups can be specified along with their rights at the object type or individual object level. This can be used to specify people with read-only or data entry rights but may be challenging to specify. A separate workgroup security file contains the settings which can be used to manage multiple databases. Workgroup security is not supported in the Access 2007 and Access 2010 ACCDB database format, although Access 2007 and Access 2010 still support it for MDB databases.

Databases can also be encrypted. The ACCDB format offers significantly advanced encryption from previous versions.[25]

Additionally, if the database design needs to be secured to prevent changes, Access databases can be locked/protected (and the source code compiled) by converting the database to a .MDE file. All changes to the VBA project (modules, forms, or reports) need to be made to the original MDB and then reconverted to MDE. In Access 2007 and Access 2010, the ACCDB database is converted to an ACCDE file. Some tools are available for unlocking and "decompiling", although certain elements including original VBA comments and formatting are normally irretrievable.

File extensions

Microsoft Access saves information under the following file formats:

File format	Extension
Protected Access Data Project (not supported in Access 2013)	.ade
Access Data Project (not supported in Access 2013)	.adp
Access Blank Project Template	.adn
Access Database (2007)	.accdb
Access Database Runtime (2007)	.accdr
Access Database Template (2007)	.accdt
Access Database (2003 and earlier)	.mdb
Access Database, used for addins (2,95,97), previously used for workgroups (2).	.mda
Access Blank Database Template (2003 and earlier)	.mdn
Access Add-in Data (2003 and earlier)	.mdt
Access Workgroup, database for user-level security.	.mdw
Access (SQL Server) detached database (2000)	.mdf
Protected Access Database, with compiled VBA and/or macros (2003 and earlier)	.mde
Protected Access Database, with compiled VBA and/or macros (2007)	.accde
Windows Shortcut: Access Macro	.mam
Windows Shortcut: Access Query	.maq
Windows Shortcut: Access Report	.mar
Windows Shortcut: Access Table	.mat
Windows Shortcut: Access Form	.maf
Access lock files (associated with .mdb)	.ldb
Access lock files (associated with .accdb)	.laccdb

Versions

Version	Version number	Release Date	Jet version	Supported OS	Office suite version
Access 1.1	1.0	1992	1.1	Windows 3.0[*citation needed*]	
Access 2.0	2.0	1993	2.0	Windows 3.1x[*citation needed*]	Office 4.3 Pro
Access for Windows 95	7.0	Aug. 24, 1995	3.0	Windows 95[*citation needed*]	Office 95 Professional
Access 97	8.0	Jan. 16, 1997	3.5	Windows 95, Windows NT 3.51 SP5, Windows NT 4.0 SP2	Office 97 Professional and Developer
Access 2000	9.0	June 7, 1999	4.0 SP1	Windows 95, Windows NT 4.0, Windows 98, Windows 2000	Office 2000 Professional, Premium and Developer
Access 2002	10.0	May 31, 2001	4.0 SP1	Windows NT 4.0 SP6, Windows 98, Windows 2000, Windows Me	Office XP Professional and Developer
Access 2003	11.0	Nov. 27, 2003	4.0 SP1	Windows 2000 SP3 or later, Windows XP, Windows Vista, Windows 7	Office 2003 Professional and Professional Enterprise
Access 2007	12.0	Jan. 27, 2007	12	Windows XP SP2, Windows Server 2003 SP1, or newer operating system	Office 2007 Professional, Professional Plus, Ultimate and Enterprise
Access 2010	14.0	July 15, 2010	14	Windows XP SP3, Windows Server 2003 SP2, Windows Server 2003 R2, Windows Vista SP1, Windows Server 2008, Windows 7, Windows Server 2008 R2, Windows Server 2012, Windows 8	Office 2010 Professional, Professional Academic and Professional Plus
Access 2013	15.0	Jan. 29, 2013	15	Windows 7, Windows Server 2008 R2, Windows Server 2012, Windows 8	Office 2013

Notes

There are no Access versions between 2.0 and 7.0 because the Office 95 version was launched with Word 7. All of the Office 95 products have OLE 2 capabilities, and Access 7 shows that it was compatible with Word 7.

Version number 13 was skipped.

VMDS

VMDS abbreviates the relational database technology called **Version Managed Data Store** provided by GE Energy as part of its Smallworld technology platform and was designed from the outset to store and analyse the highly complex spatial and topological networks typically used by enterprise utilities such as power distribution and telecommunications.

VMDS was originally introduced in 1990 as has been improved and updated over the years. Its current version is 6.0.

VMDS has been designed as a spatial database. This gives VMDS a number of distinctive characteristics when compared to conventional attribute only relational databases.

Distributed server processing

VMDS is composed of two parts: a simple, highly scalable data block server called **SWMFS** (Smallworld Master File System) and an intelligent client API written in C and Magik. Spatial and attribute data are stored in data blocks that reside in special files called data store files on the server. When the client application requests data it has sufficient intelligence to work out the optimum set of data blocks that are required. This request is then made to SWMFS which returns the data to the client via the network for processing.

This approach is particularly efficient and scalable when dealing with spatial and topological data which tends to flow in larger volumes and require more processing then plain attribute data (for example during a map redraw operation). This approach makes VMDS well suited to enterprise deployment that might involve hundreds or even thousands of concurrent clients.

Support for long transactions

Relational databases support short transactions in which changes to data are relatively small and are brief in terms in duration (the maximum period between the start and the end of a transaction is typically a few seconds or less).

VMDS supports long transactions in which the volume of data involved in the transaction can be substantial and the duration of the transaction can be significant (days, weeks or even months). These types of transaction are common in advanced network applications used by, for example, power distribution utilities.

Due to the time span of a long transaction in this context the amount of change can be significant (not only within the scope of the transaction, but also within the context of the database as a whole). Accordingly, it is likely that the

same record might be changed more than once. To cope with this scenario VMDS has inbuilt support for automatically managing such conflicts and allows applications to review changes and accept only those edits that are correct.

Spatial and topological capabilities

As well as conventional relational database features such as attribute querying, join fields, triggers and calculated fields, VMDS has numerous spatial and topological capabilities. This allows spatial data such as points, texts, polylines, polygons and raster data to be stored and analysed.

Spatial functions include: find all features within a polygon, calculate the Voronoi polygons of a set of sites and perform a cluster analysis on a set of points.

Vector spatial data such as points, polylines and polygons can be given topological attributes that allow complex networks to be modelled. Network analysis engines are provided to answer questions such as find the shortest path between two nodes or how to optimize a delivery route (the travelling salesman problem). A topology engine can be configured with a set of rules that define how topological entities interact with each other when new data is added or existing data edited.

Data abstraction

In VMDS all data is presented to the application as objects. This is different from many relational databases that present the data as rows from a table or query result using say JDBC. VMDS provides a data modelling tool and underlying infrastructure as part of the Smallworld technology platform that allows administrators to associate a table in the database with a Magik exemplar (or class). Magik get and set methods for the Magik exemplar can be automatically generated that expose a table's field (or column). Each VMDS *row* manifests itself to the application as an instance of a Magik object and is known as an **RWO** (or real world object). Tables are known as collections in Smallworld parlance.

```
# all_rwos hold all the rwos in the database and is heterogeneous
all_rwos << my_application.rwo_set()

# valve_collection holds the valve collection
valves << all_rwos.select(:collection, {:valve})
number_of_valves << valves.size
```

Queries are built up using predicate objects:

```
# find 'open' valves.
open_valves << valves.select(predicate.eq(:operating_status, "open"))
number_of_open_valves << open_valves.size
```

```
_for valve _over open_valves.elements()
_loop
  write(valve.id)
_endloop
```

Joins are implemented as methods on the parent RWO. For example a manager might have several employees who report to him:

```
# get the employee collection.
employees << my_application.database.collection(:gis, :employees)
```

```
# find a manager called 'Steve' and get the first matching element
steve << employees.select(predicate.eq(:name, "Steve").and(predicate.eq(:role, "manager")).an_element()
```

```
# display the names of his direct reports. name is a field (or column)
# on the employee collection (or table)
_for employee _over steve.direct_reports.elements()
_loop
   write(employee.name)
_endloop
```

Performing a transaction:

```
# each key in the hash table corresponds to the name of the field (or column) in
# the collection (or table)
valve_data << hash_table.new_with(
  :asset_id, 57648576,
  :material, "Iron")
```

```
# get the valve collection directly
valve_collection << my_application.database.collection(:gis, :valve)
```

```
# create an insert transaction to insert a new valve record into the collection a
# comment can be provide that describes the transaction
transaction << record_transaction.new_insert(valve_collection, valve_data, "Inserted a new valve")
transaction.run()
```

Superbase database

Superbase is an end-user desktop database program that started on the Commodore 64 and was ported from that to various operating systems over the course of more than 20 years. It also has generally included a programming language to automate database-oriented tasks, and with later versions included WYSIWYG form and report designers as well as more sophisticated programming capabilities.

History

It was originally created in 1983 by Precision Software for the Commodore 64 and 128 and later the Amiga and Atari ST. In 1989, it was the first database management system to run on a Windows computer.

Precision Software, a UK-based company, was the original creator of the product Superbase. Superbase was and still is used by a large number of people on various platforms. It was often used only as an end-user database but a very large number of applications were built throughout industry, government, and academia and these were often of significant complexity. Some of these applications continue in use to the current day, mostly in small businesses.

The initial versions were text mode only, but with the release of the Amiga version, a completely new paradigm for accessing databases was created. Superbase was the first product to use the now common VCR control panel for browsing through records. It also provided a number of different media formats that it directly supported, including images, sounds, and video. Superbase was often referred to as the *multimedia* database in early years, when such features were uncommon. Amiga version also featured an internal language and the capability to generate front end "masks" for queries and reports, years before Microsoft Access.

This version was a huge success and that resulted in a version being created for a number of platforms using the same approach. Eventually a Microsoft Windows version was released and a couple of years later the company was sold by its founders to Software Publishing Corporation. SPC sold off the non-Windows versions of the product and after releasing version 2 and in the late alpha stages of version 3, sold the product to a company called Computer Concepts Corporation.

This relatively unknown company created a subsidiary called Superbase, Inc. and after finishing off the late stage alpha of version 3 and launching it as Superbase 95, eventually appeared to have lost interest in the product, at which point it was bought by a small group of former customers and brought back to the UK. This company, Superbase Developers plc, continued to extend and support the product through Superbase Classic.

A new, next-generation rewrite of the product initially called Superbase Next Generation (SBNG) which included a new object oriented programming language called SIMPOL was begun in 1999-2000. It had primarily been an alpha product; although it was billed as a beta release in 2005 with promises that a true release would be around the corner.

In 2006, SIMPOL was sold to RealBasics Ltd which was later renamed Simpol Ltd (www.simpol.com).

In April 2009 this company launched SIMPOL Professional, which is the next generation product, as a cross-platform language and database tool set.

In February 2009, it was announced that Superbase Developers plc was in liquidation.

In March 2010 Papatuo Holdings Ltd. purchased the Superbase family of products from the official receivers of Superbase Developers plc.[1]

Uses

Superbase has been used for very basic end-user tasks, but its real strength lies in the ability of relatively untrained programmers to create complex applications. These are typically built up over time as need arises. The types of applications run the gamut from accounting systems, ERP/MRP packages, business information systems, production control systems, and similar complex products down to very basic membership list or contact management systems.

Features

It contains a high-speed versatile ISAM database engine and its own powerful dialect of BASIC, as well as sophisticated forms and report engines. It also includes powerful support for acting as the front-end for one or more SQL databases. Its biggest drawback is the fact that it was written to the 16-bit Windows API and was not easily portable to the 32-bit version. The rewritten version is intended to cure that and to make the package even easier to use and more powerful.

From a casual programmer's perspective, the fact that the database is not based on SQL is a significant advantage, since the level of complexity is far less and it is easier for the user to grasp the concepts of how to manage and traverse the database.

There are numerous powerful features in the product, a few of them are:

- Virtual Database Tables — these only exist in memory
- Virtual Database Columns — these are calculated at access time
- Peer-to-peer Client/Server (PPCS) — this technology allows any version of Superbase to act as either a database server, a client, or both. The database tables are accessed via UDP/IP.
- Small footprint — Superbase runs on every version of Windows except the 64-bit versions and requires only a minimum of 6 MB of system RAM.

Versions

- 1983 Superbase 64 for the Commodore 64
- 1983 Superbase 700 for the Commodore CBM-II
- 1983 Superbase version 2.0 for the Apple II
- 1984 Superbase for the Commodore Plus/4
- 1985 Superbase for the Amiga
- 1985 Superbase 128 for the Commodore 128
- 1986 Superbase for the Atari ST
- 1987 Superbase for GEM on the PC
- 1988 Superbase 4 version 1.0 for Windows
- 1991 Superbase 4 version 1.31 for Windows
- 1991 Superbase 4 version 1.31 for Amiga
- 1992 Superbase version 2.0 for Windows
- 1994 Superbase 95 (version 3.0) for Windows
- 1997 Superbase version 3.2 for Windows
- 1998 Superbase version 3.5 for Windows
- 1999 Superbase version 3.6i for Windows
- 2000 SuperBase 4 Pro version 1.36 for Amiga
- 2001 Superbase 2001 for Windows
- 2003 Superbase Classic for Windows

Rocket U2

Rocket U2 Product Family

Developer(s)	Rocket Software
Stable release	UniData 7.3, UniVerse 11.1, SB/XA 6.2.2, Web DE 5.0
Operating system	Cross-platform
Type	MultiValue database
License	Proprietary
Website	www.rocketsoftware.com/u2 [1]

Rocket U2 is a suite of database management (DBMS) and supporting software now owned by Rocket Software. It includes two MultiValue database platforms: *UniData* and *UniVerse*.[2] Both of these products are operating environments which run on current Unix, Linux and Windows operating systems.[3][4] They are both derivatives of the Pick operating system.[5][*citation needed*] The family also includes developer and web-enabling technologies including *SystemBuilder/SB+*, *SB/XA*, *U2 Web DE*, *UniObjects* and *wIntegrate*.

History

UniVerse was originally developed by VMark Software and UniData was originally developed by the Unidata Corporation. Both Universe and Unidata are used for vertical application development and are embedded into the vertical software applications. In 1997, the Unidata Corporation merged with VMark Systems to form Ardent Software.[6] In March 2000, Ardent Software was acquired by Informix. IBM subsequently acquired the database division of Informix in April 2001,[7] making UniVerse and UniData part of IBM's DB2 product family. IBM subsequently created the Information Management group of which Data Management is one of the sub-areas under which the IBM U2 family comprised UniData and UniVerse along with the tools, SystemBuilder Extensible Architecture (SB/XA), U2 Web Development Environment (U2 Web DE) and wIntegrate.

On 1 October 2009 it was announced that Rocket Software had purchased the entire U2 portfolio from IBM.[8][9] The U2 portfolio is grouped under the name RocketU2.

System structure

Accounts

Systems are made of one or more accounts. Accounts are directories stored on the host operating system that initially contain the set of files needed for the system to function properly. This includes the system's VOC (vocabulary) file that contains every command, filename, keyword, alias, script, and other pointers. Each of these classes of VOC entries can also be created by a user.

Files

Files are similar to tables in a relational database in that each file has a unique name to distinguish it from other files and zero to multiple unique records that are logically related to each other.

Files are made of two parts: a data file and a file dictionary (DICT). The data file contains records that store the actual data. The file dictionary may contain metadata to describe the contents or to output the contents of a file.

Hashed files

For hashed files, a U2 system uses a hashing algorithm to allocate the file's records into groups based on the record IDs. When searching for data in a hashed file, the system only searches the group where the record ID is stored, making the search process more efficient and quicker than searching through the whole file.

Nonhashed files

Nonhashed files are used to store data with little or no logical structure such as program source code, XML or plain text. This type of file is stored as a subdirectory within the account directory on the host operating system and may be read or edited using external tools.

Records

Files are made of records, which are similar to rows within tables of a traditional relational database. Each record has a unique key (called a "record ID" in U2) to distinguish it from other records in the file. These record IDs are typically hashed so that data can be retrieved quickly and efficiently.

Records (including record IDs) store the actual data as pure ASCII strings; there is no binary data stored in U2. For example, the hardware representation of a floating-point number would be converted to its ASCII equivalent before being stored. Usually these records are divided into fields (which are sometimes called "attributes" in U2). Each field is separated by a "field mark" (hexadecimal character FE).

Thus this string:

```
123-45-6789^JOHN JONES^jjones@example.com^432100^...
```

might represent a record in the EMPLOYEE file with 123-45-6789 as the Record ID, JOHN JONES as the first field, jjones@company.com as the second field and $4321.00 as a monthly salary stored in the third field. (The up-arrow (^) above is the standard Pick notation of a field mark; that is, xFE).

Thus the first three fields of this record, including the record ID and trailing field mark, would use 49 bytes of storage. A given value uses only as many bytes as needed. For example, in another record of the same file, JOHN JONES (10 bytes) may be replaced by MARJORIE Q. HUMPERDINK (21 bytes) yet each name uses only as much storage as it needs, plus one for the field mark.

Fields may be broken down into values and even subvalues. Values are separated by value marks (character xFD); subvalues are separated by subvalue marks (character xFC). Thus, if John Jones happened to get a second email address, the record may be updated to:

```
123-45-6789^JOHN JONES^jjones@example.com]johnnyjones@example.net^432100^...
```

where the close bracket (]) represents a value mark.

Since each email address can be the ID of a record in separate file (in SQL terms, an outer join; in U2 terms, a "translate"), this provides the reason why U2 may be classified as a MultiValued database.

Data

Raw information is called Data. A record is a set of logical grouped data. e.g. an employee record will have data stored in the form of fields/attributes like his name, address etc.

Programmability

Both UniVerse and UniData have a structured BASIC language (UniVerse Basic and UniBasic, respectively), similar to Pick/BASIC which naturally operates on the structures of the MultiValue database. They also have a structured database query language (RetrieVe and UniQuery) used to select records for further processing and for adhoc queries and reports.

RocketU2 provides a set of Client Tools to allow software developers to access U2 databases from other software languages.[10]

Client Tool interfaces include:

- ODBC / JDBC
- UniOLEDB - OLEDB Driver
- UniObjects (COM)
- UniObjects (.NET)
- UniObjects (Java)
- Native XML
- U2 Web Services

Professional certification

RocketU2 offers five professional certification designations related to the U2 product family. All carry the title *Certified Solutions Expert*.

- U2 Family Application Development
- U2 UniData V7.1 Administration
- U2 UniData V7.2 Administration
- U2 UniVerse V10.2 Administration
- U2 UniVerse V10.3 Administration

PointBase

PointBase

Developer(s)	PointBase Inc.
Written in	Java
Operating system	Cross-platform
Type	RDBMS

PointBase is relational database management system (RDBMS) written in the Java programming language.

History

In 1998, Bruce Scott, a co-founder of the Oracle Corporation (with Larry Ellison, Bob Miner and Ed Oates), started PointBase Inc. with Jeff Richey (an architect of Sybase) and Daren Race. It was written in pure Java, and supported DCOM and CORBA, and is an object-relational database. It was designed to integrate the internet and databases. PointBase Inc. was established in San Mateo, California, then moved to Mountain View, California. Like Java, PointBase was aimed at portable devices.

In the early 2000s it was the database that was shipped for free with the Java platform.

In 2003, the database was acquired by DataMirror of Markham, Ontario.

In September 2007, IBM acquired DataMirror.

Today (2012) PointBase's SQL Engine is part of Oracle's WebLogic platform.

Applications

It has been shipped with the Oracle WebLogic Server, a Java EE server.

PointBase is supported only for the design, development, and verification of applications; it is not supported for enterprise-quality deployment. The evaluation license of PointBase has a database size limit of 30 MB.

Versions

- PointBase Server Edition
- PointBase Mobile Edition

R:BASE System

R:BASE (or RBASE) was the first relational database program for the PC. Created by Wayne Erickson in 1981, on November 13, 1981, Erickson and his brother, Ron Erickson, incorporated the company, MicroRim, Inc. to sell the database, MicroRIM. In June 1998, A. Razzak Memon, President & CEO of R:BASE Technologies, Inc. (a privately held company in Murrysville, Pennsylvania, USA) acquired the R:BASE products from Abacus Software Group. Since 1998, R:BASE is available as R:BASE for Windows v6.1a, v7.1, v7.5, v7.6, Turbo V-8, v9.1, and now v9.5 (32/64) for Windows.

History

Founding

Created by Wayne Erickson in 1981, the original R:Base database was written on a Heathkit CPM computer that Erickson built at home. On November 13, 1981, Erickson and his brother, Ron Erickson, incorporated the company, MicroRim, Inc. to sell the database, MicroRIM. (RIM was an acronym for Relational Information Management, a mainframe database developed by Erikson at Boeing Computer Services, as part of NASA's IPAD project for which he and NASA colleagues received a NASA award, was used by NASA to track Space shuttle heat shield tiles).

The earliest version released by Microrim was called R:Base 4000 and was released in 1983. It worked with early version of Microsoft MS-DOS or IBM PC DOS (version 2 or above). It shipped with a binder-type manual and the program on 360K floppy disks. The system being DOS-based, the interface was entirely text with the exception of DOS line-draw characters.[*citation needed*]

Privately funded and ultimately venture backed, the MicroRim database products achieved significant market share in the mid-1980s in what was dubbed by some, the "database wars" between R:Base and the market share leader, Ashton-Tate's D-Base. One clever MicroRim ad stated "R-way versus D-hardway," a jab at the inferior D-Base architecture. MicroRim adhered to the rules of the father of relational database technology, Edgar F. Codd and prided itself on the elegance of its code.[*citation needed*]

In the mid-1980s, when Microsoft did not have their own database, they obtained a license to resell R:BASE in Europe so they could have a full suite of software products.[*citation needed*]

1990s

In June 1998, R:BASE Technologies, Inc. (a privately held company in Murrysville, Pennsylvania, USA) acquired the R:BASE products from Abacus Software Group.[*citation needed*]

Recent years

Some of the features included, and continue to include, a programming-free application development wizard, automatic multi-user capabilities, a full-featured 4GL programming language, form, report and label designers, and a fully ANSI SQL compliant relational language capability.[*citation needed*]

Since September 2007, R:BASE is available as R:BASE for Windows v7.6, R:BASE for DOS v7.6 and R:BASE Turbo V-8 for Windows. The Version 8.0 has an extended address management for file handling and is able to cover databases up to 2.3 million TB versus V7.6 which covers databases up to 2 GB. A German kernel has existed since R:Base V7.6.[*citation needed*]

Legacy R:BASE Products

R:BASE 4000

The earliest version released by Microrim was called R:Base 4000 and was released in 1983. It worked with early version of Microsoft MS-DOS or IBM PC DOS (version 2 or above). It shipped with a binder-type manual and the program on 360K floppy disks. The system being DOS-based, the interface was entirely text with the exception of DOS line-draw characters.

In spite of its relative ease of use and ability to create useful forms and reports, the first R:Base did not have a conventional programming language, but instead relied on SQL statements to accept input and produce output. The lack of a complete programming language meant that the product was not well received by some portions of the market. This may have helped the early, barely relational, dBase products to become dominant. The product was quickly upgraded to include Added Variables and a conventional programming Language (IF, WHILE, etc.) to the original SQL based language The update was released as R:Base 4000 Version 1.1 in March 1984. R:Base became the second most popular DOS database in the PC market (behind dBase).[*citation needed*]

Portions of the program allowed the user to design screens, called "Forms" in R:Base. Line-draw characters could implement buttons or boxes that would group text on screen. A separate utility allowed the design of printed output formats and was called "Reports." The report design system allowed a user to define and edit fields included in database reports on screen. Limited printer support was included as DOS programs each had their own unique printer driver for similar printer engines. A markup language allowed italics and bold output if the corresponding printer had a capability. Reports could be piped to the display or a serial port for testing if one were so inclined. Database names were constrained to seven characters. The actual data were contained in three files. In an example database named *Sales*, files name SALES1.RBF SALES2.RBF, AND SALES3.RBF would contain the database. Forms and reports were stored in files external to the database file.[*citation needed*]

By default, the application would start with a menu asking which database file you wanted to open. Using a startup switch, R:Base could be run entirely from a command prompt, called the "R-prompt," in system documentation. The application command prompt was an "R>" although this could be modified to other characters by editing a configuration file. In an example database named *Sales*, to query the database, you would first open it by typing "OPEN SALES" at the R-prompt. Using SQL-style queries, one could pull on-screen displays of data from tables. "SELECT FNAME LNAME CITY ZIPCODE FROM MAIN" would display one screen of data from the fields FNAME LNAME CITY ZIPCODE from the table named MAIN. Pressing the space bar would scroll to the next 24 records. A built-in help system produced text after the R> prompt if your query was invalid or the syntax was not understood by the database engine.[*citation needed*]

A feature of the program was its ability to create applications that ran scripts generated by an internal scripting system. Scripts were stored in files with an extension .APP. The system would first ask for type of menu desired, (one option was pull-down, for example,) then asked you to fill out the pull down headings. Next, you were stepped through a list of actions for each menu choice. At the end, the procedures that had been stepped through were recorded in the database file and could be called from an automatically generated menu system. To prevent a user from tampering with the generated script, an encoded version was created. The user could password protect the encoded version for configuration management.

A utility called *File Gateway* allowed import and export of common file formats of the era such as Data Interchange Format (DIF), SYLK, Lotus 1-2-3, and dBase files. Another utility, called *Recover*, was intended to recover

damaged R:Base databases.[*citation needed*]

R:BASE 5000, R:BASE 2.0

R:Base 4000 was followed by R:Base 5000, which substantially improved features and gained wider acceptance.

R:BASE 2.0 rolled out a new file format and introduced the ability to use memory above 640K. There was support for the Intel 80286 processor. The system had substantially better documentation. This version continued the evolution toward full ANSI SQL compliance. Forms, scripts, and reports were rolled into the database files. Three files with extensions .RB1, .RB2, and .RB3 contained everything for a single database.[*citation needed*]

R:BASE 3.x

R:Base 3.0 was ANSI SQL (1989?) compliant and utilized the DOS4GW memory manager. This memory manager was also seen in many DOS games of the era. R:Base 3.1 introduced a **multi-user network capability**. A version was also rolled out for the Convergent Technologies Operating System operating system, this was apparently a follow-on to Burroughs Teechnologies Operating System (BTOS).[*citation needed*]

By purchasing license packs, the database gained a multi-user capability in five-user increments. This included a sophisticated (for a DOS application in the day) record-level locking scheme. To work properly, the multi-user database had to be on a file server with all users accessing the database through a network. It was not true client-server because processing occurred in the clients. The configuration file expanded to allow language support and user-defined re-mapping of characters. For example, German characters such as the letter "ö" (o with an umlaut) could be remapped to the string *oe*. There were character fold tables and sort orders could be adjusted by the user. An "unlimited number of licenses" runtime version was offered, allowing developers to sell applications and include the run-time R:Base engine.

Example of an R:Base 3.1 command prompt transaction asking the application to list the structure of a database table of California cities, (CALIFCY):[*citation needed*]

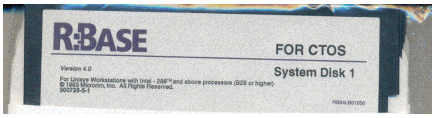
```
R> LIST CALIFCY
  # Name               Type      Index Expression
  1 STATE              TEXT    2
  2 FEATURE            TEXT   85
  3 FEATURET           TEXT    9
  4 COUNTY1            TEXT   15
  5 FIPSST             TEXT    2
  6 FIPSCO             TEXT    3
  7 LATITUDE           TEXT    7
  8 LONGITUD           TEXT    8
  9 LAT_DEC            TEXT    8
 10 LON_DEC            TEXT   10
 11 SOURCELA           TEXT    7
 12 SOURCELO           TEXT    8
 13 SOUR_lat           TEXT    8
 14 SOUR_lon           TEXT   10
 15 ELEVATIO           TEXT    5
 16 FIELD16            TEXT    8
 17 MAPNAME            TEXT   27
 18 LAT1               DOUBLE
 19 LON                DOUBLE
 20 ITEM_NO            DOUBLE
```

```
  Current number of rows:   7070

R>
```

R:BASE 4.x

R:Base 4.0 rolled out Intel 80386 support and a newer DOS4GW memory manager. It included a newer file format, replacing the format used with Version 3.1. To support legacy customers, Version 4.0 included a copy of Version 3.1 with a lot of warnings about new file format and features of 4 that were not supported in 3.1. While the documentation claimed 2GB data files were supported, there were data integrity problems with some very large tables over 1 million records. Still, the software was designed to accommodate up to 750 tables and easily handled tables with tens of thousands of records. It was faster than 3.1 and a reliable and practical application for many users.[*citation needed*]



R:Base for CTOS disk label

R:Base 4.5 rolled out another new file format and greatly improved capacity. OBDC drivers were rolled out to allow interchange of data with Microsoft Windows based applications without running the DOS-based File Gateway utility. While number of records in a database was "limited only by disk space," in practice, some users found there were problems with databases which contained over about 1.1 million records.[*citation needed*]

First R:BASE for Windows

The first product produced by Microrim for use in Microsoft Windows was named R:Base for Windows. This rolled out in 1994. This version was compatible with R:Base 4.5 files and was fully ANSI SQL Level II 1989 compliant. The application was partially ANSI SQL 1992 Level II compliant. The screen capture images in documentation look like Windows 3.1, but documentation claimed it would also run on Windows 95 or the more trustworthy Windows inside OS/2 Warp version 3. A variety of run-time licensing schemes were available to developers.[*citation needed*]

Current Generation R:BASE Products

- R:BASE 7.6 for Windows
- R:BASE 7.6 for DOS
- R:BASE Turbo V-8 for Windows
- R:BASE 9.1 for DOS
- R:BASE eXtreme 9.1 (32) for Windows
- R:BASE eXtreme 9.1 (64) for Windows
- **R:BASE eXtreme 9.5 (32) for Windows**
- **R:BASE eXtreme 9.5 (64) for Windows**

REAL Server

REAL Server is a relational database management system (RDBMS) built on top of the sqlite database engine.

History

REAL Server evolved from the SQLiteServer originally developed by SQLabs in 2004. In May 2005 Real Software, Inc., creator of Realbasic, purchased the source code and the copyrights of the SQLiteServer and invested in its development. In 2007/2008 the first version of the REAL SQL Server was released. A new version was released in April 2009 and renamed REAL Server. In September 2010 SQLabs repurchased all the server's Intellectual Properties and a new major release is now under development by the SQLabs team.[*citation needed*]

Features

- Event based,
- Asynchronous sockets,
- Multi-core and multiprocessor aware,
- Strong AES encryption (128, 192 and 256 bit),
- Supports unlimited connections (For each supported operating system, REAL Server uses a state of the art event API, kqueue on Mac OS X, epool on Linux and I/O Completion Ports on Windows),
- Full ACID (Atomic, Consistent, Isolated, Durable) compliant,
- Platform independent storage engine,
- Full support of triggers and transactions,
- Journal engine for crash recovery,
- Supports databases of 2 terabytes,
- Supports sqlite 3 databases,
- Automatic logging,
- Automatic compression,
- Multiversion concurrency control (MVCC),
- Plugins for extending the SQL language and the custom commands supported by the server,
- Restore and backup support,
- Mac OS X, Windows and Linux support.

Connectivity

REAL Server can be used with the following:

- Realbasic
- PHP
- C SDK
- ODBC

MaxDB

MaxDB

Developer(s)	SAP AG
Stable release	7.6.06.10/7.7.07.16 / March, 2010
Development status	Active
Written in	C++
Operating system	Cross-platform
Available in	English
Type	RDBMS
License	SAP freeware license agreement for MaxDB (closed source)
Website	http://maxdb.sap.com/

MaxDB is an ANSI SQL-92 (entry level) compliant relational database management system (RDBMS) from SAP AG, which was delivered also by MySQL AB from 2003 to 2007. MaxDB is targeted for large SAP environments e.g. mySAP Business Suite and other applications that require enterprise-level database functionality. It is able to run terabyte-range data in continuous operation.[*citation needed*]

History

The database development started in 1977 as a research project at the Technical University of Berlin headed by Rudolf Munz. In the early 1980s it became a database product that subsequently was owned by Nixdorf Computer, Siemens-Nixdorf, Software AG and today by SAP AG. Along this line it has been named VDN, RDS, Reflex, Supra 2, DDB/4, Entire SQL-DB-Server and Adabas D. In 1997 SAP acquired the software from Software AG and developed it as SAP DB, releasing the source code under the GNU General Public License in October 2000.

In 2003 SAP AG and MySQL AB joined a partnership and re-branded the database system to MaxDB. In October 2007 this reselling was terminated and sales and support of the database reverted to SAP.[1] SAP AG is now managing MaxDB development, distribution, and support. Source code of MaxDB is no longer available under the GNU General Public License. SAP also stated that "Further commercial support concepts to cover mission critical use requirements outside of SAP scenarios are currently subject to discussion."[2]

Version 7.5 of MaxDB is a direct advancement of the SAP DB 7.4 code base. Therefore, the MaxDB software version 7.5 can be used as a direct upgrade of previous SAP DB versions starting 7.2.04 and higher.

Features

MaxDB is delivered with a set of administration and development tools. Most tools are GUI based and have CLI (Command Line Interface) based counterparts. It offers bindings for JDBC; ODBC; SQLDBC (native C/C++ interface); Precompiler; PHP; Perl; Python; WebDAV; OLE DB, ADO, DAO, RDO and .NET via ODBC; Delphi and Tcl via Third Party Programming Interfaces. MaxDB is Cross-platform, offering releases for HP-UX, IBM AIX, Linux, Solaris, Microsoft Windows 2000, Microsoft Windows Server 2003, and Microsoft Windows XP. SAP users should check the details of the platform availability on the SAP product pages for the product that will be used together with MaxDB. MaxDB is subjected to SAP AG's quality assurance process before it is shipped.

Distinguishing features

MaxDB offers built-in hot backup, does not need any online reorganizations and claims to be SQL 92 Entry-Level compatible. One current development goal is "zero administration" and by this "low TCO". It is also fair to expect good online transaction processing (OLTP) performance combined with relatively low hardware requirements.

High availability mode and small fault record is another historically observed feature of MaxDB, which holds some appraisal from the open source software and db communities.

Future releases

The next release will have the name MaxDB 7.7.00. One possible future feature for 7.7.00 is the use of Multiversion Concurrency Control (MVCC) instead of the current lock based implementation.

Licensing

MaxDB was licensed under the GNU GPL from versions 7.2 through 7.6. Programming interfaces were licensed under the GPL with exceptions for projects released under other Open Source licenses.

SAP DB 7.3 and 7.4 were licensed as GPL with LGPL drivers. MaxDB 7.5 was offered under dual licensing.i.e. licensed as GPL with GPL drivers or a commercial license.

From version 7.5 through version 7.6 onwards distribution of MaxDB (previously SAP DB) to the open source community was provided by MySQL AB, the same company that develops the open-source software database, MySQL. Development was done by SAP AG, MySQL AB and the open-source software community.

In October 2007, SAP assumed full sales and commercial support for MaxDB. MaxDB 7.6 is now closed source, available free-of-charge (without support, and with usage restrictions) for use with non-SAP applications. Commercial support models for using MaxDB outside of SAP environments are under consideration.

Adaptive Server Enterprise

Adaptive Server Enterprise

Developer(s)	Sybase - An SAP Company
Initial release	May 23, 1980
Written in	C, C++
Operating system	Cross-platform
Available in	English
Type	RDBMS
License	Proprietary EULA
Website	ASE [1]

Adaptive Server Enterprise (ASE) is a relational model database server product for businesses developed by Sybase Corporation which became part of SAP AG. ASE is predominantly used on the Unix platform, but is also available for Microsoft Windows.

History

Originally for Unix platforms in 1987, Sybase Corporation's primary relational database management system product was initially marketed under the name Sybase SQL Server. In 1988, SQL Server for OS/2 was co-developed for the PC by Sybase, Microsoft, and Ashton-Tate. Ashton-Tate divested its interest and Microsoft became the lead partner after porting SQL Server to Windows NT. Microsoft and Sybase sold and supported the product through version 4.2.1.

Sybase released SQL Server 4.8 in 1992. This release included internationalization and localization and support for symmetric multiprocessing systems.

In 1993, the co-development licensing agreement between Microsoft and Sybase ended, and the companies parted ways while continuing to develop their respective versions of the software. Sybase released SQL Server 10.0, which was part of the System 10 product family, which also included Back-up Server, Open Client/Server APIs, SQL Monitor, SA Companion and OmniSQL Gateway.

Sybase provides native low-level programming interfaces to its database server which uses a protocol called Tabular Data Stream. Prior to version 10, DBLIB (DataBase LIBrary) was used. Version 10 and onwards uses CTLIB (Client LIBrary).

In 1995, Sybase released SQL Server 11.0. Starting with version 11.5 released in 1996, Sybase moved to differentiate its product from Microsoft SQL Server by renaming it to Adaptive Server Enterprise.

In 1998, ASE 11.9.2 was rolled out with support for row-level locking, distributed joins and improved SMP performance. ASE 12.0 was released in 1999, providing support for Java, high availability and distributed transaction management. In 2001, ASE 12.5 was released, providing features such as dynamic memory allocation, an EJB container, and support for XML and SSL.

In 2005, Sybase released ASE 15.0. It included support for partitioning table rows in a database across individual disk devices, and "virtual columns" which are computed only when required. In ASE 15.0, many parameters that had been static (which required server reboot for the changes to take place) were made dynamic (changes take effect immediately). This improved performance and reduced downtime. For example, one parameter that was made dynamic was the "tape retention in days" (the number of days that the backup is kept on the tape media without

overwriting the existing contents in the production environment).

Structure

A single stand alone installation of ASE typically comprises one "dataserver" and one corresponding "backup server". In multi server installation many dataservers can share one single backup server though. A dataserver consists of system databases and user's databases. Minimum system databases that are mandatory for normal working of dataserver are 'master', 'tempdb', 'model', 'sybsystemdb' and 'sybsystemprocs'. 'master' database holds critical system related information that includes, logins, passwords, and dataserver configuration parameters. 'tempdb' is used for storage of data that are required for intermediate processing of queries, and temporary data. 'model' is used a template for creating new databases. 'sybsystemprocs' consists of system supplied stored procedures that queries system tables and manipulates data in them.

ASE is a single process multithreaded dataserver application, it means when server is up and running there is one single OS process.

Versions

SAP also has a developer edition that can be used for free to develop against (but not for production use).[2] It only allows 1 engine and 25 connections.[3] There is also an SAP Sybase ASE, express edition available which is limited to 1 server engine, 2 Gb of memory and 5 Gb of disk space per server. This edition is free for production purposes.

Advantage Database Server

Advantage Database Server

Developer(s)	Sybase
Initial release	August, 1993
Written in	C, C++
Operating system	Cross-platform
Available in	English
Type	RDBMS
Website	advantagedatabase.com [1]

Advantage Database Server is a relational database management system (RDBMS) for small to medium sized businesses by Sybase iAnywhere. Database author Cary Jensen describes Advantage as follows: "Advantage has been around since 1993, when it was introduced to provide a stable solution for Clipper developers who were tired of slow performance and corrupt indexes inherent to file server-based databases. Over the years, ADS has grown in both popularity and features. Advantage is now a mature product with an impressive collection of features that rival many of the more expensive and complicated database servers".[2]

“In short, the Advantage Database Server is a high-performance, low-maintenance, remote database server that permits you to easily build and deploy client/server applications and web-based applications”.[3]

Uses

Advantage Database Server is most popular among application developers as a client/server backend solution for shared, networked, standalone, mobile and Internet database applications. ADS is unique among other database offerings because it provides both ISAM table-based and SQL based data access.

Features

- Replication
- Online Backup
- ISAM access (Navigational Access)
- SQL-92 compliant
- SQL Query Optimizer
- User Defined Functions
- Triggers
- Stored Procedures
- Views
- Server Side Aliases
- Encrypted indexes and communications
- DBF tables and memos greater than 4 gigabytes
- Transactions
- Events / Notifications
- 64-bit support
- Full Text Search
- Multiple Processor support

- Small footprint
- Odata Web Service
- Native DBF data format support
- Unicode Support

Programming Languages

- Popular development environments including CodeGear Delphi, CodeGear C++Builder, Microsoft Visual Basic, Microsoft Visual C++, CA-Visual Objects, CA-Clipper and Microsoft Visual FoxPro.
- Supports standard interfaces such as ODBC, OLE DB, JDBC, PHP, and ADO.NET.

History

- August 1993 – Initially released as Advantage xBase server by Extended Systems.
- December 1995 – version 4.0 release, now called Advantage Database Server. This release included the first ODBC driver.
- February 1997 – Advantage Internet Server released.
- April 2000 – Advantage ODBC driver with StreamlineSQL released.
- November 2005 – Advantage Database Server: The Official Guide published.[4]
- November 2005 – Extended Systems acquired by Sybase, rolled in to iAnywhere Solutions subsidiary.
- November 2008 – Advantage Database Server 9.1.
- June 2010 – Advantage Database Server 10.0
- December 2010 - Advantage Database Server 10.1
- July 2012 – Advantage Database Server 11.0

Ingres (database)

Ingres

Ingres Corporation logo from 2007	
Original author(s)	University of California, Berkeley
Developer(s)	Actian Corporation
Stable release	Ingres Database 10 / October 12, 2010
Written in	C
Operating system	Cross-platform
Type	RDBMS
License	GNU General Public License or proprietary
Website	www.actian.com [1]

Ingres Database (/ɪŋˈgrɛs/ *ing-**GRESS***) is a commercially supported, open-source SQL relational database management system intended to support large commercial and government applications. Ingres Database is fully open source with a global community of contributors. However, Actian Corporation controls the development of Ingres and makes certified binaries available for download, as well as providing worldwide support.

Ingres began as a research project at the University of California, Berkeley, starting in the early 1970s and ending in 1985. The original code, like that from other projects at Berkeley, was available at minimal cost under a version of the BSD license. Ingres spawned a number of commercial database applications, including Sybase, Microsoft SQL Server, NonStop SQL and a number of others. Postgres (**Post** I**ngres**), a project which started in the mid-1980s, later evolved into PostgreSQL.

Ingres is ACID and is fully transactional (including all DDL statements).

Ingres is part of the Lisog open-source stack initiative.

History

In 1973 when the System R project was getting started at IBM, the research team released a series of papers describing the system they were building. Two scientists at Berkeley, Michael Stonebraker and Eugene Wong, became interested in the concept after reading the papers, and started a relational database research project of their own, named *University INGRES*.

They had already raised money for researching a geographic database system for Berkeley's economics group, which they called **Ingres**, for **IN**teractive **G**raphics **RE**trieval **S**ystem. They decided to use this money to fund their relational project instead, and used this as a seed for a new and much larger project. For further funding, Stonebraker approached the DARPA, the obvious funding source for computing research and development at the time, but both the DARPA and the Office of Naval Research (ONR) turned them down as they were already funding database research elsewhere. Stonebraker then introduced his idea to other agencies, and, with help from his colleagues he eventually obtained modest support from the NSF and three military agencies: the Air Force Office of Scientific Research, the Army Research Office, and the Navy Electronic Systems Command.

Thus funded, Ingres was developed during the mid-1970s by a rotating team of students and staff. Ingres went through an evolution similar to that of System R, with an early prototype in 1974 followed by major revisions to make the code maintainable. Ingres was then disseminated to a small user community, and project members rewrote the prototype repeatedly to incorporate accumulated experience, feedback from users, and new ideas. The research

projected ended in 1985. Ingres remained largely similar to IBM's System R in concept, but it was based on "low-end" systems, namely Unix on DEC machines.

Commercialization

Unlike System R, the Ingres source code was available (on tape) for a modest fee. By 1980 some 1,000 copies had been distributed, primarily to universities. Many students from U.C. Berkeley and other universities who used the Ingres source code, worked on various commercial database software systems.

Berkeley students Jerry Held and later Karel Youseffi moved to Tandem Computers, where they built a system that evolved into NonStop SQL. The Tandem database system was a re-implementation of the Ingres technology. It evolved into a system that ran effectively on parallel computers; that is, it included functionality for distributed data, distributed execution, and distributed transactions (the last being fairly difficult). Components of the system were first released in the late 1970s. By 1989, the system could run queries in parallel and the product became fairly famous for being one of the few systems that scales almost linearly with the number of processors in the machine: adding a second CPU to an existing NonStop SQL server will almost exactly double its performance. Tandem was later purchased by Compaq, which started a re-write in 2000, and now the product is at Hewlett-Packard.

In the early 1980s, Ingres competed head-to-head with Oracle. The two products were widely regarded as the leading hardware-independent relational database implementations; they had comparable functionality, performance, market share, and pricing, and many commentators considered Ingres to be a (perhaps marginally) superior product. From around 1985, however, Ingres steadily lost market share. One reason was Oracle's aggressive marketing; another was the increasing recognition of SQL as the preferred relational query language. Ingres originally had provided a different language, Quel, and the conversion to SQL (delivered in Ingres version 6) took about three years, losing valuable time in the race.

Robert Epstein, the chief programmer on the project while he was at Berkeley, formed Britton Lee, Inc. along with other students from the Ingres Project, Paula Hawthorn and Michael Ubell; they were joined later by Eric Allman. Later, Epstein founded Sybase. Sybase had been the #2 product (behind Oracle) for some time through the 1980s and into the 1990s, before Informix came "out of nowhere" and took over in 1997. Sybase's product line had also been licensed to Microsoft in 1992, who rebranded it as Microsoft SQL Server. This relationship soured in the late 1990s, and today SQL Server outsells Sybase by a wide margin.

Several companies used the Ingres source code to produce products. The most successful was a company named Relational Technology, Inc. (RTI), founded in 1980 by Stonebraker and Wong, and another Berkeley professor, Lawrence A. Rowe. RTI was renamed Ingres Corporation in the late 1980s. The company converted the code to DEC VAX/VMS, which was the commercial operating system for DEC VAX computers. They also developed a collection of front-end tools for creating and manipulating databases (e.g., reporterwriters, forms entry and update, etc.) and application development tools. Over time, much of the source was rewritten to add functionality (for example, multiple-statement transactions, SQL, B-tree access method, date/time datatypes, etc.) and improve performance (for example, compiled queries, multithreaded server). The company was purchased by ASK Corporation in November 1990. The founders left the company over the next several months. In 1994, ASK/Ingres was purchased by Computer Associates, who continued to offer Ingres under a variety of brand names (for example, OpenIngres, Ingres II, or Advantage Ingres).

In 2004, Computer Associates released Ingres r3 under an open source license. The code includes the DBMS server and utilities and the character-based front-end and application-development tools. In essence, the code has everything except OpenROAD, the Windows 4GL GUI-based development environment. In November 2005, Garnett & Helfrich Capital, in partnership with Computer Associates, created a new company called Ingres Corporation, which provided support and services for Ingres, OpenROAD, and the connectivity products.

Recent years

In February 2006, Ingres Corporation released Ingres 2006 under the GNU General Public Licence. Ingres 9.3 was released on October 7, 2009. It was a limited release targeted at new application development on Linux and Windows only.[2]

Ingres 10 was released on October 12, 2010, as a full release, supporting upgrade from earlier versions of the product. It was available on 32-bit and 64-bit Linux, and 32-bit Microsoft Windows.

Open-source community initiatives with Ingres included:

Community Bundles – Alliances with other open-source providers and projects, such as Alfresco, JasperSoft, Hibernate, Apache Tomcat, and Eclipse, enable Ingres to provide its platform and technology with other open-source technologies.

Established by Ingres and Carleton University, a series of Open Source Boot Camps were held in 2008 to work with other open-source communities and projects to introduce university and college students and staff to the concepts and realities of open source.

Other involvement includes: Global Ingres University Alliances, Ingres Engineering Summit, Ingres Janitors Project and several memberships in open-source initiatives.

Ingres Icebreaker is an appliance that combines the Ingres Database with the Linux operating system, enabling people to simultaneously deploy and manage a database and operating system.

Ingres CAFÉ (Consolidated Application Foundation for Eclipse), created by a team of developers at Carleton University, is an integrated environment that helps software architects accelerate and simplify Java application development.[3]

Ingres Geospatial was community-based project to create industry-standards-compliant geospatial storage features in the Ingres DBMS. In other words, for storing map data and providing powerful analysis functions within the DBMS.[4]

In November 2010 Garnett & Helfrich Capital acquired the last 20% of equity in Ingres Corp that it did not already own. On September 22, 2011, Ingres Corporation became Actian Corporation. It focused on Action Apps, which use Ingres or Vectorwise RDBMS systems.

Postgres

The Postgres project was started to address limitations of existing database-management implementations of the relational model. Primary among these was their inability to let the user define new domains (or "types") which are combinations of simpler domains (see relational model for an explanation of the term "domain"). The project explored other ideas including the incorporation of write-once media (e.g., optical disks), the use of massive storage (e.g., never delete data), inferencing, and object-oriented data models. The implementation also experimented with new interfaces between the database and application programs (e.g., "portals", which are sometimes referred to as "fat cursors").

The resulting project, named "Postgres", aimed at introducing the minimum number of features needed to add complete types support. These included the ability to define types, but also the ability to fully describe relationships – which up until this time had been widely used but maintained entirely by the user. In Postgres, the database "understood" relationships, and could retrieve information in related tables in a natural way using *rules*.

In the 1990s, Stonebraker started a new company to commercialize Postgres, under the name **Illustra**. The company and technology were later purchased by Informix.

Installation

Ingres may be installed as a *Client Installation* or as a *Server Installation*, the difference being that the Client has no databases associated with it, but allows access to databases created in Server Installations.

A typical site would install Ingres Client Installations on its employees' PCs, and these would communicate with the Ingres Server installations on the site's core computing facility.

Note that the expression "instance" is a synonym for "installation".

An installation can be viewed as a collection of server processes, shared memory and semaphores for interprocess communication, as well as disk-based files used for transaction processing and (in the event of a failure of the host or of the installation) for database recovery.

Installation identifier

An installation is often referred to by its installation identifier. This is a two-character case-sensitive identifier, beginning with a letter. The default identifier is II. The installation identifier is used internally to compute what ports the Ingres servers will listen on. For example "II" indicates that the servers will listen on port 21064 plus the 7 port numbers after that.

Any host (machine or virtual machine) may have multiple Ingres installations on it, but each installation must use unique identifiers to ensure that its clients and components communicate with the correct installation.

A single installation may use multiple installation identifiers. The classic example is when wishing to run more than eight server processes. Furthermore, although Ingres database servers (iidbms) and Ingres communication servers (iigcc) conventionally use the same installation identifier, there is no requirement to do so.

Installation paths

At the point of creating the installation, several critical paths need to be assigned. Once created, these cannot be changed without re-installing, hence care should be taken in their choice.

These paths appear in the following table. Note that the 'II_' prefix does not indicate that these are for the 'II' installation. Each installation, regardless of its identifier, will have its own set of these variables.

Name	Purpose
II_SYSTEM	The installations binaries, utilities, text files used for configuration etc. are kept under this path.
II_DATABASE	The primary data location for the installation.
II_CHECKPOINT	The location used when creating backups of the installations databases.
II_JOURNAL	The transaction journaling location for the installations databases. Journals are used by the recovery system to provide point-of-failure recovery. They may also be used for auditing purposes.
II_DUMP	The location of the installations 'dump' files. These may be generated during a databases 'on-line' backup and are essential for the databases recovery.
II_WORK	Used to hold work files generated by the server when performing queries on the database.

Patching

The installation is created by a privileged user of the host (i.e. username "root"). However, the addition of software patches to the installation is performed by the installation owner (typically the user: ingres).

In Ingres, software patches are cumulative and sequentially numbered. Hence installing patch *N+1* will automatically include all the additions by patch *N*.

To determine the current installation version and patch level, it is simply a matter of inspecting the text file: II_SYSTEM/ingres/version.rel.

The text file "II_SYSTEM/ingres/version.dat" provides extra information on the date of installation.

Note that both files are cumulative, and the top entry is the current version and patch.

Databases

An Ingres installation (or instance) may support many databases, each being owned by any user known to the installation. The installation will allow many databases to be available concurrently. The number available is a configurable quantity. Note this simply restricts the number of databases available at any instant, and many more databases may be created.

On creation of an Ingres Server installation, the databases named "iidbdb" and "imadb" are created. These databases are owned by the user "$ingres". The database iidbdb is also known as the "Master Catalog database", and it contains many tables specific to the management of the installation itself. The database imadb is the Ingres Management Architecture database, and it also contains many registered objects useful for management of the installation.

Of particular note is that databases do not need to be "pre-sized". Each database in the installation is permitted to grow as large as the available disk space will permit.

Multiple data locations

Each database may be created on any data location known to the installation. If no data location is specified, then the primary data location indicated by the installation default of II_DATABASE is assumed. Once created, the database may then be extended to use any (or all) of the other data locations known to the installation.

A database with multiple locations has the advantage of allowing parallel backups, and hence it can potentially reduce the backup time.

Public or private

Databases may be marked as public or private, at the point of creation, or afterwards. A public database is accessible to all known Ingres users in the installation – unless they have been specifically denied access. A private database is accessible only to specified permitted users, groups and roles.

Unicode

A database may be created with a specific Unicode collation. This attribute can also be added after creation. Ingres supports the Unicode collation algorithm; optional Unicode support allows Ingres to minimize its resource requirements.

Distributed databases

Ingres provides a distributed database system via the IngresSTAR server.

A database must be created as distributed by suffixing the database name with the "/star" service class. Once they have been created, the tables, views and procedures from other databases may be registered within the distributed database. The distributed database may also have its own tables, views and procedures.

The IngresNET server allows the source databases to be on any other Ingres installation as well as on the installation which holds the distributed database. The IngresBRIDGE server allows the source databases to be non-Ingres databases as well.

User access to the distributed database is exactly as per regular databases. User grants to the registered tables and views are determined by the database from which they are registered.

Queries may then be run across the tables as per normal, although there are some restrictions on query types. Furthermore a user transparent two-phase commit is inbuilt to the system.

Database objects

Catalogs

Regardless of ownership, each database is created with a set of tables and views owned by the user "$ingres". These are referred to as *catalogs* and are used to control many aspects of the databases interaction with the world.

The Master Catalog Database "iidbdb" has a specific set of catalogs which will not be loaded into any other database.

Catalogs are publicly readable, but cannot be altered by anyone other than a privileged user.

Tables

The database owner and permitted users are allowed to create tables as they wish, within the database and may share access to these as they wish. Note that regardless of the database access mode (public/private), a table is private until the owner of the table grants other users some access to it.

Tables are not "pre-sized" at the point of creation. Ingres makes no restrictions and will allow any table to grow as far as disk space permits.

The same table name may be used by multiple table owners. When a distinction needs to be made in the application code, it may specify the full schema name of "table_owner.table_name". If the schema has not been specified, then the system will check to see if the current user has a table of this name, and if not, it will then check if the database owner has a table of this name.

Ingres supports four table types, and has compressed subtypes available for each. These types are: Heap, Hash, ISAM (indexed sequential), B-tree (binary tree). The Heap type is unstructured; all others are structured tables where a "Primary Key" is designated. These table types allow tables to be tailored to suit the needs of queries and considerably improve query performance.

The table type dictates the way in which data is stored within the table, and the tables response to insert, update, delete or select requests. The frequency of such activity dictates the occasional maintenance requirement of restructuring the table to ensure optimum query response.

A table may be located on any of the data locations that the database has been permitted to use. The table may be spread across multiple locations -a feature of particular use for large tables and for parallel backups. Ingres will attempt to spread the data evenly across all locations the table is permitted to use.

A table is composed of pages. The data and the keying details for the table structure are all stored on these pages. Each table is permitted to grow to approx. 8.4 million pages. All the pages for the table are of a fixed size, specified at creation or when last restructured. The six available page sizes are: 2K, 4K, 8K, 16K, 32K, 64K. The installation

must be configured to support the chosen size. Typically an installation defaults to provide 2K, 4K and 8K pages.

Once a table has been created with a specific size, it may be subsequently restructured to a different page size. The correct choice of page size for a table can be beneficial in allowing both increased size in the table and in allowing the possibility of row-level locking (available on page sizes of 4K and above).

Each page may hold a maximum of 512 rows of data. No row may span a page. A certain amount of each page is reserved for system purposes, hence the entire space is not available to data. For example, a 2K page has only 2,008 bytes (of the total 2,048) available for data.

If larger tables are required, the table may be partitioned. Each partition of the table is effectively a separate table, and each may grow to 8.4 million pages. The set of partitions then makes a logical table, completely transparently to the users accessing the table. The partitions may also be partitioned, effectively providing a limitless table size. This feature allows Ingres databases to seamlessly grow from a few megabytes to several terabytes.

Indexes

Each table may have zero, one or more indexes created upon it. An index may be of any structured type i.e. HASH, ISAM or B-TREE. The addition of a secondary index on the table can give improved access to the table data for specific queries.

Indexes may be queried directly. In most respects, they behave just like tables. An index may be created with a different page size to its base table.

Both primary key and secondary-index keys may be designated as unique or non-unique.

Temporary tables

Ingres supports the creation of "lightweight" or temporary tables, which exist purely for the lifetime of the connected session which creates them. These tables can be structured as per regular tables, but may not be shared. The temporary table exists within the server, until it grows too large, at which point its details will be transparently written to a disk. If this occurs, the details will be removed as soon as the session disconnects.

They are useful in holding temporary data for reports and for simplifying complicated queries.

Views

A view is a logical object with no physical disk presence other than its definition. A view is like a predefined select query on one or more tables or other views. A view may be treated like any table, but cannot have an index or structure imposed upon it.

Constraints

Ingres supports the following table constraints, as well as propagation constraint and ON UPDATE CASCADE on foreign keys.

- Check Constraint, where a column value is mandated to be a specific value or within a range of values on the basis of a simple calculation.
- Unique Constraint, where a column value will have uniqueness enforced.
- Foreign Key Constraint, where a column value must exist in another table.
- Primary Key Constraint, where nominated columns within the table are grouped into a unique primary key. This is an adjunct to the normal Ingres Primary Key which may be defined upon the table.

Most of these constraints require a secondary index to perform their function. If such an index is not nominated, then Ingres will automatically create an appropriate index on the table.

Constraints may be created when the table is created, or added afterwards.

Database procedures

A Database Procedure (DBP) is a named routine consisting of SQL and procedural statements that is stored in the database, close to the data. When a DBP is created, Ingres optimizes and compiles the procedure and caches the generated code. The database procedure can then be invoked directly from a client application program or from another database procedure, or it can be triggered by a rule (see below).

Most of the usual SQL statements are available, supplemented by procedural code features, such as variable creation and assignment, flow of control and event and error-control statements.

Some advantages of Database Procedures

- **Performance:** The DBP code typically only needs to be compiled once by Ingres and a DBP can reduce the data traffic between an application and Ingres by performing calculations in situ.
- **Integrity:** Similarly to "getter" and "setter" methods, DBPs can be used to control access to the tables. Users can also program Ingres to execute a DBP when a table undergoes a specific change.
- **Security:** DBPs can be used to restrict the operations available to the tables. The SQL GRANT statement can be used to provide execute permission for a DBP accessing the tables, even though the tables provide no access permission.
- **Control**: DBPs can be used as a central place to maintain the data manipulation logic used by a whole variety of applications. In this way the DBP logic can be updated without needing to change each application (the DBP signature/contract must be maintained), and it is even possible to update a DBP on a live system (if careful).
- **Portability**: An Ingres DBP will work unchanged in any Ingres DBMS regardless of the underlying operating system or platform.

Database rules

Database Rules may be created on tables, also called "triggers". Rules are typically used to enforce integrity checks which would be too complicated for simple constraints. However, they may be employed to perform other tasks, such as raise events, etc.

Rules are triggered *before* or *after* nominated action(s) on the associated table. Note that older versions of Ingres allowed only *after* rules to be defined. There is no restriction on the number of rules a table may have. If an action causes multiple rules to fire, then the order of firing is undefined.

The rules will cause an associated database procedure to be executed. That procedure is referred to as a Rules Fired Procedure or RFP. In most respects RFPs and DEPs are similar in capability, however there are some restrictions on the RFPs:

- They must not return a value or rows.
- They cannot take a temporary table as a parameter.
- They may not issue either the *commit* or *rollback* statement.
- If the rule is triggered by a *before* action then it may not directly perform insert, update or delete activity on the database. It is believed that this restriction may be removed in a future release. In the mean time a *work-around* is for the RFP to call another procedure to perform any required insert, update or delete activity.

There are also differences in the effects of errors being raised by RFPs and DEPs. In an RFP, raising an error will cause the procedure to stop, all statements executed by the procedure will be rolled back and the statement which caused the rule to fire will also be rolled back.

Parameters to an RFP may be passed by value or reference. For example *before* fired rules may use a parameter passed by reference to install a desired value in a column of the row of data which initially caused the rule to be fired.

Data types

Ingres supports the conventional data types such as:

- integers (1 byte, 2 byte, 4 byte and 8 byte)
- floats (4 byte, 8 byte)
- fixed precision numbers (numeric/decimal)
- characters (fixed and variable length)
- binary (fixed and variable length)
- dates and times (ANSI date, time, and timestamp)

Ingres supports user defined types though the Object Management Extension

- You can use a user-defined data type in any context in which you can use a standard Ingres data type
- You can use user-defined SQL functions in queries to manipulate both user-defined data types
- To support new data types and functions, you can add new capabilities to existing SQL comparison and arithmetic operators.

Ingres supports Unicode with types:

- nchar
- nvarchar

Ingres supports large objects with:

- long varchar
- long byte

Ingres supports proprietary types such as:

- ingres date
- money

Ingres supports geospatial data types (version 10S and later):

- point, multipoint
- linestring, multilinestring
- polygon, multipolygon
- geometry, geometrycollection

Backup and recovery

Journaling

Ingres is a fully transactional DBMS. These transactions may be recorded as **journals** associated with the database under the II_JOURNAL path. The journals created by the DBMS may then be examined as part of auditing activity or used in a database recovery.

To enable journaling on a database is a two step process. Namely:

- Enable journaling on the database as a whole. This is done by specifying the "+j" flag to the **ckpdb** command.
- Nominate tables within the database for journaling. Note that indexes do not need to be nominated, views cannot be journaled.

Note that the configuration of the Ingres DBMS allows for the new tables to be automatically journal-enabled via the *default journaling* parameter. Some care should be taken with this facility as not all tables should be journaled. For example, a work table which is constantly emptied and refreshed should not be journaled as it places extra data in the journal system, data which are generally irrelevant to auditing and not required for database recovery.

A table's journaling status may be easily altered. However if journaling is enabled on the table the journaling will not commence until after the next occasion the database is backed up using the **ckpdb** command. If the table is created journal-enabled, the journaling will commence immediately. If journaling is disabled the effect is also immediate.

To examine the journals for a database in a human readable form is simply a matter of using the **auditdb** command. The command is option-rich and has many features for auditing transactions committed within a given time frame, by specified users on a nominated set of tables, etc. The command has other options which can be used as part of an *audit trail recovery* for a database.

Backup

The principal backup utility provided in the dbms is the command: **ckpdb**

Ingres backups may be taken *On-line* where some user activity is permitted on the database, or *Off-line* where no user activity is permitted on the database. During On-line checkpoints users may still select, insert, update or delete from the database but are not permitted to drop tables, modify existing structures or other DDL statements.

Backups will capture the entire database by default, however the ckpdb command may be directed to restrict itself to specific tables.

This ckpdb utility would typically create a tar file snapshot of the database. These snapshots are referred to as *checkpoints*. The files created are stored in the databases II_CHECKPOINT location. To allow for changes being made to the databases tables during the lifetime of the backup, the system will also create **dump** files. These reflect the changes being made and are used to ensure the database will be restored to a consistent state as at the start of the checkpoint if a database recovery is required. The dump files created are stored in the databases II_DUMP area.

A databases backup history may be examined using the **infodb** command. It will print a human readable summary of the databases backup history ... as well as other datum. For example *infodb iidbdb* would generate the backup history of the master catalog database iidbdb.

Other archiving tools may be used. More recent versions of ingres also provide a *cpio*-based version. Furthermore, some customisation of the backup is achievable by editing the *Checkpoint template file*. A typical user customisation is to direct tar to use compression.

Multiple template files may be created and a specific one selected by pointing to it with the environment variable II_CKTMPL_FILE. The default template file is: II_SYSTEM/ingres/files/cktmpl.def.

The alternatives to ckpdb are the utilities: **copydb** or **unloaddb**. These provide static snapshots only. If these utilities are used, care should be taken to ensure the correct representation of floating point numbers and dates.

It is not a good idea to back up an Ingres database with an OS dump of the database's data areas.

Recovery

The principal means of recovering an Ingres database from a checkpoint is the utility: "rollforwarddb".

By default rollforwarddb will restore the database from its most recent valid backup and then apply all the databases journals and thus restore the database as completely as possible. Furthermore, the command is option rich, and it may be directed to:

- use an older checkpoint,
- not apply journals,
- apply journals up to a specified end time. The time ensuring all transaction **committed** at or before this time are restored.
- apply journals from a specified begin time. The time ensuring that all transactions **committed** on or after this time are restored. This is a rarely employed option.

Note that for time-based recoveries the critical feature is when the transaction was **committed**, not when it was started. If it becomes necessary to see what transactions will be included in the recovery the time parameters can be used in the **auditdb** utility. That utility will display the included transactions and their details.

Customisation of the rollforwarddb utility may also be performed by editing the *checkpoint template file*. For example, if the checkpoints were compressed the rollforwarddb command will need a customisation installed to allow it to process the compressed tar file.

Normal Form

Data redundancy

Data redundancy occurs in database systems which have a field that is repeated in two or more tables. For instance, when customer data is duplicated and attached with each product bought then redundancy of data is a known source of inconsistency, since customer might appear with different values for given attribute. Data redundancy leads to data anomalies and corruption and generally should be avoided by design. Database normalization prevents redundancy and makes the best possible usage of storage. Proper use of foreign keys can minimize data redundancy and chance of destructive anomalies. However, concerns of efficiency and convenience can sometimes result in redundant data design despite the risk of corrupting the data.

Notes and references

Database normalization

Database normalization is the process of organizing the fields and tables of a relational database to minimize redundancy and dependency. Normalization usually involves dividing large tables into smaller (and less redundant) tables and defining relationships between them. The objective is to isolate data so that additions, deletions, and modifications of a field can be made in just one table and then propagated through the rest of the database using the defined relationships.

Edgar F. Codd, the inventor of the relational model, introduced the concept of normalization and what we now know as the First Normal Form (1NF) in 1970. Codd went on to define the Second Normal Form (2NF) and Third Normal Form (3NF) in 1971,[1] and Codd and Raymond F. Boyce defined the Boyce-Codd Normal Form (BCNF) in 1974.[2] Informally, a relational database table is often described as "normalized" if it is in the Third Normal Form.[3] Most 3NF tables are free of insertion, update, and deletion anomalies.

A standard piece of database design guidance is that the designer should first create a fully normalized design; then selective denormalization can be performed for performance reasons.[4]

Objectives

A basic objective of the first normal form defined by Edgar Frank "Ted" Codd in 1970 was to permit data to be queried and manipulated using a "universal data sub-language" grounded in first-order logic.[5] (SQL is an example of such a data sub-language, albeit one that Codd regarded as seriously flawed.)[6]

The objectives of normalization beyond 1NF (First Normal Form) were stated as follows by Codd:

1. To free the collection of relations from undesirable insertion, update and deletion dependencies;

2. To reduce the need for restructuring the collection of relations, as new types of data are introduced, and thus increase the life span of application programs;

3. To make the relational model more informative to users;

4. To make the collection of relations neutral to the query statistics, where these statistics are liable to change as time goes by.

— E.F. Codd, *"Further Normalization of the Data Base Relational Model"*[7]

The sections below give details of each of these objectives.

Free the database of modification anomalies

When an attempt is made to modify (update, insert into, or delete from) a table, undesired side-effects may follow. Not all tables can suffer from these side-effects; rather, the side-effects can only arise in tables that have not been sufficiently normalized. An insufficiently normalized table might have one or more of the following characteristics:

Employees' Skills

Employee ID	Employee Address	Skill
426	87 Sycamore Grove	Typing
426	87 Sycamore Grove	Shorthand
519	94 Chestnut Street	Public Speaking
519	96 Walnut Avenue	Carpentry

An **update anomaly**. Employee 519 is shown as having different addresses on different records.

Faculty and Their Courses

Faculty ID	Faculty Name	Faculty Hire Date	Course Code
389	Dr. Giddens	10-Feb-1985	ENG-206
407	Dr. Saperstein	19-Apr-1999	CMP-101
407	Dr. Saperstein	19-Apr-1999	CMP-201
424	Dr. Newsome	29-Mar-2007	?

An **insertion anomaly**. Until the new faculty member, Dr. Newsome, is assigned to teach at least one course, his details cannot be recorded.

Faculty and Their Courses

Faculty ID	Faculty Name	Faculty Hire Date	Course Code
389	Dr. Giddens	10-Feb-1985	ENG-206
407	Dr. Saperstein	19-Apr-1999	CMP-101
407	Dr. Saperstein	19-Apr-1999	CMP-201

DELETE

A **deletion anomaly**. All information about Dr. Giddens is lost if he temporarily ceases to be assigned to any courses.

- The same information can be expressed on multiple rows; therefore updates to the table may result in logical inconsistencies. For example, each record in an "Employees' Skills" table might contain an Employee ID, Employee Address, and Skill; thus a change of address for a particular employee will potentially need to be applied to multiple records (one for each skill). If the update is not carried through successfully—if, that is, the employee's address is updated on some records but not others—then the table is left in an inconsistent state. Specifically, the table provides conflicting answers to the question of what this particular employee's address is. This phenomenon is known as an **update anomaly**.
- There are circumstances in which certain facts cannot be recorded at all. For example, each record in a "Faculty and Their Courses" table might contain a Faculty ID, Faculty Name, Faculty Hire Date, and Course Code—thus we can record the details of any faculty member who teaches at least one course, but we cannot record the details of a newly hired faculty member who has not yet been assigned to teach any courses except by setting the Course Code to null. This phenomenon is known as an **insertion anomaly**.
- Under certain circumstances, deletion of data representing certain facts necessitates deletion of data representing completely different facts. The "Faculty and Their Courses" table described in the previous example suffers from this type of anomaly, for if a faculty member temporarily ceases to be assigned to any courses, we must delete the last of the records on which that faculty member appears, effectively also deleting the faculty member. This phenomenon is known as a **deletion anomaly**.

Minimize redesign when extending the database structure

When a fully normalized database structure is extended to allow it to accommodate new types of data, the pre-existing aspects of the database structure can remain largely or entirely unchanged. As a result, applications interacting with the database are minimally affected.

Make the data model more informative to users

Normalized tables, and the relationship between one normalized table and another, mirror real-world concepts and their interrelationships.

Avoid bias towards any particular pattern of querying

Normalized tables are suitable for general-purpose querying. This means any queries against these tables, including future queries whose details cannot be anticipated, are supported. In contrast, tables that are not normalized lend themselves to some types of queries, but not others.

For example, consider an online bookseller whose customers maintain wishlists of books they'd like to have. For the obvious, anticipated query—what books does this customer want?—it's enough to store the customer's wishlist in the table as, say, a homogeneous string of authors and titles.

With this design, though, the database can answer only that one single query. It cannot by itself answer interesting but unanticipated queries: What is the most-wished-for book? Which customers are interested in WWII espionage? How does Lord Byron stack up against his contemporary poets? Answers to these questions must come from special adaptive tools completely separate from the database. One tool might be software written especially to handle such queries. This special adaptive software has just one single purpose: in effect to normalize the non-normalized field.

Unforeseen queries can be answered trivially, and entirely within the database framework, with a normalized table.

Example

Querying and manipulating the data within a data structure which is not normalized, such as the following non-1NF representation of customers' credit card transactions, involves more complexity than is really necessary:

Customer Jones Wilkinson Stevens Transactions

Tr. ID	Date	Amount
12890	14-Oct-2003	−87
12904	15-Oct-2003	−50

Tr. ID	Date	Amount
12898	14-Oct-2003	−21

Tr. ID	Date	Amount
12907	15-Oct-2003	−18
14920	20-Nov-2003	−70
15003	27-Nov-2003	−60

To each customer corresponds a *repeating group* of transactions. The automated evaluation of any query relating to customers' transactions therefore would broadly involve two stages:

1. Unpacking one or more customers' groups of transactions allowing the individual transactions in a group to be examined, and
2. Deriving a query result based on the results of the first stage

For example, in order to find out the monetary sum of all transactions that occurred in October 2003 for all customers, the system would have to know that it must first unpack the *Transactions* group of each customer, then sum the *Amounts* of all transactions thus obtained where the *Date* of the transaction falls in October 2003.

One of Codd's important insights was that this structural complexity could always be removed completely, leading to much greater power and flexibility in the way queries could be formulated (by users and applications) and evaluated (by the DBMS). The normalized equivalent of the structure above would look like this:

Customer	Tr. ID	Date	Amount
Jones	12890	14-Oct-2003	−87
Jones	12904	15-Oct-2003	−50
Wilkins	12898	14-Oct-2003	−21
Stevens	12907	15-Oct-2003	−18
Stevens	14920	20-Nov-2003	−70
Stevens	15003	27-Nov-2003	−60

Now each row represents an individual credit card transaction, and the DBMS can obtain the answer of interest, simply by finding all rows with a Date falling in October, and summing their Amounts. The data structure places all of the values on an equal footing, exposing each to the DBMS directly, so each can potentially participate directly in queries; whereas in the previous situation some values were embedded in lower-level structures that had to be handled specially. Accordingly, the normalized design lends itself to general-purpose query processing, whereas the unnormalized design does not.

Background to normalization: definitions

Functional dependency

> In a given table, an attribute *Y* is said to have a functional dependency on a set of attributes *X* (written $X \rightarrow Y$) if and only if each *X* value is associated with precisely one *Y* value. For example, in an "Employee" table that includes the attributes "Employee ID" and "Employee Date of Birth", the functional dependency {Employee ID} $\rightarrow$ {Employee Date of Birth} would hold. It follows from the previous two sentences that each {Employee ID} is associated with precisely one {Employee Date of Birth}.

Full functional dependency

> An attribute is fully functionally dependent on a set of attributes X if it is:

- functionally dependent on X, and
- not functionally dependent on any proper subset of X. {Employee Address} has a functional dependency on {Employee ID, Skill}, but not a *full* functional dependency, because it is also dependent on {Employee

ID}.Even by the removal of {Skill} functional dependency still holds between {Employee Address} and {Employee ID}.

Transitive dependency

A transitive dependency is an indirect functional dependency, one in which $X \to Z$ only by virtue of $X \to Y$ and $Y \to Z$.

Trivial functional dependency

A trivial functional dependency is a functional dependency of an attribute on a superset of itself. {Employee ID, Employee Address} → {Employee Address} is trivial, as is {Employee Address} → {Employee Address}.

Multivalued dependency

A multivalued dependency is a constraint according to which the presence of certain rows in a table implies the presence of certain other rows.

Join dependency

A table *T* is subject to a join dependency if *T* can always be recreated by joining multiple tables each having a subset of the attributes of *T*.

Superkey

A superkey is a combination of attributes that can be used to uniquely identify a database record. A table might have many superkeys.

Candidate key

A candidate key is a special subset of superkeys that do not have any extraneous information in them: it is a minimal superkey.

Example:

A table with the fields <Name>, <Age>, <SSN> and <Phone Extension> has many possible superkeys. Three of these are <SSN>, <Phone Extension, Name> and <SSN, Name>. Of those, only <SSN> is a candidate key as the others contain information not necessary to uniquely identify records ('SSN' here refers to Social Security Number, which is unique to each person).

Non-prime attribute

A non-prime attribute is an attribute that does not occur in any candidate key. Employee Address would be a non-prime attribute in the "Employees' Skills" table.

Prime attribute

A prime attribute, conversely, is an attribute that does occur in some candidate key.

Primary key

One candidate key in a relation may be designated the primary key. While that may be a common practice (or even a required one in some environments), it is strictly notational and has no bearing on normalization. With respect to normalization, all candidate keys have equal standing and are treated the same.

Normal forms

The **normal forms** (abbrev. **NF**) of relational database theory provide criteria for determining a table's degree of immunity against logical inconsistencies and anomalies. The higher the normal form applicable to a table, the less vulnerable it is. Each table has a "**highest normal form**" (**HNF**): by definition, a table always meets the requirements of its HNF and of all normal forms lower than its HNF; also by definition, a table fails to meet the requirements of any normal form higher than its HNF.

The normal forms are applicable to individual tables; to say that an entire database is in normal form *n* is to say that all of its tables are in normal form *n*.

Newcomers to database design sometimes suppose that normalization proceeds in an iterative fashion, i.e. a 1NF design is first normalized to 2NF, then to 3NF, and so on. This is not an accurate description of how normalization typically works. A sensibly designed table is likely to be in 3NF on the first attempt; furthermore, if it is 3NF, it is overwhelmingly likely to have an HNF of 5NF. Achieving the "higher" normal forms (above 3NF) does not usually require an extra expenditure of effort on the part of the designer, because 3NF tables usually need no modification to meet the requirements of these higher normal forms.

The main normal forms are summarized below.

	Normal form	Defined by	In	Brief definition
1NF	First normal form	Two versions: E.F. Codd (1970), C.J. Date (2003)	1970 and 2003[8]	A relation is in first normal form if the domain of each attribute contains only atomic values, and the value of each attribute contains only a single value from that domain.
2NF	Second normal form	E.F. Codd	1971	No non-prime attribute in the table is functionally dependent on a proper subset of any candidate key
3NF	Third normal form	Two versions: E.F. Codd (1971), C. Zaniolo (1982)	1971 and 1982[9]	Every non-prime attribute is non-transitively dependent on every candidate key in the table. The attributes that do not contribute to the description of the primary key are removed from the table. In other words, no transitive dependency is allowed.
EKNF	Elementary Key Normal Form	C. Zaniolo	1982	Every non-trivial functional dependency in the table is either the dependency of an elementary key attribute or a dependency on a superkey
BCNF	Boyce–Codd normal form	Raymond F. Boyce and E.F. Codd	1974[10]	Every non-trivial functional dependency in the table is a dependency on a superkey
4NF	Fourth normal form	Ronald Fagin	1977	Every non-trivial multivalued dependency in the table is a dependency on a superkey
5NF	Fifth normal form	Ronald Fagin	1979[11]	Every non-trivial join dependency in the table is implied by the superkeys of the table
DKNF	Domain/key normal form	Ronald Fagin	1981[12]	Every constraint on the table is a logical consequence of the table's domain constraints and key constraints
6NF	Sixth normal form	C.J. Date, Hugh Darwen, and Nikos Lorentzos	2002[13]	Table features no non-trivial join dependencies at all (with reference to generalized join operator)

Denormalization

Databases intended for online transaction processing (OLTP) are typically more normalized than databases intended for online analytical processing (OLAP). OLTP applications are characterized by a high volume of small transactions such as updating a sales record at a supermarket checkout counter. The expectation is that each transaction will leave the database in a consistent state. By contrast, databases intended for OLAP operations are primarily "read mostly" databases. OLAP applications tend to extract historical data that has accumulated over a long period of time. For such databases, redundant or "denormalized" data may facilitate business intelligence applications. Specifically, dimensional tables in a star schema often contain denormalized data. The denormalized or redundant data must be carefully controlled during extract, transform, load (ETL) processing, and users should not be permitted to see the data until it is in a consistent state. The normalized alternative to the star schema is the snowflake schema. In many cases, the need for denormalization has waned as computers and RDBMS software have become more powerful, but since data volumes have generally increased along with hardware and software performance, OLAP databases often still use denormalized schemas.

Denormalization is also used to improve performance on smaller computers as in computerized cash-registers and mobile devices, since these may use the data for look-up only (e.g. price lookups). Denormalization may also be used when no RDBMS exists for a platform (such as Palm), or no changes are to be made to the data and a swift response is crucial.

Non-first normal form (NF² or N1NF)

Denormalization is the opposite of normalization. In recognition that denormalization can be deliberate and useful, the non-first normal form is a definition of database designs which do not conform to first normal form, by allowing "sets and sets of sets to be attribute domains" (Schek 1982). The languages used to query and manipulate data in the model must be extended accordingly to support such values.

One way of looking at this is to consider such structured values as being specialized types of values (domains), with their own domain-specific languages. However, what is usually meant by non-1NF models is the approach in which the relational model and the languages used to query it are extended with a general mechanism for such structure; for instance, the nested relational model supports the use of relations as domain values, by adding two additional operators (*nest* and *unnest*) to the relational algebra that can create and flatten nested relations, respectively.

Consider the following table:

First Normal Form

Person	Favourite Colour
Bob	blue
Bob	red
Jane	green
Jane	yellow
Jane	red

Assume a person has several favourite colours. Obviously, favourite colours consist of a set of colours modeled by the given table. To transform a 1NF into an NF² table a "nest" operator is required which extends the relational algebra of the higher normal forms. Applying the "nest" operator to the 1NF table yields the following NF² table:

Non-First Normal Form

Person	Favourite Colours
Bob	**Favourite Colour** blue red
Jane	**Favourite Colour** green yellow red

To transform this NF² table back into a 1NF an "unnest" operator is required which extends the relational algebra of the higher normal forms. The unnest, in this case, would make "colours" into its own table.

Although "unnest" is the mathematical inverse to "nest", the operator "nest" is not always the mathematical inverse of "unnest". Another constraint required is for the operators to be bijective, which is covered by the Partitioned Normal Form (PNF).

Functional dependency

In relational database theory, a **functional dependency** is a **constraint** between two sets of attributes in a relation from a database.

Given a relation *R*, a set of attributes *X* in *R* is said to **functionally determine** another set of attributes *Y*, also in *R*, (written $X \rightarrow Y$) if, and only if, each *X* value is associated with precisely one *Y* value; *R* is then said to *satisfy* the functional dependency $X \rightarrow Y$. Equivalently, the projection $\pi_{X,Y}R$ is a function, i.e. *Y* is a function of *X*. In simple words, if the values for the *X* attributes are known (say they are *x*), then the values for the *Y* attributes corresponding to *x* can be determined by looking them up in *any* tuple of *R* containing *x*. Customarily *X* is called the *determinant* set and *Y* the *dependent* set. A functional dependency FD: $X \rightarrow Y$ is called *trivial* if *Y* is a subset of *X*.

The determination of functional dependencies is an important part of designing databases in the relational model, and in database normalization and denormalization. A simple application of functional dependencies is **Heath's theorem**; it says that a relation *R* over an attribute set *U* and satisfying a functional dependency $X \rightarrow Y$ can be safely split in two relations having the lossless-join decomposition property, namely into $\pi_{XY}(R) \bowtie \pi_{XZ}(R) = R$ where $Z = U - XY$ are the rest of the attributes. (Unions of attribute sets are customarily denoted by mere juxtapositions in database theory.) An important notion in this context is a candidate key, defined as a minimal set of attributes that functionally determine all of the attributes in a relation. The functional dependencies, along with the attribute domains, are selected so as to generate constraints that would exclude as much data inappropriate to the user domain from the system as possible.

A notion of logical implication is defined for functional dependencies in the following way: a set of functional dependencies $\sum$ logically implies another set of dependencies $\prod$, if any relation *R* satisfying all dependencies from $\sum$ also satisfies all dependencies from $\prod$; this is usually written $\Sigma \models \Gamma$. The notion of logical implication for functional dependencies admits a sound and complete finite axiomatization, known as **Armstrong's axioms**.

Examples

Cars

Suppose one is designing a system to track vehicles and the capacity of their engines. Each vehicle has a unique vehicle identification number (VIN). One would write **VIN** → **EngineCapacity** because it would be inappropriate for a vehicle's engine to have more than one capacity. (Assuming, in this case, that vehicles only have one engine.) However, *EngineCapacity* → *VIN*, is incorrect because there could be many vehicles with the same engine capacity.

This functional dependency may suggest that the attribute EngineCapacity be placed in a relation with candidate key VIN. However, that may not always be appropriate. For example, if that functional dependency occurs as a result of the transitive functional dependencies VIN → VehicleModel and VehicleModel → EngineCapacity then that would not result in a normalized relation.

Lectures

This example illustrates the concept of functional dependency. The situation modelled is that of college students visiting one or more lectures in each of which they are assigned a teaching assistant (TA). Let's further assume that every student is in some semester and is identified by a unique integer ID.

StudentID	Semester	Lecture	TA
1234	6	Numerical Methods	Azhar
2380	4	Numerical Methods	Peter
1234	6	Visual Computing	Ahmed
1201	4	Numerical Methods	Peter
1201	4	Physics II	Simone

We notice that whenever two rows in this table feature the same StudentID, they also necessarily have the same Semester values. This basic fact can be expressed by a functional dependency:

- StudentID → Semester.

Other nontrivial functional dependencies can be identified, for example:

- {StudentID, Lecture} → TA
- {StudentID, Lecture} → {TA, Semester}

The latter expresses the fact that the set {StudentID, Lecture} is a superkey of the relation.

Properties and axiomatization of functional dependencies

Given that *X*, *Y*, and *Z* are sets of attributes in a relation *R*, one can derive several properties of functional dependencies. Among the most important are the following, usually called Armstrong's axioms:

- **Reflexivity**: If *Y* is a subset of *X*, then $X \to Y$
- **Augmentation**: If $X \to Y$, then $XZ \to YZ$
- **Transitivity**: If $X \to Y$ and $Y \to Z$, then $X \to Z$

"Reflexivity" can be weakened to just $X \to \varnothing$, i.e. it is an actual axiom, where the other two are proper inference rules, more precisely giving rise to the following rules of syntactic consequence:[1]

$\vdash X \to \varnothing$
$X \to Y \vdash XZ \to YZ$
$X \to Y, Y \to Z \vdash X \to Z$.

These three rules are a sound and complete axiomatization of functional dependencies. This axiomatization is sometimes described as finite because the number of inference rules is finite, with the caveat that the axiom and rules of inference are all schemata, meaning that the *X*, *Y* and *Z* range over all ground terms (attribute sets).

From these rules, we can derive these secondary rules:

- **Union**: If $X \to Y$ and $X \to Z$, then $X \to YZ$
- **Decomposition**: If $X \to YZ$, then $X \to Y$ and $X \to Z$
- **Pseudotransitivity**: If $X \to Y$ and $WY \to Z$, then $WX \to Z$

The union and decomposition rules can be combined in a logical equivalence stating that $X \to YZ$, holds iff $X \to Y$ and $X \to Z$. This is sometimes called the splitting/combining rule.

Another rule that is sometimes handy is:

- **Composition**: If $X \to Y$ and $Z \to W$, then $XZ \to YW$

Equivalent sets of functional dependencies are called *covers* of each other. Every set of functional dependencies has a canonical cover.

Applications to normalization

Heath's theorem

An important property (yielding an immediate application) of functional dependencies is that if *R* is a relation with columns named from some set of attributes *U* and *R* satisfies some functional dependency $X \to Y$ then $R = \pi_{XY}(R) \bowtie \pi_{XZ}(R)$ where $Z = U - XY$. Intuitively, if a functional dependency $X \to Y$ holds in *R*, then the relation can be safely split in two relations alongside the column *X* (which is a key for $\pi_{XY}(R) \bowtie \pi_{XZ}(R)$) ensuring that when the two parts are joined back no data is lost, i.e. a functional dependency provides a simple way to construct a lossless-join decomposition of *R* in two smaller relations. This fact is sometimes called **Heath's theorem**; it is one of the early results in database theory.[2]

Heath's theorem effectively says we can pull out the values of *Y* from the big relation *R* and store them into one, $\pi_{XY}(R)$, which has no value repetitions in the row for *X* and is effectively a lookup table for *Y* keyed by *X* and consequently has only one place to update the *Y* corresponding to each *X* unlike the "big" relation *R* where there are potentially many copies of each *X*, each one with its copy of *Y* which need to be kept synchronized on updates. (This elimination of redundancy is an advantage in OLTP contexts, where many changes are expected, but not so much in OLAP contexts, which involve mostly queries.) Heath's decomposition leaves only *X* to act as a foreign key in the remainder of the big table $\pi_{XZ}(R)$.

Functional dependencies however should not be confused with inclusion dependencies, which are the formalism for foreign keys; even though they are used for normalization, functional dependencies express constraints over one relation (schema), whereas inclusion dependencies express constraints between relation schemas in a database schema.Furthermore, the two notions do not even intersect in the classification of dependencies: functional dependencies are equality-generating dependencies whereas inclusion dependencies are tuple-generating dependencies. Enforcing referential constraints after relation schema decomposition (normalization) requires a new formalism, i.e. inclusion dependencies. In the decomposition resulting from Heath's theorem, there's nothing preventing the insertion of tuples in $\pi_{XZ}(R)$ having some value of *X* not found in $\pi_{XY}(R)$.

Normal forms

Normal forms are database normalization levels which determine the "goodness" of a table. Generally, the third normal form is considered to be a "good" standard for a relational database.[*citation needed*]

Normalization aims to free the database from update, insertion and deletion anomalies. It also ensures that when a new value is introduced into the relation, it has minimal effect on the database, and thus minimal effect on the applications using the database.[*citation needed*]

Irreducible function depending set

A functional depending set S is irreducible if the set has the following three properties:

1. Each right set of a functional dependency of S contains only one attribute.
2. Each left set of a functional dependency of S is irreducible. It means that reducing any one attribute from left set will change the content of S (S will lose some information).
3. Reducing any functional dependency will change the content of S.

Sets of Functional Dependencies(FD) with these properties are also called *canonical* or *minimal*.

Armstrong's axioms

Armstrong's axioms are a set of axioms (or, more precisely, inference rules) used to infer all the functional dependencies on a relational database. They were developed by William W. Armstrong on his 1974 paper.[1] The axioms are sound in generating only functional dependencies in the closure of a set of functional dependencies (denoted as F^+) when applied to that set (denoted as F). They are also complete in that repeated application of these rules will generate all functional dependencies in the closure F^+.

More formally, let $< R (U), F >$ denote a relational scheme over the set of attributes U with a set of functional dependencies F. We say that a functional dependency f is logically implied by F,and denote it with $F \models f$ if and only if for every instance r of R that satisfies the functional dependencies in F, r also satisfies f. We denote by F^+ the set of all functional dependencies that are logically implied by F.

Furthermore, with respect to a set of inference rules A, we say that a functional dependency f is derivable from the functional dependencies in F by the set of inference rules A, and we denote it by $F \vdash_A f$ if and only if f is obtainable by means of repeatedly applying the inference rules in A to functional dependencies in F. We denote by F_A^* the set of all functional dependencies that are derivable from F by inference rules in A.

Then, a set of inference rules A is sound if and only if the following holds:

$F_A^* \subseteq F^+$

that is to say, we cannot derive by means of A functional dependencies that are not logically implied by F. The set of inference rules A is said to be complete if the following holds:

$F^+ \subseteq F_A^*$

more simply put, we are able to derive by A all the functional dependencies that are logically implied by F.

Axioms

Let $R (U)$ be a relation scheme over the set of attributes U. Henceforth we will denote by letters X, Y, Z any subset of U and, for short, the union of two sets of attributes X and Y by XY instead of the usual $X \cup Y$; this notation is rather standard in database theory when dealing with sets of attributes.

Axiom of Reflexivity

If $Y \subseteq X$, then $X \rightarrow Y$

Axiom of augmentation

If $X \rightarrow Y$, then $XZ \rightarrow YZ$ for any Z

Axiom of transitivity

If $X \to Y$ and $Y \to Z$, then $X \to Z$

Additional rules

These rules can be derived from above axioms.

Union

If $X \to Y$ and $X \to Z$ then $X \to YZ$

Decomposition

If $X \to YZ$ then $X \to Y$ and $X \to Z$

Pseudo transitivity

If $A \to B$ and $BC \to D$ then $AC \to D$

Armstrong relation

Given a set of functional dependencies F, the **Armstrong relation** is a relation which satisfies all the functional dependencies in the closure F^+ and only those dependencies. Unfortunately, the minimum-size Armstrong relation for a given set of dependencies can have a size which is an exponential function of the number of attributes in the dependencies considered.

Transitive dependency

In Database Management System, a **transitive dependency** is a functional dependency which holds by virtue of transitivity. A transitive dependency can occur only in a relation that has three or more attributes. Let A, B, and C designate three distinct attributes (or distinct collections of attributes) in the relation. Suppose all three of the following conditions hold:

1. $A \rightarrow B$
2. It is not the case that $B \rightarrow A$
3. $B \rightarrow C$

Then the functional dependency $A \rightarrow C$ (which follows from 1 and 3 by the axiom of transitivity) is a transitive dependency.

In database normalization, one of the important features of third normal form is that it excludes certain types of transitive dependencies. E.F. Codd, the inventor of the relational model, introduced the concepts of transitive dependence and third normal form in 1971.[1]

Example

A transitive dependency occurs in the following relation:

Book	Genre	Author	Author Nationality
Twenty Thousand Leagues Under the Sea	Science Fiction	Jules Verne	French
Journey to the Center of the Earth	Science Fiction	Jules Verne	French
Leaves of Grass	Poetry	Walt Whitman	American
Anna Karenina	Literary Fiction	Leo Tolstoy	Russian
A Confession	Religious Autobiography	Leo Tolstoy	Russian

The functional dependency {Book} → {Author Nationality} applies; that is, if we know the book, we know the author's nationality. Furthermore:

- {Book} → {Author}
- {Author} does not → {Book}
- {Author} → {Author Nationality}

Therefore {Book} → {Author Nationality} is a transitive dependency.

Transitive dependency occurred because a non-key attribute (Author) was determining another non-key attribute (Author Nationality).

See pages 45-51, which cover third normal form and transitive dependence.

Superkey

A **superkey** is defined in the relational model of database organization as a set of attributes of a relation variable for which it holds that in all relations assigned to that variable, there are no two distinct tuples (rows) that have the same values for the attributes in this set. Equivalently a superkey can also be defined as a set of attributes of a relation schema upon which all attributes of the schema are functionally dependent.

Note that the set of **all** attributes is a trivial superkey, because in relational algebra duplicate rows are not permitted.

Also note that if attribute set *K* is a superkey of relation *R*, then at all times it is the case that the projection of *R* over *K* has the same cardinality as *R* itself.

Informally, a superkey is a set of attributes within a table whose values can be used to uniquely identify a tuple. A candidate key is a minimal set of attributes necessary to identify a tuple, this is also called a minimal superkey. For example, given an employee schema, consisting of the attributes employeeID, name, job, and departmentID, we could use the employeeID in combination with any or all other attributes of this table to uniquely identify a tuple in the table. Examples of superkeys in this schema would be {employeeID, Name}, {employeeID, Name, job}, and {employeeID, Name, job, departmentID}. The last example is known as trivial superkey, because it uses all attributes of this table to identify the tuple.

In a real database we do not need values for all of those attributes to identify a tuple. We only need, per our example, the set {employeeID}. This is a **minimal superkey –** that is, a minimal set of attributes that can be used to identify a single tuple. So, employeeID is a candidate key.

Example

English Monarchs

Monarch Name	Monarch Number	Royal House
Edward	II	Plantagenet
Edward	III	Plantagenet
Richard	III	Plantagenet
Henry	IV	Lancaster

First, list out all the (non-empty) sets of attributes:

- {Monarch Name}
- {Monarch Number}
- {Royal House}
- {Monarch Name, Monarch Number}
- {Monarch Name, Royal House}
- {Monarch Number, Royal House}
- {Monarch Name, Monarch Number, Royal House}

Second, eliminate all the sets which **do not** meet superkey's requirement. For example, {Monarch Name, Royal House} cannot be a superkey because for the same attribute values (Edward, Plantagenet), there are two distinct tuples:

- (Edward, **II**, Plantagenet)
- (Edward, **III**, Plantagenet)

Finally, after elimination, the remaining sets of attributes are the only possible superkeys in this example:

- {Monarch Name, Monarch Number} **(Candidate Key)**
- {Monarch Name, Monarch Number, Royal House}

In real situations, however, superkeys are normally not determined by this method, which is very tedious and time-consuming, but by analyzing functional dependencies.

First normal form

First normal form (**1NF**) is a property of a relation in a relational database. A relation is in first normal form if the domain of each attribute contains only atomic values, and the value of each attribute contains only a single value from that domain.

Edgar Codd, in a 1971 conference paper, defined a relation in first normal form to be one such that none of the domains of that relation should have elements which are themselves sets.

First normal form is an essential property of a relation in a relational database. Database normalization is the process of representing a database in terms of relations in standard normal forms, where first normal is a minimal requirement.

Examples

The following scenario illustrates how a database design might violate first normal form.

Domains and values

Suppose a designer wishes to record the names and telephone numbers of customers. He defines a customer table which looks like this:

Customer

Customer ID	First Name	Surname	Telephone Number
123	Robert	Ingram	555-861-2025
456	Jane	Wright	555-403-1659
789	Maria	Fernandez	555-808-9633

The designer then becomes aware of a requirement to record **multiple** telephone numbers for some customers. He reasons that the simplest way of doing this is to allow the "Telephone Number" field in any given record to contain more than one value:

Customer

Customer ID	First Name	Surname	Telephone Number
123	Robert	Ingram	555-861-2025
456	Jane	Wright	555-403-1659 555-776-4100
789	Maria	Fernandez	555-808-9633

Assuming, however, that the Telephone Number column is defined on some telephone number-like domain, such as the domain of 12-character strings, the representation above is not in first normal form. It is in violation of first normal form as a single field has been allowed to contain multiple values. A typical relational database management system will not allow fields in a table to contain multiple values in this way.

A design that complies with 1NF

A design that is unambiguously in first normal form makes use of two tables: a Customer Name table and a Customer Telephone Number table.

Customer ID	First Name	Surname
123	Robert	Ingram
456	Jane	Wright
789	Maria	Fernandez

Customer ID	Telephone Number
123	555-861-2025
456	555-403-1659
456	555-776-4100
789	555-808-9633

Repeating groups of telephone numbers do not occur in this design. Instead, each Customer-to-Telephone Number link appears on its own record. With Customer ID as key, a one-to-many relationship exists between the two tables. A record in the "parent" table, Customer Name, can have many telephone number records in the "child" table, Customer Telephone Number, but each telephone number belongs to one, and only one customer. It is worth noting that this design meets the additional requirements for second and third normal form.

Atomicity

Edgar F. Codd's definition of 1NF makes reference to the concept of 'atomicity'. Codd states that the "values in the domains on which each relation is defined are required to be atomic with respect to the DBMS."[1] Codd defines an atomic value as one that "cannot be decomposed into smaller pieces by the DBMS (excluding certain special functions)"[2] meaning a field should not be divided into parts with more than one kind of data in it such that what one part means to the DBMS depends on another part of the same field.

Hugh Darwen and Chris Date have suggested that Codd's concept of an "atomic value" is ambiguous, and that this ambiguity has led to widespread confusion about how 1NF should be understood.[3][4] In particular, the notion of a "value that cannot be decomposed" is problematic, as it would seem to imply that few, if any, data types are atomic:

- A character string would seem not to be atomic, as the RDBMS typically provides operators to decompose it into substrings.
- A fixed-point number would seem not to be atomic, as the RDBMS typically provides operators to decompose it into integer and fractional components.
- An ISBN would seem not to be atomic, as it includes language and publisher identifiers.

Date suggests that "the notion of atomicity *has no absolute meaning*":[5] a value may be considered atomic for some purposes, but may be considered an assemblage of more basic elements for other purposes. If this position is

accepted, 1NF cannot be defined with reference to atomicity. Columns of any conceivable data type (from string types and numeric types to array types and table types) are then acceptable in a 1NF table—although perhaps not always desirable; for example, it would be more desirable to separate a Customer Name field into two separate fields as First Name, Surname.

First normal form, as defined by Chris Date, permits relation-valued attributes (tables within tables). Date argues that relation-valued attributes, by means of which a field within a table can contain a table, are useful in rare cases.[6]

1NF tables as representations of relations

According to Date's definition, a table is in first normal form if and only if it is "isomorphic to some relation", which means, specifically, that it satisfies the following five conditions:[7]

1. There's no top-to-bottom ordering to the rows.
2. There's no left-to-right ordering to the columns.
3. There are no duplicate rows.
4. Every row-and-column intersection contains exactly one value from the applicable domain (and nothing else).
5. All columns are regular [i.e. rows have no hidden components such as row IDs, object IDs, or hidden timestamps].

Violation of any of these conditions would mean that the table is not strictly relational, and therefore that it is not in first normal form.

Examples of tables (or views) that would not meet this definition of first normal form are:

- A table that lacks a unique key. Such a table would be able to accommodate duplicate rows, in violation of condition 3.
- A view whose definition mandates that results be returned in a particular order, so that the row-ordering is an intrinsic and meaningful aspect of the view.[8] This violates condition 1. The tuples in true relations are not ordered with respect to each other.
- A table with at least one nullable attribute. A nullable attribute would be in violation of condition 4, which requires every field to contain exactly one value from its column's domain. It should be noted, however, that this aspect of condition 4 is controversial. It marks an important departure from Codd's later vision of the relational model,[9] which made explicit provision for nulls.[10]

Second normal form

Second normal form (**2NF**) is a normal form used in database normalization. 2NF was originally defined by E.F. Codd in 1971.[1]

A table that is in first normal form (1NF) must meet additional criteria if it is to qualify for second normal form. Specifically: a table is in 2NF if and only if it is in 1NF and no non-prime attribute is dependent on any proper subset of any candidate key of the table. A non-prime attribute of a table is an attribute that is not a part of any candidate key of the table.

Put simply, a table is in 2NF if and only if it is in 1NF and every non-prime attribute of the table is dependent on the whole of a candidate key.

Example

Consider a table describing employees' skills:

Employees' Skills

Employee	Skill	Current Work Location
Brown	Light Cleaning	73 Industrial Way
Brown	Typing	73 Industrial Way
Harrison	Light Cleaning	73 Industrial Way
Jones	Shorthand	114 Main Street
Jones	Typing	114 Main Street
Jones	Whittling	114 Main Street

Neither {Employee} nor {Skill} is a candidate key for the table. This is because a given Employee might need to appear more than once (he might have multiple Skills), and a given Skill might need to appear more than once (it might be possessed by multiple Employees). Only the composite key {Employee, Skill} qualifies as a candidate key for the table.

The remaining attribute, Current Work Location, is dependent on only part of the candidate key, namely Employee. Therefore the table is not in 2NF. Note the redundancy in the way Current Work Locations are represented: we are told three times that Jones works at 114 Main Street, and twice that Brown works at 73 Industrial Way. This redundancy makes the table vulnerable to update anomalies: it is, for example, possible to update Jones' work location on his "**Shorthand**" and "**Typing**" records and not update his "**Whittling**" record. The resulting data would imply contradictory answers to the question "What is Jones' current work location?"

A 2NF alternative to this design would represent the same information in two tables: an "Employees" table with candidate key {Employee}, and an "Employees' Skills" table with candidate key {Employee, Skill}:

Employee	Current Work Location
Brown	73 Industrial Way
Harrison	73 Industrial Way
Jones	114 Main Street

Employee	Skill
Brown	Light Cleaning
Brown	Typing
Harrison	Light Cleaning
Jones	Shorthand
Jones	Typing
Jones	Whittling

Neither of these tables can suffer from update anomalies.

Not all 2NF tables are free from update anomalies, however. An example of a 2NF table which suffers from update anomalies is:

Tournament Winners

Tournament	Year	Winner	Winner Date of Birth
Des Moines Masters	1998	Chip Masterson	14 March 1977
Indiana Invitational	1998	Al Fredrickson	21 July 1975
Cleveland Open	1999	Bob Albertson	28 September 1968
Des Moines Masters	1999	Al Fredrickson	21 July 1975
Indiana Invitational	1999	Chip Masterson	14 March 1977

Even though Winner and Winner Date of Birth are determined by the whole key {Tournament, Year} and not part of it, particular Winner / Winner Date of Birth combinations are shown redundantly on multiple records. This leads to an update anomaly: if updates are not carried out consistently, a particular winner could be shown as having two different dates of birth.

The underlying problem is the transitive dependency to which the Winner Date of Birth attribute is subject. Winner Date of Birth actually depends on Winner, which in turn depends on the key Tournament / Year.

This problem is addressed by third normal form (3NF).

2NF and candidate keys

A table for which there are no partial functional dependencies on the primary key is typically, but not always, in 2NF. In addition to the primary key, the table may contain other candidate keys; it is necessary to establish that no non-prime attributes have part-key dependencies on **any** of these candidate keys.

Multiple candidate keys occur in the following table:

Electric Toothbrush Models

Manufacturer	Model	Model Full Name	Manufacturer Country
Forte	X-Prime	Forte X-Prime	Italy
Forte	Ultraclean	Forte Ultraclean	Italy
Dent-o-Fresh	EZbrush	Dent-o-Fresh EZbrush	USA
Kobayashi	ST-60	Kobayashi ST-60	Japan
Hoch	Toothmaster	Hoch Toothmaster	Germany
Hoch	X-Prime	Hoch X-Prime	Germany

Even if the designer has specified the primary key as {Model Full Name}, the table is not in 2NF. {Manufacturer, Model} is also a candidate key, and Manufacturer Country is dependent on a proper subset of it: Manufacturer. To make the design conform to 2NF, it is necessary to have two tables:

Electric Toothbrush Manufacturers

Manufacturer	Manufacturer Country
Forte	Italy
Dent-o-Fresh	USA
Kobayashi	Japan
Hoch	Germany

Electric Toothbrush Models

Manufacturer	Model	Model Full Name
Forte	X-Prime	Forte X-Prime
Forte	Ultraclean	Forte Ultraclean
Dent-o-Fresh	EZbrush	Dent-o-Fresh EZbrush
Kobayashi	ST-60	Kobayashi ST-60
Hoch	Toothmaster	Hoch Toothmaster
Hoch	X-Prime	Hoch X-Prime

Third normal form

The **third normal form** (**3NF**) is a normal form used in database normalization. 3NF was originally defined by E.F. Codd in 1971.[1] Codd's definition states that a table is in 3NF if and only if both of the following conditions hold:

- The relation R (table) is in second normal form (**2NF**)
- Every non-prime attribute of R is non-transitively dependent (i.e. directly dependent) on every superkey of R.

A **non-prime attribute** of R is an attribute that does not belong to any candidate key of R.[2] A transitive dependency is a functional dependency in which $X \to Z$ (X determines Z) indirectly, by virtue of $X \to Y$ and $Y \to Z$ (where it is not the case that $Y \to X$).[3]

A 3NF definition that is equivalent to Codd's, but expressed differently, was given by Carlo Zaniolo in 1982. This definition states that a table is in 3NF if and only if, for each of its functional dependencies $X \to A$, **at least one** of the following conditions holds:

- X contains A (that is, $X \to A$ is trivial functional dependency), or
- X is a superkey, or
- Every element of A-X, the set difference between A and X, is a **prime attribute** (i.e., each attribute in A-X is contained in some candidate key)[4][5]Wikipedia:Verifiability

Zaniolo's definition gives a clear sense of the difference between 3NF and the more stringent Boyce–Codd normal form (BCNF). BCNF simply eliminates the third alternative ("Every element of A-X, the set difference between A and X, is a prime attribute").

"Nothing but the key"

A memorable statement of Codd's definition of 3NF, paralleling the traditional pledge to give true evidence in a court of law, was given by Bill Kent: "[Every] non-key [attribute] must provide a fact about the key, the whole key, and nothing but the key."[6] A common variation supplements this definition with the oath: "so help me Codd".[7]

Requiring existence of "the key" ensures that the table is in 1NF; requiring that non-key attributes be dependent on "the whole key" ensures 2NF; further requiring that non-key attributes be dependent on "nothing but the key" ensures 3NF.

Chris Date refers to Kent's summary as "an intuitively attractive characterization" of 3NF, and notes that with slight adaptation it may serve as a definition of the slightly stronger Boyce–Codd normal form: "Each attribute must represent a fact about the key, the whole key, and nothing but the key."[8] The 3NF version of the definition is weaker than Date's BCNF variation, as the former is concerned only with ensuring that *non-key* attributes are dependent on keys. Prime attributes (which are keys or parts of keys) must not be functionally dependent at all; they each represent a fact about the key in the sense of providing part or all of the key itself. (It should be noted here that this rule applies only to functionally dependent attributes, as applying it to all attributes would implicitly prohibit composite candidate keys, since each part of any such key would violate the "whole key" clause.)

An example of a 2NF table that fails to meet the requirements of 3NF is:

Tournament Winners

Tournament	Year	Winner	Winner Date of Birth
Indiana Invitational	1998	Al Fredrickson	21 July 1975
Cleveland Open	1999	Bob Albertson	28 September 1968
Des Moines Masters	1999	Al Fredrickson	21 July 1975
Indiana Invitational	1999	Chip Masterson	14 March 1977

Because each row in the table needs to tell us who won a particular Tournament in a particular Year, the composite key {Tournament, Year} is a minimal set of attributes guaranteed to uniquely identify a row. That is, {Tournament, Year} is a candidate key for the table.

The breach of 3NF occurs because the non-prime attribute Winner Date of Birth is transitively dependent on the candidate key {Tournament, Year} via the non-prime attribute Winner. The fact that Winner Date of Birth is functionally dependent on Winner makes the table vulnerable to logical inconsistencies, as there is nothing to stop the same person from being shown with different dates of birth on different records.

In order to express the same facts without violating 3NF, it is necessary to split the table into two:

Tournament	Year	Winner
Indiana Invitational	1998	Al Fredrickson
Cleveland Open	1999	Bob Albertson
Des Moines Masters	1999	Al Fredrickson
Indiana Invitational	1999	Chip Masterson

Player	Date of Birth
Chip Masterson	14 March 1977
Al Fredrickson	21 July 1975
Bob Albertson	28 September 1968

Update anomalies cannot occur in these tables, which are both in 3NF.

Derivation of Zaniolo's conditions

The definition of 3NF offered by Carlo Zaniolo in 1982, and given above, is proved in the following way: Let $X \to A$ be a nontrivial FD (i.e. one where X does not contain A) and let A be a non-key attribute. Also let Y be a key of R. Then $Y \to X$.

Normalization beyond 3NF

Most 3NF tables are free of update, insertion, and deletion anomalies. Certain types of 3NF tables, rarely met with in practice, are affected by such anomalies; these are tables which either fall short of Boyce–Codd normal form (BCNF) or, if they meet BCNF, fall short of the higher normal forms 4NF or 5NF.

Boyce–Codd normal form

Boyce–Codd normal form (or **BCNF** or **3.5NF**) is a normal form used in database normalization. It is a slightly stronger version of the third normal form (3NF). BCNF was developed in 1974 by Raymond F. Boyce and Edgar F. Codd to address certain types of anomaly not dealt with by 3NF as originally defined.[1]

If a relational schema is in BCNF then all redundancy based on functional dependency has been removed, although other types of redundancy may still exist. A relational schema R is in Boyce–Codd normal form if and only if for every one of its dependencies $X \rightarrow Y$, at least one of the following conditions hold:

- $X \rightarrow Y$ is a trivial functional dependency ($Y \subseteq X$)
- X is a superkey for schema R

Chris Date has pointed out that a definition of what we now know as BCNF appeared in a paper by Ian Heath in 1971.[2] Date writes:

> "Since that definition predated Boyce and Codd's own definition by some three years, it seems to me that BCNF ought by rights to be called *Heath* normal form. But it isn't."[3]

Edgar F.Codd released his original paper 'A Relational Model of Data for Large Shared Databanks' in June 1970. This was the first time the notion of a relational database was published. All work after this, including the Boyce-Codd normal form method was based on this relational model.

3NF tables not meeting BCNF (Boyce–Codd normal form)

Only in rare cases does a 3NF table not meet the requirements of BCNF. A 3NF table which does not have multiple overlapping candidate keys is guaranteed to be in BCNF.[4] Depending on what its functional dependencies are, a 3NF table with two or more overlapping candidate keys may or may not be in BCNF.

An example of a 3NF table that does not meet BCNF is:

Today's Court Bookings

Court	Start Time	End Time	Rate Type
1	09:30	10:30	SAVER
1	11:00	12:00	SAVER
1	14:00	15:30	STANDARD
2	10:00	11:30	PREMIUM-B
2	11:30	13:30	PREMIUM-B
2	15:00	16:30	PREMIUM-A

- Each row in the table represents a court booking at a tennis club that has one hard court (Court 1) and one grass court (Court 2)
- A booking is defined by its Court and the period for which the Court is reserved
- Additionally, each booking has a Rate Type associated with it. There are four distinct rate types:
  - SAVER, for Court 1 bookings made by members
  - STANDARD, for Court 1 bookings made by non-members
  - PREMIUM-A, for Court 2 bookings made by members
  - PREMIUM-B, for Court 2 bookings made by non-members

The table's superkeys are:

- S_1 = {Court, Start Time}

- S_2 = {Court, End Time}
- S_3 = {Rate Type, Start Time}
- S_4 = {Rate Type, End Time}
- S_5 = {Court, Start Time, End Time}
- S_6 = {Rate Type, Start Time, End Time}
- S_7 = {Court, Rate Type, Start Time}
- S_8 = {Court, Rate Type, End Time}
- S_T = {Court, Rate Type, Start Time, End Time}, the trivial superkey

Note that even though in the above table *Start Time* and *End Time* attributes have no duplicate values for each of them, we still have to admit that in some other days two different bookings on court 1 and court 2 could *start at the same time* or *end at the same time*. This is the reason why {Start Time} and {End Time} cannot be considered as the table's superkeys.

However, only S_1, S_2, S_3 and S_4 are candidate keys (that is, minimal superkeys for that relation) because e.g. $S_1 \subset S_5$, so S_5 cannot be a candidate key.

Recall that 2NF prohibits partial functional dependencies of non-prime attributes (i.e. an attribute that does not occur in ANY candidate key) on candidate keys, and that 3NF prohibits transitive functional dependencies of non-prime attributes on candidate keys.

In **Today's Court Bookings** table, there are no non-prime attributes: that is, all attributes belong to some candidate key. Therefore the table adheres to both 2NF and 3NF.

The table does not adhere to BCNF. This is because of the dependency Rate Type → Court, in which the determining attribute (Rate Type) is neither a candidate key nor a superset of a candidate key.

Dependency Rate Type → Court is respected as a Rate Type should only ever apply to a single Court.

The design can be amended so that it meets BCNF:

Rate Types

Rate Type	Court	Member Flag
SAVER	1	Yes
STANDARD	1	No
PREMIUM-A	2	Yes
PREMIUM-B	2	No

Today's Bookings

Rate Type	Start Time	End Time
SAVER	09:30	10:30
SAVER	11:00	12:00
STANDARD	14:00	15:30
PREMIUM-B	10:00	11:30
PREMIUM-B	11:30	13:30
PREMIUM-A	15:00	16:30

The candidate keys for the Rate Types table are {Rate Type} and {Court, Member Flag}; the candidate keys for the Today's Bookings table are {Rate Type, Start Time} and {Rate Type, End Time}. Both tables are in BCNF. When {Rate Type} is a key in the Rate Types table, having one Rate Type associated with two different Courts is

impossible, so by using {Rate Type} as a key in the Rate Types table, the anomaly affecting the original table has been eliminated.

Achievability of BCNF

In some cases, a non-BCNF table cannot be decomposed into tables that satisfy BCNF and preserve the dependencies that held in the original table. Beeri and Bernstein showed in 1979 that, for example, a set of functional dependencies {AB → C, C → B} cannot be represented by a BCNF schema.[5] Thus, unlike the first three normal forms, BCNF is not always achievable.

Consider the following non-BCNF table whose functional dependencies follow the {AB → C, C → B} pattern:

Nearest Shops

Person	Shop Type	Nearest Shop
Davidson	Optician	Eagle Eye
Davidson	Hairdresser	Snippets
Wright	Bookshop	Merlin Books
Fuller	Bakery	Doughy's
Fuller	Hairdresser	Sweeney Todd's
Fuller	Optician	Eagle Eye

For each Person / Shop Type combination, the table tells us which shop of this type is geographically nearest to the person's home. We assume for simplicity that a single shop cannot be of more than one type.

The candidate keys of the table are:

- {Person, Shop Type}
- {Person, Nearest Shop}

Because all three attributes are prime attributes (i.e. belong to candidate keys), the table is in 3NF. The table is not in BCNF, however, as the Shop Type attribute is functionally dependent on a non-superkey: Nearest Shop.

The violation of BCNF means that the table is subject to anomalies. For example, Eagle Eye might have its Shop Type changed to "Optometrist" on its "Fuller" record while retaining the Shop Type "Optician" on its "Davidson" record. This would imply contradictory answers to the question: "What is Eagle Eye's Shop Type?" Holding each shop's Shop Type only once would seem preferable, as doing so would prevent such anomalies from occurring:

Shop Near Person

Person	Shop
Davidson	Eagle Eye
Davidson	Snippets
Wright	Merlin Books
Fuller	Doughy's
Fuller	Sweeney Todd's
Fuller	Eagle Eye

Shop

Shop	Shop Type
Eagle Eye	Optician
Snippets	Hairdresser
Merlin Books	Bookshop
Doughy's	Bakery
Sweeney Todd's	Hairdresser

In this revised design, the "Shop Near Person" table has a candidate key of {Person, Shop}, and the "Shop" table has a candidate key of {Shop}. Unfortunately, although this design adheres to BCNF, it is unacceptable on different grounds: it allows us to record multiple shops of the same type against the same person. In other words, its candidate keys do not guarantee that the functional dependency {Person, Shop Type} → {Shop} will be respected.

A design that eliminates all of these anomalies (but does not conform to BCNF) is possible. This design introduces a new normal form, known as Elementary Key Normal Form.[6] This design consists of the original "Nearest Shops" table supplemented by the "Shop" table described above. The table structure generated by Bernstein's schema generation algorithm [7] is actually EKNF, although that enhancement to 3NF had not been recognized at the time the algorithm was designed

Nearest Shops

Person	Shop Type	Nearest Shop
Davidson	Optician	Eagle Eye
Davidson	Hairdresser	Snippets
Wright	Bookshop	Merlin Books
Fuller	Bakery	Doughy's
Fuller	Hairdresser	Sweeney Todd's
Fuller	Optician	Eagle Eye

Shop

Shop	Shop Type
Eagle Eye	Optician
Snippets	Hairdresser
Merlin Books	Bookshop
Doughy's	Bakery
Sweeney Todd's	Hairdresser

If a referential integrity constraint is defined to the effect that {Shop Type, Nearest Shop} from the first table must refer to a {Shop Type, Shop} from the second table, then the data anomalies described previously are prevented.

Lossless-Join Decomposition

In computer science the concept of a **Lossless-Join Decomposition** is central in removing redundancy safely from databases while preserving the original data.

Lossless-join Decomposition

Can also be called Nonadditive. If you decompose a relation R into relations R_1 and R_2 you will guarantee a Lossless-Join if $R_1 \bowtie R_2 = R$.

If R is split into R1 and R2, for the decomposition to be lossless then at least one of the two should hold true.

Projecting on R1 and R2, and joining back, results in the relation you started with.[1] Let R be a relation schema.

Let F be a set of functional dependencies on R .

Let R_1 and R_2 form a decomposition of R .

The decomposition is a lossless-join decomposition of R if at least one of the following functional dependencies are in F^+ (where F^+ stands for the closure for every attribute in F):

- $R_1 \cap R_2 \rightarrow R_1 - R_2$
- $R_1 \cap R_2 \rightarrow R_2 - R_1$

Example

- Let $R = (A, B, C, D)$ be the relation schema, with A , B , C and D attributes.
- Let $F = \{A \rightarrow BC\}$ be the set of functional dependencies.
- Decomposition into $R_1 = (A, B, C)$ and $R_2 = (A, D)$ is lossless under F because $R_1 \cap R_2 = (A)$ and $A \rightarrow BC$ so $R_1 \cap R_2 \rightarrow R_1 - R_2$.

Join dependency

In dependency theory, a **join dependency** is a constraint on the set of legal relations over a database scheme. A table T is subject to a join dependency if T can always be recreated by joining multiple tables each having a subset of the attributes of T. If one of the tables in the join has all the attributes of the table T, the join dependency is called trivial.

The join dependency plays an important role in the Fifth normal form, also known as *project-join normal form*, because it can be proven that if you decompose a scheme R in tables R_1 to R_n , the decomposition will be a lossless-join decomposition if you restrict the legal relations on R to a join dependency on R called $*(R_1, R_2, ...R_n)$.

Another way to describe a join dependency is to say that the set of relationships in the join dependency is independent of each other.

Unlike in the case of functional dependencies, there is no sound and complete axiomatization for join dependencies,[1] though axiomatization exist for more expressive dependency languages such as full typed dependencies.[2] However, implication of join dependencies is decidable.[3]

Formal definition

> Let R be a relation schema and let $R_1, R_2, ..., R_n$ be a decomposition of R .
> The relation $r(R)$ *satisfies* the join dependency $*(R_1, R_2, ...R_n)$ if $\bowtie_{i=1}^{n} \Pi_{R_i}(r) = r$.
> A join dependency is trivial if one of the R_i is R itself.
> —Silberschatz, Korth. *Database System Concepts*, 1st Edition[4]

2-ary join dependencies are called multivalued dependency as a historical artifact of the fact that they were studied before the general case. More specifically if *U* is a set of attributes and *R* a relation over it, then *R* satisfies $X \twoheadrightarrow Y$ iff *R* satisfies $*(X \cup Y, X \cup (U - Y))$

Example

Given a pizza-chain that models purchases in table Customer = { order-number, customer-name, pizza-name, courier}. It is obvious that you can derive the following relations:

- customer-name depends on order-number
- pizza-name depends on order-number
- courier depends on order-number

Since the relationships are independent you can say there is a join dependency as follows: *((order-number, customer-name), (order-number, pizza-name), (order-number,courier)).

If each customer has his own courier however, you could have a join-dependency like this: *((order-number, customer-name), (order-number, courier), (customer-name, courier), (order-number,pizza-name)), but *((order-number, customer-name, courier), (order-number,pizza-name)) would be valid as well. This makes it obvious that just having a join dependency is not enough to normalize a database scheme.

Multivalued dependency

In database theory, **multivalued dependency** *is a full constraint* between two sets of attributes in a relation.

In contrast to the functional dependency, the **multivalued dependency** requires that certain tuples be present in a relation. Therefore, a multivalued dependency is a special case of *tuple-generating dependency*. The multivalued dependency plays a role in the 4NF database normalization.

A multivalued dependency is a special case of a join dependency, with only two sets of values involved, i.e. it is a 2-ary join dependency.

Formal definition

The formal definition is given as follows.

Let R be a relation schema and let $\alpha \subseteq R$ and $\beta \subseteq R$ (subsets). The multivalued dependency

$\alpha \twoheadrightarrow \beta$

(which can be read as α multidetermines β) holds on R if, in any legal relation $r(R)$, for all pairs of tuples t_1 and t_2 in r such that $t_1[\alpha] = t_2[\alpha]$, there exist tuples t_3 and t_4 in r such that

$t_1[\alpha] = t_2[\alpha] = t_3[\alpha] = t_4[\alpha]$

$t_3[\beta] = t_1[\beta]$

$t_3[R - \beta] = t_2[R - \beta]$

$t_4[\beta] = t_2[\beta]$

$t_4[R - \beta] = t_1[R - \beta]$

In more simple words the above condition can be expressed as follows: if we denote by (x, y, z) the tuple having values for α, β, $R - \alpha - \beta$ collectively equal to x, y, z, correspondingly, then whenever the tuples (a, b, c) and (a, d, e) exist in r , the tuples (a, b, e) and (a, d, c) should also exist in r .

Example

Consider this example of a database of teaching courses, the books recommended for the course, and the lecturers who will be teaching the course:

Course	Book	Lecturer
AHA	Silberschatz	John D
AHA	Nederpelt	William M
AHA	Silberschatz	William M
AHA	Nederpelt	John D
AHA	Silberschatz	Christian G
AHA	Nederpelt	Christian G
OSO	Silberschatz	John D
OSO	Silberschatz	William M

Because the lecturers attached to the course and the books attached to the course are independent of each other, this database design has a multivalued dependency; if we were to add a new book to the AHA course, we would have to add one record for each of the lecturers on that course, and vice versa.

Put formally, there are two multivalued dependencies in this relation: {course} $\twoheadrightarrow$ {book} and equivalently {course} $\twoheadrightarrow$ {lecturer}.

Databases with multivalued dependencies thus exhibit redundancy. In database normalization, fourth normal form requires that either every multivalued dependency $X \twoheadrightarrow Y$ is trivial or for every nontrivial multivalued dependency $X \twoheadrightarrow Y$, X is a superkey.

Interesting properties

- If $\alpha \twoheadrightarrow \beta$, Then $\alpha \twoheadrightarrow R - \beta$
- If $\alpha \twoheadrightarrow \beta$ and $\gamma \subseteq \delta$, Then $\alpha\delta \twoheadrightarrow \beta\gamma$
- If $\alpha \twoheadrightarrow \beta$ and $\beta \twoheadrightarrow \gamma$, then $\alpha \twoheadrightarrow \gamma - \beta$

The following also involve functional dependencies:

- If $\alpha \rightarrow \beta$, then $\alpha \twoheadrightarrow \beta$
- If $\alpha \twoheadrightarrow \beta$ and $\beta \rightarrow \gamma$, then $\alpha \twoheadrightarrow \gamma - \beta$

The above rules are sound and complete.

- A decomposition of R into (X, Y) and (X, $R - Y$) is a lossless-join decomposition if and only if $X \twoheadrightarrow Y$ holds in R.

Definitions

full constraint

> A constraint which expresses something about *all* attributes in a database. (In contrast to an **embedded constraint**.) That a multivalued dependency is a *full constraint* follows from its definition,as where it says something about the attributes $R - \beta$.

tuple-generating dependency

> A dependency which explicitly requires certain tuples to be present in the relation.

trivial multivalued dependency 1

A multivalued dependency which involves all the attributes of a relation i.e. $R = \alpha \cup \beta$. A trivial multivalued dependency implies, for tuples t_1 and t_2, tuples t_3 and t_4 which are equal to t_1 and t_2.

trivial multivalued dependency 2

A multivalued dependency for which $\beta \subseteq \alpha$.

Fourth normal form

Fourth normal form (**4NF**) is a normal form used in database normalization. Introduced by Ronald Fagin in 1977, 4NF is the next level of normalization after Boyce–Codd normal form (BCNF). Whereas the second, third, and Boyce–Codd normal forms are concerned with functional dependencies, 4NF is concerned with a more general type of dependency known as a multivalued dependency. A Table is in 4NF if and only if, for every one of its non-trivial multivalued dependencies $X \twoheadrightarrow Y$, X is a superkey—that is, X is either a candidate key or a superset thereof.[1]

Multivalued dependencies

If the column headings in a relational database table are divided into three disjoint groupings X, Y, and Z, then, in the context of a particular row, we can refer to the data beneath each group of headings as x, y, and z respectively. A multivalued dependency $X \twoheadrightarrow Y$ signifies that if we choose any x actually occurring in the table (call this choice x_c), and compile a list of all the $x_c yz$ combinations that occur in the table, we will find that x_c is associated with the same y entries regardless of z. So essentially the presence of z provides no useful information to constrain the possible values of y.

A **trivial multivalued dependency** $X \twoheadrightarrow Y$ is one where either Y is a subset of X, or X and Y together form the whole set of attributes of the relation.

A functional dependency is a special case of multivalued dependency. In a functional dependency $X \to Y$, every x determines *exactly one* y, never more than one.

Example

Consider the following example:

Pizza Delivery Permutations

Restaurant	Pizza Variety	Delivery Area
A1 Pizza	Thick Crust	Springfield
A1 Pizza	Thick Crust	Shelbyville
A1 Pizza	Thick Crust	Capital City
A1 Pizza	Stuffed Crust	Springfield
A1 Pizza	Stuffed Crust	Shelbyville
A1 Pizza	Stuffed Crust	Capital City
Elite Pizza	Thin Crust	Capital City
Elite Pizza	Stuffed Crust	Capital City
Vincenzo's Pizza	Thick Crust	Springfield
Vincenzo's Pizza	Thick Crust	Shelbyville
Vincenzo's Pizza	Thin Crust	Springfield
Vincenzo's Pizza	Thin Crust	Shelbyville

Each row indicates that a given restaurant can deliver a given variety of pizza to a given area.

The table has no non-key attributes because its only key is {Restaurant, Pizza Variety, Delivery Area}. Therefore it meets all normal forms up to BCNF. If we assume, however, that pizza varieties offered by a restaurant are not affected by delivery area, then it does not meet 4NF. The problem is that the table features two non-trivial multivalued dependencies on the {Restaurant} attribute (which is not a superkey). The dependencies are:

- {Restaurant} $\twoheadrightarrow$ {Pizza Variety}
- {Restaurant} $\twoheadrightarrow$ {Delivery Area}

These non-trivial multivalued dependencies on a non-superkey reflect the fact that the varieties of pizza a restaurant offers are independent from the areas to which the restaurant delivers. This state of affairs leads to redundancy in the table: for example, we are told three times that A1 Pizza offers Stuffed Crust, and if A1 Pizza starts producing Cheese Crust pizzas then we will need to add multiple rows, one for each of A1 Pizza's delivery areas. There is, moreover, nothing to prevent us from doing this incorrectly: we might add Cheese Crust rows for all but one of A1 Pizza's delivery areas, thereby failing to respect the multivalued dependency {Restaurant} $\twoheadrightarrow$ {Pizza Variety}.

To eliminate the possibility of these anomalies, we must place the facts about varieties offered into a different table from the facts about delivery areas, yielding two tables that are both in 4NF:

Varieties By Restaurant

Restaurant	Pizza Variety
A1 Pizza	Thick Crust
A1 Pizza	Stuffed Crust
Elite Pizza	Thin Crust
Elite Pizza	Stuffed Crust
Vincenzo's Pizza	Thick Crust
Vincenzo's Pizza	Thin Crust

Delivery Areas By Restaurant

Restaurant	Delivery Area
A1 Pizza	Springfield
A1 Pizza	Shelbyville
A1 Pizza	Capital City
Elite Pizza	Capital City
Vincenzo's Pizza	Springfield
Vincenzo's Pizza	Shelbyville

In contrast, if the pizza varieties offered by a restaurant sometimes did legitimately vary from one delivery area to another, the original three-column table would satisfy 4NF.

Ronald Fagin demonstrated that it is always possible to achieve 4NF.[2] Rissanen's theorem is also applicable on multivalued dependencies.

4NF in practice

A 1992 paper by Margaret S. Wu notes that the teaching of database normalization typically stops short of 4NF, perhaps because of a belief that tables violating 4NF (but meeting all lower normal forms) are rarely encountered in business applications. This belief may not be accurate, however. Wu reports that in a study of forty organizational databases, over 20% contained one or more tables that violated 4NF while meeting all lower normal forms.

References

[1] "A relation schema R* is in fourth normal form (4NF) if, whenever a nontrivial multivalued dependency $X \twoheadrightarrow Y$ holds for R*, then so does the functional dependency $X \rightarrow A$ for every column name A of R*. Intuitively all dependencies are the result of keys."

Fifth normal form

Fifth normal form (**5NF**), also known as **project-join normal form** (**PJ/NF**) is a level of database normalization designed to reduce redundancy in relational databases recording multi-valued facts by isolating semantically related multiple relationships. A table is said to be in the 5NF if and only if every non-trivial join dependency in it is implied by the candidate keys.

A join dependency *{A, B, … Z} on R is implied by the candidate key(s) of R if and only if each of A, B, …, Z is a superkey for R.[1]

Example

Consider the following example:

Traveling Salesman Product Availability By Brand

Traveling Salesman	Brand	Product Type
Jack Schneider	Acme	Vacuum Cleaner
Jack Schneider	Acme	Breadbox
Willy Loman	Robusto	Pruning Shears
Willy Loman	Robusto	Vacuum Cleaner
Willy Loman	Robusto	Breadbox
Willy Loman	Robusto	Umbrella Stand
Louis Ferguson	Robusto	Vacuum Cleaner
Louis Ferguson	Robusto	Telescope
Louis Ferguson	Acme	Vacuum Cleaner
Louis Ferguson	Acme	Lava Lamp
Louis Ferguson	Nimbus	Tie Rack

The table's predicate is: Products of the type designated by *Product Type*, made by the brand designated by *Brand*, are available from the traveling salesman designated by *Traveling Salesman*.

In the absence of any rules restricting the valid possible combinations of Traveling Salesman, Brand, and Product Type, the three-attribute table above is necessary in order to model the situation correctly.

Suppose, however, that the following rule applies: *A Traveling Salesman has certain Brands and certain Product Types in his repertoire. If Brand B1 and Brand B2 are in his repertoire, and Product Type P is in his repertoire, then (assuming Brand B1 and Brand B2 both make Product Type P), the Traveling Salesman must offer products of Product Type P those made by Brand B1 and those made by Brand B2.*

In that case, it is possible to split the table into three:

Product Types By Traveling Salesman

Traveling Salesman	Product Type
Jack Schneider	Vacuum Cleaner
Jack Schneider	Breadbox
Willy Loman	Pruning Shears
Willy Loman	Vacuum Cleaner
Willy Loman	Breadbox
Willy Loman	Umbrella Stand
Louis Ferguson	Telescope
Louis Ferguson	Vacuum Cleaner
Louis Ferguson	Lava Lamp
Louis Ferguson	Tie Rack

Brands By Traveling Salesman

Traveling Salesman	Brand
Jack Schneider	Acme
Willy Loman	Robusto
Louis Ferguson	Robusto
Louis Ferguson	Acme
Louis Ferguson	Nimbus

Product Types By Brand

Brand	Product Type
Acme	Vacuum Cleaner
Acme	Breadbox
Acme	Lava Lamp
Robusto	Pruning Shears
Robusto	Vacuum Cleaner
Robusto	Breadbox
Robusto	Umbrella Stand
Robusto	Telescope
Nimbus	Tie Rack

In this case, it's impossible for Louis Ferguson to refuse to offer Vacuum Cleaners made by ACME (assuming ACME makes Vacuum Cleaners) if he sells anything else made by Acme (Lava Lamp) and he also sells Vacuum Cleaners made by any other brand (Robusto).

Note how this setup helps to remove redundancy. Suppose that Jack Schneider starts selling Robusto's products Breadboxes and Vacuum Cleaners. In the previous setup we would have to add two new entries one for each product type (<Jack Schneider, Robusto, Breadboxes>, <Jack Schneider, Robusto, Vacuum Cleaners>). With the new setup we need to add only a single entry (<Jack Schneider, Robusto>)in Brands By Traveling Salesman.

Usage

Only in rare situations does a 4NF table not conform to 5NF. These are situations in which a complex real-world constraint governing the valid combinations of attribute values in the 4NF table is not implicit in the structure of that table. If such a table is not normalized to 5NF, the burden of maintaining the logical consistency of the data within the table must be carried partly by the application responsible for insertions, deletions, and updates to it; and there is a heightened risk that the data within the table will become inconsistent. In contrast, the 5NF design excludes the possibility of such inconsistencies.

Sixth normal form

Sixth normal form (**6NF**) is a term in relational database theory, used in two different ways.

6NF (C. Date's definition)

A book by Christopher J. Date and others on temporal databases,[1] defined sixth normal form as a normal form for databases based on an extension of the relational algebra.

In this work, the relational operators, such as *join*, are generalized to support a natural treatment of interval data, such as sequences of dates or moments in time.[2] Sixth normal form is then based on this generalized join, as follows:

> A relvar R [table] is in **sixth normal form** (abbreviated 6NF) if and only if it satisfies no nontrivial join dependencies at all — where, as before, a join dependency is trivial if and only if at least one of the projections (possibly U_projections) involved is taken over the set of all attributes of the relvar [table] concerned.[Date et al.][3]

Any relation in 6NF is also in 5NF.

Sixth normal form is intended to decompose relation variables to irreducible components. Though this may be relatively unimportant for non-temporal relation variables, it can be important when dealing with temporal variables or other interval data. For instance, if a relation comprises a supplier's name, status, and city, we may also want to add temporal data, such as the time during which these values are, or were, valid (e.g., for historical data) but the three values may vary independently of each other and at different rates. We may, for instance, wish to trace the history of changes to Status.

For further discussion on Temporal Aggregation in SQL, see also Zimanyi.[4] For a different approach, see TSQL2.[5]

DKNF

Some authors use the term **sixth normal form** differently, namely, as a synonym for Domain/key normal form (DKNF). This usage predates Date et al.'s work.[6]

Usage

The sixth normal form is currently being used in some data warehouses where the benefits outweigh the drawbacks,[7] for example using Anchor Modeling. Although using 6NF leads to an explosion of tables, modern databases can prune the tables from select queries (using a process called 'table elimination') where they are not required and thus speed up queries that only access several attributes.

Denormalization

In computing, **denormalization** is the process of attempting to optimize the read performance of a database by adding redundant data or by grouping data.[1][2] In some cases, denormalization is a means of addressing performance or scalability in relational database software.

A normalized design will often store different but related pieces of information in separate logical tables (called relations). If these relations are stored physically as separate disk files, completing a database query that draws information from several relations (a *join operation*) can be slow. If many relations are joined, it may be prohibitively slow. There are two strategies for dealing with this. The preferred method is to keep the logical design normalized, but allow the database management system (DBMS) to store additional redundant information on disk to optimise query response. In this case it is the DBMS software's responsibility to ensure that any redundant copies are kept consistent. This method is often implemented in SQL as indexed views (Microsoft SQL Server) or materialised views (Oracle). A view represents information in a format convenient for querying, and the index ensures that queries against the view are optimised.

The more usual approach is to denormalize the logical data design. With care this can achieve a similar improvement in query response, but at a cost—it is now the database designer's responsibility to ensure that the denormalized database does not become inconsistent. This is done by creating rules in the database called *constraints*, that specify how the redundant copies of information must be kept synchronised. It is the increase in logical complexity of the database design and the added complexity of the additional constraints that make this approach hazardous. Moreover, constraints introduce a trade-off, speeding up reads (`SELECT` in SQL) while slowing down writes (`INSERT`, `UPDATE`, and `DELETE`). This means a denormalized database under heavy write load may actually offer *worse* performance than its functionally equivalent normalized counterpart.

A denormalized data model is not the same as a data model that has not been normalized, and denormalization should only take place after a satisfactory level of normalization has taken place and that any required constraints and/or rules have been created to deal with the inherent anomalies in the design. For example, all the relations are in third normal form and any relations with join and multi-valued dependencies are handled appropriately.

Examples of denormalization techniques include:

- Materialised views, which may implement the following:
  - Storing the count of the "many" objects in a one-to-many relationship as an attribute of the "one" relation
  - Adding attributes to a relation from another relation with which it will be joined
- Star schemas, which are also known as fact-dimension models and have been extended to snowflake schemas
- Prebuilt summarisation or OLAP cubes

Denormalization techniques are often used to improve the scalability of Web applications.[3]

Domain/key normal form

Domain/key normal form (**DKNF**) is a normal form used in database normalization which requires that the database contains no constraints other than domain constraints and key constraints.

A domain constraint specifies the permissible values for a given attribute, while a key constraint specifies the attributes that uniquely identify a row in a given table.

The domain/key normal form is achieved when every constraint on the relation is a logical consequence of the definition of keys and domains, and enforcing key and domain restraints and conditions causes all constraints to be met. Thus, it avoids all non-temporal anomalies.

The reason to use domain/key normal form is to avoid having general constraints in the database that are not clear domain or key constraints. Most databases can easily test domain and key constraints on attributes. General constraints however would normally require special database programming in the form of stored procedures that are expensive to maintain and expensive for the database to execute. Therefore general constraints are split into domain and key constraints.

It's much easier to build a database in domain/key normal form than it is to convert lesser databases which may contain numerous anomalies. However, successfully building a domain/key normal form database remains a difficult task, even for experienced database programmers. Thus, while the domain/key normal form eliminates the problems found in most databases, it tends to be the most costly normal form to achieve. However, failing to achieve the domain/key normal form may carry long-term, hidden costs due to anomalies which appear in databases adhering only to lower normal forms over time.

The third normal form, Boyce–Codd normal form, fourth normal form and fifth normal form are special cases of the domain/key normal form. All have either functional, multi-valued or join dependencies that can be converted into (super)keys. The domains on those normal forms were unconstrained so all domain constraints are satisfied. However, transforming a higher normal form into domain/key normal form is not always a dependency-preserving transformation and therefore not always possible.

Example

A violation of DKNF occurs in the following table:

Wealthy Person

Wealthy Person	Wealthy Person Type	Net Worth in Dollars
Steve	Eccentric Millionaire	124,543,621
Roderick	Evil Billionaire	6,553,228,893
Katrina	Eccentric Billionaire	8,829,462,998
Gary	Evil Millionaire	495,565,211

(Assume that the domain for Wealthy Person consists of the names of all wealthy people in a pre-defined sample of wealthy people; the domain for Wealthy Person Type consists of the values 'Eccentric Millionaire', 'Eccentric Billionaire', 'Evil Millionaire', and 'Evil Billionaire'; and the domain for Net Worth in Dollars consists of all integers greater than or equal to 1,000,000.)

There is a constraint linking Wealthy Person Type to Net Worth in Dollars, even though we cannot deduce one from the other. The constraint dictates that an Eccentric Millionaire or Evil Millionaire will have a net worth of 1,000,000 to 999,999,999 inclusive, while an Eccentric Billionaire or Evil Billionaire will have a net worth of 1,000,000,000 or higher. This constraint is neither a domain constraint nor a key constraint; therefore we cannot rely on domain

constraints and key constraints to guarantee that an inconsistent Wealthy Person Type / Net Worth in Dollars combination does not make its way into the database.

The DKNF violation could be eliminated by altering the Wealthy Person Type domain to make it consist of just two values, 'Evil' and 'Eccentric' (the wealthy person's status as a millionaire or billionaire is implicit in their Net Worth in Dollars, so no useful information is lost).

Wealthy Person

Wealthy Person	Wealthy Person Type	Net Worth in Dollars
Steve	Eccentric	124,543,621
Roderick	Evil	6,553,228,893
Katrina	Eccentric	8,829,462,998
Gary	Evil	495,565,211

Wealthiness Status

Status	Minimum	Maximum
Millionaire	1,000,000	999,999,999
Billionaire	1,000,000,000	999,999,999,999

DKNF is frequently difficult to achieve in practice.[*citation needed*]

Single Source of Truth

In Information Systems design and theory, as instantiated at the *Enterprise Level*, **Single Source Of Truth** (SSOT) refers to the practice of structuring information models and associated schemata such that every data element is stored exactly once (e.g., in no more than a single row of a single table). Any possible linkages to this data element (possibly in other areas of the relational schema or even in distant federated databases) are by reference only. Thus, when any such data element is updated, this update propagates to the enterprise at large, without the possibility of a duplicate value somewhere in the distant enterprise not being updated (because there would be no duplicate values that *needed* updating).[*citation needed*]

Deployment of an SSOT architecture is becoming increasingly important in enterprise settings where incorrectly linked duplicate or de-normalized data elements (a direct consequence of intentional or unintentional denormalization of any explicit data model) poses a risk for retrieval of outdated, and therefore incorrect, information. A common example would be the electronic health record, where it is imperative to accurately validate patient identity against a single referential repository, which serves as the SSOT. Duplicate representations of data within the enterprise would be implemented by the use of pointers rather than duplicate database tables, rows, or cells. This ensures that data updates to elements in the authoritative location are comprehensively distributed to all federated database constituencies in the larger overall enterprise architecture.[*citation needed*]

SSOT systems provide data that is authentic, relevant, and referable.Wikipedia:Please clarify[*citation needed*]

Implementing a Single Source of Truth

The "ideal" implementation of SSOT as described above is rarely possible in most enterprises. This is because many organisations have multiple information systems, each of which needs access to data relating to the same entities (e.g., customer). Often these systems are purchased "off-the-shelf" from vendors and cannot be modified in non-trivial ways. Each of these various systems therefore needs to store its own version of common data or entities, and therefore each system must retain its own copy of a record (hence immediately violating the SSOT approach defined above). For example, an ERP (Enterprise Resource Planning) system (such as SAP or Oracle e-Business Suite) may store a customer record; the CRM (Customer Relationship Management) system also needs a copy of the customer record (or part of it) and the warehouse despatch system might also need a copy of some or all of the customer data (e.g., shipping address). In cases where vendors do not support such modifications, it is not always possible to replace these records with pointers to the SSOT.

For organisations (with more than one information system) wishing to implement a Single Source of Truth (without modifying all but one master system to store pointers to other systems for all entities), three supporting technologies are commonly used:[*citation needed*]

- Enterprise Service Bus (ESB)
- Master Data Management (MDM)
- Data Warehouse (DW)

Enterprise Service Bus (ESB)

An Enterprise Service Bus (ESB) allows any number of systems in an organisation to receive updates of data that has changed in another system. To implement a Single Source of Truth, a single source system of correct data for any entity must be identified. Changes to this entity (creates, updates, and deletes) are then published via the ESB; other systems which need to retain a copy of that data subscribe to this update, and update their own records accordingly. For any given entity, the master source must be identified (sometimes called the Golden Record). It should be noted that any given system could publish (be the source of truth for) information on a particular entity (e.g., customer) and also subscribe to updates from another system for information on some other entity (e.g., product).[*citation needed*]

An alternative approach is point-to-point data updates, but these become exponentially more expensive to maintain as the number of systems increases, and this approach is increasingly out of favour as an IT architecture.[*citation needed*]

Master Data Management (MDM)

An MDM system can act as the source of truth for any given entity that might not necessarily have an alternative "source of truth" in another system. Typically the MDM acts as a hub for multiple systems, many of which could allow (be the source of truth for) updates to different aspects of information on a given entity. For example, the CRM system may be the "source of truth" for most aspects of the customer, and is updated by a call centre operator. However, a customer may (for example) also update their address via a customer service web site, with a different back-end database from the CRM system. The MDM application receives updates from multiple sources, acts as a broker to determine which updates are to be regarded as authoritative (the Golden Record) and then syndicates this updated data to all subscribing systems. The MDM application normally requires an ESB to syndicate its data to multiple subscribing systems.[*citation needed*]

Customer Data Integration (CDI), as a common application of Master Data Management, is sometimes abbreviated CDI-MDM.[*citation needed*]

Data Warehouse (DW)

While the primary purpose of a data warehouse is to support reporting and analysis of data that has been combined from multiple sources, the fact that such data has been combined (according to business logic embedded in the data transformation and integration processes) means that the data warehouse is often used as a *de facto* SSOT. Generally, however, the data available from the data warehouse is not used to update other systems; rather the DW becomes the "single source of truth" for reporting to multiple stakeholders. In this context, the Data Warehouse is more correctly referred to as a "Single Version of the Truth" since other versions of the truth exist in its operational data sources (no data originates in the DW; it is simply a reporting mechanism for data loaded from operational systems).[*citation needed*]

References

Single version of the truth

In computerized business management, **SVOT**, or **Single Version of the Truth**, is a technical concept describing the data warehousing ideal of having either a single centralised database, or at least a distributed synchronised database, which stores all of an organisation's data in a consistent and non-redundant form. This contrasts with the related concept of Single Source of Truth (SSOT), which refers to is a data storage principle to always source a particular piece of information from one place.[*citation needed*]

SVOT applied to message sequencing

In some systems and in the context of message processing systems (often realtime systems), this term also refers to the goal of establishing a single agreed sequence of messages within a database formed by a particular but arbitrary sequencing of records. The key concept is that data combined in a certain sequence is a "truth" which may be analyzed and processed giving particular results, and that although the sequence is arbitrary (and thus another correct but equally arbitrary sequencing would ultimately provide different results in any analysis), it is desirable to agree that the sequence enshrined in the "single version of the truth" is the version that will be considered "the truth", and that any conclusions drawn from analysis of the database are valid and unarguable, and (in a technical context) the database may be duplicated to a backup environment to ensure a persistent record is kept of the "single version of the truth".

The key point is when the database is created using an external data source (such as a sequence of trading messages from a stock exchange) an arbitrary selection is made of one possibility from two or more equally valid representations of the input data, but henceforth the decision sets "in stone" one and only one version of the truth.

Critique of SVOT as applied to message sequencing

Critics of "SVOT as applied to message sequencing" argue that this concept is not scalable. As the world moves towards systems spread over many processing nodes, the effort involved in negotiating a single agreed-upon sequence becomes prohibitive.

Principle of Orthogonal Design

The **Principle of Orthogonal Design** (abbreviated POOD) was developed by database researchers David McGoveran and Christopher J. Date in the early 1990s, and first published "A New Database Design Principle" in the July 1994 issue of Database Programming and Design and reprinted several times. It is the second of the two principles of database design, which seek to prevent databases from being too complicated or redundant, the first principle being the Principle of Full Normalization (POFN).

Simply put, it says that no two relations in a relational database should be defined in such a way that they can represent the same facts. As with database normalization, POOD serves to eliminate uncontrolled storage redundancy and expressive ambiguity, especially useful for applying updates to virtual relations (e.g., view (database)). Although simple in concept, POOD is frequently misunderstood and the formal expression of POOD continues to be refined.

The principle is a restatement of the requirement that a database is a minimum cover set of the relational algebra. The relational algebra allows data duplication in the relations that are the elements of the algebra. One of the efficiency requirements of a database is that there be no data duplication. This requirement is met by the minimum cover set of the relational algebra.

Transaction Management

Database transaction

A **transaction** comprises a unit of work performed within a database management system (or similar system) against a database, and treated in a coherent and reliable way independent of other transactions. Transactions in a database environment have two main purposes:

1. To provide reliable units of work that allow correct recovery from failures and keep a database consistent even in cases of system failure, when execution stops (completely or partially) and many operations upon a database remain uncompleted, with unclear status.
2. To provide isolation between programs accessing a database concurrently. If this isolation is not provided, the program's outcome are possibly erroneous.

A database transaction, by definition, must be atomic, consistent, isolated and durable.[1] Database practitioners often refer to these properties of database transactions using the acronym ACID.

Transactions provide an "all-or-nothing" proposition, stating that each work-unit performed in a database must either complete in its entirety or have no effect whatsoever. Further, the system must isolate each transaction from other transactions, results must conform to existing constraints in the database, and transactions that complete successfully must get written to durable storage.

Purpose

Databases and other data stores which treat the integrity of data as paramount often include the ability to handle transactions to maintain the integrity of data. A single transaction consists of one or more independent units of work, each reading and/or writing information to a database or other data store. When this happens it is often important to ensure that all such processing leaves the database or data store in a consistent state.

Examples from double-entry accounting systems often illustrate the concept of transactions. In double-entry accounting every debit requires the recording of an associated credit. If one writes a check for $100 to buy groceries, a transactional double-entry accounting system must record the following two entries to cover the single transaction:

1. Debit $100 to Groceries Expense Account
2. Credit $100 to Checking Account

A transactional system would make both entries pass or both entries would fail. By treating the recording of multiple entries as an atomic transactional unit of work the system maintains the integrity of the data recorded. In other words, nobody ends up with a situation in which a debit is recorded but no associated credit is recorded, or vice versa.

Transactional databases

A **transactional database** is a DBMS where write transactions on the database are able to be rolled back if they are not completed properly (e.g. due to power or connectivity loss).

Most modern[2] relational database management systems fall into the category of databases that support transactions.

In a database system a transaction might consist of one or more data-manipulation statements and queries, each reading and/or writing information in the database. Users of database systems consider consistency and integrity of data as highly important. A simple transaction is usually issued to the database system in a language like SQL wrapped in a transaction, using a pattern similar to the following:

1. Begin the transaction
2. Execute a set of data manipulations and/or queries
3. If no errors occur then commit the transaction and end it
4. If errors occur then rollback the transaction and end it

If no errors occurred during the execution of the transaction then the system commits the transaction. A transaction commit operation applies all data manipulations within the scope of the transaction and persists the results to the database. If an error occurs during the transaction, or if the user specifies a rollback operation, the data manipulations within the transaction are not persisted to the database. In no case can a partial transaction be committed to the database since that would leave the database in an inconsistent state.

Internally, multi-user databases store and process transactions, often by using a transaction ID or XID.

There are multiple varying ways for transactions to be implemented other than the simple way documented above. Nested transactions, for example, are transactions which contain statements within them that start new transactions (i.e. sub-transactions). *Multi-level transactions* are a variant of nested transactions where the sub-transactions take place at different levels of a layered system architecture (e.g., with one operation at the database-engine level, one operation at the operating-system level) [2] Another type of transaction is the compensating transaction.

In SQL

Transactions are available in most SQL database implementations, though with varying levels of robustness. (MySQL, for example, does not support transactions in the MyISAM storage engine, which was its default storage engine before version 5.5.)

A transaction is typically started using the command `BEGIN` (although the SQL standard specifies `START TRANSACTION`). When the system processes a `COMMIT` statement, the transaction ends with successful completion. A `ROLLBACK` statement can also end the transaction, undoing any work performed since `BEGIN TRANSACTION`. If autocommit was disabled using `START TRANSACTION`, autocommit will also be re-enabled at the transaction's end.

One can set the isolation level for individual transactional operations as well as globally. At the READ COMMITTED level, the result of any work done after a transaction has commenced, but before it has ended, will remain invisible to other database-users until it has ended. At the lowest level (READ UNCOMMITTED), which may occasionally be used to ensure high concurrency, such changes will be visible.

Distributed transactions

Database systems implement distributed transactions as transactions against multiple applications or hosts. A distributed transaction enforces the ACID properties over multiple systems or data stores, and might include systems such as databases, file systems, messaging systems, and other applications. In a distributed transaction a coordinating service ensures that all parts of the transaction are applied to all relevant systems. As with database and other transactions, if any part of the transaction fails, the entire transaction is rolled back across all affected systems.

Transactional filesystems

The Namesys Reiser4 filesystem for Linux[3] supports transactions, and as of Microsoft Windows Vista, the Microsoft NTFS filesystem[4] supports distributed transactions across networks.

Transaction processing

In computer science, **transaction processing** is information processing that is divided into individual, indivisible operations, called *transactions.* Each transaction must succeed or fail as a complete unit; it cannot be only partially complete.

Since most, though not necessarily all, transaction processing today is interactive the term is often treated as synonymous with *online transaction processing*.

Description

Transaction processing is designed to maintain a systems Integrity (typically a database or some modern filesystems) in a known, consistent state, by ensuring that interdependent operations on the system are either all completed successfully or all canceled successfully.

For example, consider a typical banking transaction that involves moving $700 from a customer's savings account to a customer's checking account. This transaction involves at least two separate operations in computer terms: debiting the savings account by $700, and crediting the checking account by $700. If one operation succeeds but the other does not, the books of the bank will not balance at the end of the day. There must therefore be a way to ensure that either both operations succeed or both fail, so that there is never any inconsistency in the bank's database as a whole.

Transaction processing links multiple individual operations in a single, indivisible transaction, and ensures that either all operations in a transaction are completed without error, or none of them are. If some of the operations are completed but errors occur when the others are attempted, the transaction-processing system "rolls back" *all* of the operations of the transaction (including the successful ones), thereby erasing all traces of the transaction and restoring the system to the consistent, known state that it was in before processing of the transaction began. If all operations of a transaction are completed successfully, the transaction is committed by the system, and all changes to the database are made permanent; the transaction cannot be rolled back once this is done.

Transaction processing guards against hardware and software errors that might leave a transaction partially completed. If the computer system crashes in the middle of a transaction, the transaction processing system guarantees that all operations in any uncommitted transactions are cancelled.

Generally, transactions are issued concurrently. If they overlap (i.e. need to touch the same portion of the database), this can create conflicts. For example, if the customer mentioned in the example above has $150 in his savings account and attempts to transfer $100 to a different person while at the same time moving $100 to the checking account, only one of them can succeed. However, forcing transactions to be processed sequentially is inefficient. Therefore, concurrent implementations of transaction processing is programmed to guarantee that the end result reflects a conflict-free outcome, the same as could be reached if executing the transactions sequentially in any order (a property called serializability). In our example, this means that no matter which transaction was issued first, either the transfer to a different person or the move to the checking account succeeds, while the other one fails.

Methodology

The basic principles of all transaction-processing systems are the same. However, the terminology may vary from one transaction-processing system to another, and the terms used below are not necessarily universal.

Rollback

Transaction-processing systems ensure database integrity by recording intermediate states of the database as it is modified, then using these records to restore the database to a known state if a transaction cannot be committed. For example, copies of information on the database *prior* to its modification by a transaction are set aside by the system before the transaction can make any modifications (this is sometimes called a *before image*). If any part of the transaction fails before it is committed, these copies are used to restore the database to the state it was in before the transaction began.

Rollforward

It is also possible to keep a separate journal of all modifications to a database (sometimes called *after images*). This is not required for rollback of failed transactions but it is useful for updating the database in the event of a database failure, so some transaction-processing systems provide it. If the database fails entirely, it must be restored from the most recent back-up. The back-up will not reflect transactions committed since the back-up was made. However, once the database is restored, the journal of after images can be applied to the database (*rollforward*) to bring the database up to date. Any transactions in progress at the time of the failure can then be rolled back. The result is a database in a consistent, known state that includes the results of all transactions committed up to the moment of failure.

Deadlocks

In some cases, two transactions may, in the course of their processing, attempt to access the same portion of a database at the same time, in a way that prevents them from proceeding. For example, transaction A may access portion X of the database, and transaction B may access portion Y of the database. If, at that point, transaction A then tries to access portion Y of the database while transaction B tries to access portion X, a *deadlock* occurs, and neither transaction can move forward. Transaction-processing systems are designed to detect these deadlocks when they occur. Typically both transactions will be cancelled and rolled back, and then they will be started again in a different order, automatically, so that the deadlock doesn't occur again. Or sometimes, just one of the deadlocked transactions will be cancelled, rolled back, and automatically restarted after a short delay.

Deadlocks can also occur between three or more transactions. The more transactions involved, the more difficult they are to detect, to the point that transaction processing systems find there is a practical limit to the deadlocks they can detect.

Compensating transaction

In systems where commit and rollback mechanisms are not available or undesirable, a compensating transaction is often used to undo failed transactions and restore the system to a previous state.

ACID criteria

Jim Gray defined properties of a reliable transaction system in the late 1970s under the acronym *ACID* — atomicity, consistency, isolation, and durability.

Atomicity

A transaction's changes to the state are atomic: either all happen or none happen. These changes include database changes, messages, and actions on transducers.

Consistency

Consistency: A transaction is a correct transformation of the state. The actions taken as a group do not violate any of the integrity constraints associated with the state.

Isolation

Even though transactions execute concurrently, it appears to each transaction T, that others executed either before T or after T, but not both.

Durability

Once a transaction completes successfully (commits), its changes to the state survive failures.

Benefits

Transaction processing has these benefits:

- It allows sharing of computer resources among many users
- It shifts the time of job processing to when the computing resources are less busy
- It avoids idling the computing resources without minute-by-minute human interaction and supervision
- It is used on expensive classes of computers to help amortize the cost by keeping high rates of utilization of those expensive resources

Implementations

Standard transaction-processing software, notably IBM's Information Management System, was first developed in the 1960s, and was often closely coupled to particular database management systems. Client–server computing implemented similar principles in the 1980s with mixed success. However, in more recent years, the distributed client–server model has become considerably more difficult to maintain. As the number of transactions grew in response to various online services (especially the Web), a single distributed database was not a practical solution. In addition, most online systems consist of a whole suite of programs operating together, as opposed to a strict client–server model where the single server could handle the transaction processing. Today a number of transaction processing systems are available that work at the inter-program level and which scale to large systems, including mainframes.

One well-known[*citation needed*] (and open) industry standard is the X/Open Distributed Transaction Processing (DTP) (see also JTA the Java Transaction API). However, proprietary transaction-processing environments such as IBM's CICS are still very popular,[*citation needed*] although CICS has evolved to include open industry standards as well.

The term 'Extreme Transaction Processing' (XTP) has been used to describe transaction processing systems with uncommonly challenging requirements, particularly throughput requirements (transactions per second). Such systems may be implemented via distributed or cluster style architectures.

Concurrency control

In information technology and computer science, especially in the fields of computer programming, operating systems, multiprocessors, and databases, **concurrency control** ensures that correct results for concurrent operations are generated, while getting those results as quickly as possible.

Computer systems, both software and hardware, consist of modules, or components. Each component is designed to operate correctly, i.e., to obey or to meet certain consistency rules. When components that operate concurrently interact by messaging or by sharing accessed data (in memory or storage), a certain component's consistency may be violated by another component. The general area of concurrency control provides rules, methods, design methodologies, and theories to maintain the consistency of components operating concurrently while interacting, and thus the consistency and correctness of the whole system. Introducing concurrency control into a system means applying operation constraints which typically result in some performance reduction. Operation consistency and correctness should be achieved with as good as possible efficiency, without reducing performance below reasonable levels. Concurrency control can require significant additional complexity and overhead in a concurrent algorithm compared to the simpler sequential algorithm.

For example, a failure in concurrency control can result in data corruption from torn read or write operations.

Concurrency control in databases

Comments:

1. This section is applicable to all transactional systems, i.e., to all systems that use *database transactions* (*atomic transactions*; e.g., transactional objects in Systems management and in networks of smartphones which typically implement private, dedicated database systems), not only general-purpose database management systems (DBMSs).
2. DBMSs need to deal also with concurrency control issues not typical just to database transactions but rather to operating systems in general. These issues (e.g., see *Concurrency control in operating systems* below) are out of the scope of this section.

Concurrency control in Database management systems (DBMS; e.g., Bernstein et al. 1987, Weikum and Vossen 2001), other transactional objects, and related distributed applications (e.g., Grid computing and Cloud computing) ensures that *database transactions* are performed concurrently without violating the data integrity of the respective databases. Thus concurrency control is an essential element for correctness in any system where two database transactions or more, executed with time overlap, can access the same data, e.g., virtually in any general-purpose database system. Consequently a vast body of related research has been accumulated since database systems emerged in the early 1970s. A well established concurrency control theory for database systems is outlined in the references mentioned above: serializability theory, which allows to effectively design and analyze concurrency control methods and mechanisms. An alternative theory for concurrency control of atomic transactions over abstract data types is presented in (Lynch et al. 1993), and not utilized below. This theory is more refined, complex, with a wider scope, and has been less utilized in the Database literature than the classical theory above. Each theory has its pros and cons, emphasis and insight. To some extent they are complementary, and their merging may be useful.

To ensure correctness, a DBMS usually guarantees that only *serializable* transaction schedules are generated, unless *serializability* is intentionally relaxed to increase performance, but only in cases where application correctness is not harmed. For maintaining correctness in cases of failed (aborted) transactions (which can always happen for many reasons) schedules also need to have the *recoverability* (from abort) property. A DBMS also guarantees that no effect of *committed* transactions is lost, and no effect of *aborted* (rolled back) transactions remains in the related database. Overall transaction characterization is usually summarized by the ACID rules below. As databases have become distributed, or needed to cooperate in distributed environments (e.g., Federated databases in the early 1990, and Cloud computing currently), the effective distribution of concurrency control mechanisms has received special attention.

Database transaction and the ACID rules

The concept of a *database transaction* (or *atomic transaction*) has evolved in order to enable both a well understood database system behavior in a faulty environment where crashes can happen any time, and *recovery* from a crash to a well understood database state. A database transaction is a unit of work, typically encapsulating a number of operations over a database (e.g., reading a database object, writing, acquiring lock, etc.), an abstraction supported in database and also other systems. Each transaction has well defined boundaries in terms of which program/code executions are included in that transaction (determined by the transaction's programmer via special transaction commands). Every database transaction obeys the following rules (by support in the database system; i.e., a database system is designed to guarantee them for the transactions it runs):

- **Atomicity** - Either the effects of all or none of its operations remain ("all or nothing" semantics) when a transaction is completed (*committed* or *aborted* respectively). In other words, to the outside world a committed transaction appears (by its effects on the database) to be indivisible, atomic, and an aborted transaction does not leave effects on the database at all, as if never existed.
- **Consistency** - Every transaction must leave the database in a consistent (correct) state, i.e., maintain the predetermined integrity rules of the database (constraints upon and among the database's objects). A transaction

must transform a database from one consistent state to another consistent state (however, it is the responsibility of the transaction's programmer to make sure that the transaction itself is correct, i.e., performs correctly what it intends to perform (from the application's point of view) while the predefined integrity rules are enforced by the DBMS). Thus since a database can be normally changed only by transactions, all the database's states are consistent. An aborted transaction does not change the database state it has started from, as if it never existed (atomicity above).

- **Isolation** - Transactions cannot interfere with each other (as an end result of their executions). Moreover, usually (depending on concurrency control method) the effects of an incomplete transaction are not even visible to another transaction. Providing isolation is the main goal of concurrency control.
- **Durability** - Effects of successful (committed) transactions must persist through crashes (typically by recording the transaction's effects and its commit event in a non-volatile memory).

The concept of atomic transaction has been extended during the years to what has become Business transactions which actually implement types of Workflow and are not atomic. However also such enhanced transactions typically utilize atomic transactions as components.

Why is concurrency control needed?

If transactions are executed *serially*, i.e., sequentially with no overlap in time, no transaction concurrency exists. However, if concurrent transactions with interleaving operations are allowed in an uncontrolled manner, some unexpected, undesirable result may occur. Here are some typical examples:

1. The lost update problem: A second transaction writes a second value of a data-item (datum) on top of a first value written by a first concurrent transaction, and the first value is lost to other transactions running concurrently which need, by their precedence, to read the first value. The transactions that have read the wrong value end with incorrect results.
2. The dirty read problem: Transactions read a value written by a transaction that has been later aborted. This value disappears from the database upon abort, and should not have been read by any transaction ("dirty read"). The reading transactions end with incorrect results.
3. The incorrect summary problem: While one transaction takes a summary over the values of all the instances of a repeated data-item, a second transaction updates some instances of that data-item. The resulting summary does not reflect a correct result for any (usually needed for correctness) precedence order between the two transactions (if one is executed before the other), but rather some random result, depending on the timing of the updates, and whether certain update results have been included in the summary or not.

Most high-performance transactional systems need to run transactions concurrently to meet their performance requirements. Thus, without concurrency control such systems can neither provide correct results nor maintain their databases consistent.

Concurrency control mechanisms

Categories

The main categories of concurrency control mechanisms are:

- **Optimistic** - Delay the checking of whether a transaction meets the isolation and other integrity rules (e.g., serializability and recoverability) until its end, without blocking any of its (read, write) operations ("...and be optimistic about the rules being met..."), and then abort a transaction to prevent the violation, if the desired rules are to be violated upon its commit. An aborted transaction is immediately restarted and re-executed, which incurs an obvious overhead (versus executing it to the end only once). If not too many transactions are aborted, then being optimistic is usually a good strategy.

- **Pessimistic** - Block an operation of a transaction, if it may cause violation of the rules, until the possibility of violation disappears. Blocking operations is typically involved with performance reduction.
- **Semi-optimistic** - Block operations in some situations, if they may cause violation of some rules, and do not block in other situations while delaying rules checking (if needed) to transaction's end, as done with optimistic.

Different categories provide different performance, i.e., different average transaction completion rates (*throughput*), depending on transaction types mix, computing level of parallelism, and other factors. If selection and knowledge about trade-offs are available, then category and method should be chosen to provide the highest performance.

The mutual blocking between two transactions (where each one blocks the other) or more results in a deadlock, where the transactions involved are stalled and cannot reach completion. Most non-optimistic mechanisms (with blocking) are prone to deadlocks which are resolved by an intentional abort of a stalled transaction (which releases the other transactions in that deadlock), and its immediate restart and re-execution. The likelihood of a deadlock is typically low.

Blocking, deadlocks, and aborts all result in performance reduction, and hence the trade-offs between the categories.

Methods

Many methods for concurrency control exist. Most of them can be implemented within either main category above. The major methods,[1] which have each many variants, and in some cases may overlap or be combined, are:

1. Locking (e.g., **Two-phase locking** - 2PL) - Controlling access to data by locks assigned to the data. Access of a transaction to a data item (database object) locked by another transaction may be blocked (depending on lock type and access operation type) until lock release.
2. **Serialization graph checking** (also called Serializability, or Conflict, or Precedence graph checking) - Checking for cycles in the schedule's graph and breaking them by aborts.
3. **Timestamp ordering** (TO) - Assigning timestamps to transactions, and controlling or checking access to data by timestamp order.
4. **Commitment ordering** (or Commit ordering; CO) - Controlling or checking transactions' chronological order of commit events to be compatible with their respective precedence order.

Other major concurrency control types that are utilized in conjunction with the methods above include:

- **Multiversion concurrency control** (MVCC) - Increasing concurrency and performance by generating a new version of a database object each time the object is written, and allowing transactions' read operations of several last relevant versions (of each object) depending on scheduling method.
- **Index concurrency control** - Synchronizing access operations to indexes, rather than to user data. Specialized methods provide substantial performance gains.
- **Private workspace model** (**Deferred update**) - Each transaction maintains a private workspace for its accessed data, and its changed data become visible outside the transaction only upon its commit (e.g., Weikum and Vossen 2001). This model provides a different concurrency control behavior with benefits in many cases.

The most common mechanism type in database systems since their early days in the 1970s has been *Strong strict Two-phase locking* (SS2PL; also called *Rigorous scheduling* or *Rigorous 2PL*) which is a special case (variant) of both Two-phase locking (2PL) and Commitment ordering (CO). It is pessimistic. In spite of its long name (for historical reasons) the idea of the **SS2PL** mechanism is simple: "Release all locks applied by a transaction only after the transaction has ended." SS2PL (or Rigorousness) is also the name of the set of all schedules that can be generated by this mechanism, i.e., these are SS2PL (or Rigorous) schedules, have the SS2PL (or Rigorousness) property.

Major goals of concurrency control mechanisms

Concurrency control mechanisms firstly need to operate correctly, i.e., to maintain each transaction's integrity rules (as related to concurrency; application-specific integrity rule are out of the scope here) while transactions are running concurrently, and thus the integrity of the entire transactional system. Correctness needs to be achieved with as good performance as possible. In addition, increasingly a need exists to operate effectively while transactions are distributed over processes, computers, and computer networks. Other subjects that may affect concurrency control are recovery and replication.

Correctness

Serializability

For correctness, a common major goal of most concurrency control mechanisms is generating schedules with the *Serializability* property. Without serializability undesirable phenomena may occur, e.g., money may disappear from accounts, or be generated from nowhere. **Serializability** of a schedule means equivalence (in the resulting database values) to some *serial* schedule with the same transactions (i.e., in which transactions are sequential with no overlap in time, and thus completely isolated from each other: No concurrent access by any two transactions to the same data is possible). Serializability is considered the highest level of isolation among database transactions, and the major correctness criterion for concurrent transactions. In some cases compromised, relaxed forms of serializability are allowed for better performance (e.g., the popular *Snapshot isolation* mechanism) or to meet availability requirements in highly distributed systems (see *Eventual consistency*), but only if application's correctness is not violated by the relaxation (e.g., no relaxation is allowed for money transactions, since by relaxation money can disappear, or appear from nowhere).

Almost all implemented concurrency control mechanisms achieve serializability by providing *Conflict serializablity*, a broad special case of serializability (i.e., it covers, enables most serializable schedules, and does not impose significant additional delay-causing constraints) which can be implemented efficiently.

Recoverability

See *Recoverability* in *Serializability*

Comment: While in the general area of systems the term "recoverability" may refer to the ability of a system to recover from failure or from an incorrect/forbidden state, within concurrency control of database systems this term has received a specific meaning.

Concurrency control typically also ensures the *Recoverability* property of schedules for maintaining correctness in cases of aborted transactions (which can always happen for many reasons). **Recoverability** (from abort) means that no committed transaction in a schedule has read data written by an aborted transaction. Such data disappear from the database (upon the abort) and are parts of an incorrect database state. Reading such data violates the consistency rule of ACID. Unlike Serializability, Recoverability cannot be compromised, relaxed at any case, since any relaxation results in quick database integrity violation upon aborts. The major methods listed above provide serializability mechanisms. None of them in its general form automatically provides recoverability, and special considerations and mechanism enhancements are needed to support recoverability. A commonly utilized special case of recoverability is *Strictness*, which allows efficient database recovery from failure (but excludes optimistic implementations; e.g., Strict CO (SCO) cannot have an optimistic implementation, but has semi-optimistic ones).

Comment: Note that the *Recoverability* property is needed even if no database failure occurs and no database *recovery* from failure is needed. It is rather needed to correctly automatically handle transaction aborts, which may be unrelated to database failure and recovery from it.

Distribution

With the fast technological development of computing the difference between local and distributed computing over low latency networks or buses is blurring. Thus the quite effective utilization of local techniques in such distributed environments is common, e.g., in computer clusters and multi-core processors. However the local techniques have their limitations and use multi-processes (or threads) supported by multi-processors (or multi-cores) to scale. This often turns transactions into distributed ones, if they themselves need to span multi-processes. In these cases most local concurrency control techniques do not scale well.

Distributed serializability and Commitment ordering

See *Distributed serializability* in *Serializability*

As database systems have become distributed, or started to cooperate in distributed environments (e.g., Federated databases in the early 1990s, and nowadays Grid computing, Cloud computing, and networks with smartphones), some transactions have become distributed. A distributed transaction means that the transaction spans processes, and may span computers and geographical sites. This generates a need in effective distributed concurrency control mechanisms. Achieving the Serializability property of a distributed system's schedule (see *Distributed serializability* and *Global serializability* (*Modular serializability*)) effectively poses special challenges typically not met by most of the regular serializability mechanisms, originally designed to operate locally. This is especially due to a need in costly distribution of concurrency control information amid communication and computer latency. The only known general effective technique for distribution is Commitment ordering, which was disclosed publicly in 1991 (after being patented). **Commitment ordering** (Commit ordering, CO; Raz 1992) means that transactions' chronological order of commit events is kept compatible with their respective precedence order. CO does not require the distribution of concurrency control information and provides a general effective solution (reliable, high-performance, and scalable) for both distributed and global serializability, also in a heterogeneous environment with database systems (or other transactional objects) with different (any) concurrency control mechanisms. CO is indifferent to which mechanism is utilized, since it does not interfere with any transaction operation scheduling (which most mechanisms control), and only determines the order of commit events. Thus, CO enables the efficient distribution of all other mechanisms, and also the distribution of a mix of different (any) local mechanisms, for achieving distributed and global serializability. The existence of such a solution has been considered "unlikely" until 1991, and by many experts also later, due to misunderstanding of the CO solution (see Quotations in *Global serializability*). An important side-benefit of CO is automatic distributed deadlock resolution. Contrary to CO, virtually all other techniques (when not combined with CO) are prone to distributed deadlocks (also called global deadlocks) which need special handling. CO is also the name of the resulting schedule property: A schedule has the CO property if the chronological order of its transactions' commit events is compatible with the respective transactions' precedence (partial) order.

SS2PL mentioned above is a variant (special case) of CO and thus also effective to achieve distributed and global serializability. It also provides automatic distributed deadlock resolution (a fact overlooked in the research literature even after CO's publication), as well as Strictness and thus Recoverability. Possessing these desired properties together with known efficient locking based implementations explains SS2PL's popularity. SS2PL has been utilized to efficiently achieve Distributed and Global serializability since the 1980, and has become the de facto standard for it. However, SS2PL is blocking and constraining (pessimistic), and with the proliferation of distribution and utilization of systems different from traditional database systems (e.g., as in Cloud computing), less constraining types of CO (e.g., Optimistic CO) may be needed for better performance.

Comments:

1. The *Distributed conflict serializability* property in its general form is difficult to achieve efficiently, but it is achieved efficiently via its special case *Distributed CO*: Each local component (e.g., a local DBMS) needs both to provide some form of CO, and enforce a special *vote ordering strategy* for the *Two-phase commit protocol* (2PC:

utilized to commit distributed transactions). Differently from the general Distributed CO, *Distributed SS2PL* exists automatically when all local components are SS2PL based (in each component CO exists, implied, and the vote ordering strategy is now met automatically). This fact has been known and utilized since the 1980s (i.e., that SS2PL exists globally, without knowing about CO) for efficient Distributed SS2PL, which implies Distributed serializability and strictness (e.g., see Raz 1992, page 293; it is also implied in Bernstein et al. 1987, page 78). Less constrained Distributed serializability and strictness can be efficiently achieved by Distributed Strict CO (SCO), or by a mix of SS2PL based and SCO based local components.

2. About the references and Commitment ordering: (Bernstein et al. 1987) was published before the discovery of CO in 1990. The CO schedule property is called *Dynamic atomicity* in (Lynch et al. 1993, page 201). CO is described in (Weikum and Vossen 2001, pages 102, 700), but the description is partial and misses CO's essence. (Raz 1992) was the first refereed and accepted for publication article about CO algorithms (however, publications about an equivalent Dynamic atomicity property can be traced to 1988). Other CO articles followed. (Bernstein and Newcomer 2009) note CO as one of the four major concurrency control methods, and CO's ability to provide interoperability among other methods.

Distributed recoverability

Unlike Serializability, *Distributed recoverability* and *Distributed strictness* can be achieved efficiently in a straightforward way, similarly to the way Distributed CO is achieved: In each database system they have to be applied locally, and employ a vote ordering strategy for the Two-phase commit protocol (2PC; Raz 1992, page 307).

As has been mentioned above, Distributed SS2PL, including Distributed strictness (recoverability) and Distributed commitment ordering (serializability), automatically employs the needed vote ordering strategy, and is achieved (globally) when employed locally in each (local) database system (as has been known and utilized for many years; as a matter of fact locality is defined by the boundary of a 2PC participant (Raz 1992)).

Other major subjects of attention

The design of concurrency control mechanisms is often influenced by the following subjects:

Recovery

All systems are prone to failures, and handling *recovery* from failure is a must. The properties of the generated schedules, which are dictated by the concurrency control mechanism, may have an impact on the effectiveness and efficiency of recovery. For example, the Strictness property (mentioned in the section Recoverability above) is often desirable for an efficient recovery.

Replication

For high availability database objects are often *replicated*. Updates of replicas of a same database object need to be kept synchronized. This may affect the way concurrency control is done (e.g., Gray et al. 1996).

Concurrency control in operating systems

Multitasking operating systems, especially real-time operating systems, need to maintain the illusion that all tasks running on top of them are all running at the same time, even though only one or a few tasks really are running at any given moment due to the limitations of the hardware the operating system is running on. Such multitasking is fairly simple when all tasks are independent from each other. However, when several tasks try to use the same resource, or when tasks try to share information, it can lead to confusion and inconsistency. The task of concurrent computing is to solve that problem. Some solutions involve "locks" similar to the locks used in databases, but they risk causing problems of their own such as deadlock. Other solutions are Non-blocking algorithms and Read-copy-update.

Transaction Control Language

A **Transaction Control Language** (**TCL**) is a computer language and a subset of SQL, used to control transactional processing in a database. A transaction is logical unit of work that comprises one or more SQL statements, usually a group of Data Manipulation Language (DML) statements.

Examples of TCL commands include:

- **COMMIT** to apply the transaction by saving the database changes.
- **ROLLBACK** to undo all changes of a transaction.
- **SAVEPOINT** to divide the transaction into smaller sections. It defines breakpoints for a transaction to allow partial rollbacks.

ACID

In computer science, **ACID** (*Atomicity, Consistency, Isolation, Durability*) is a set of properties that guarantee that database transactions are processed reliably. In the context of databases, a single logical operation on the data is called a transaction. For example, a transfer of funds from one bank account to another, even involving multiple changes such as debiting one account and crediting another, is a single transaction.

Jim Gray defined these properties of a reliable transaction system in the late 1970s and developed technologies to achieve them automatically.[1]

In 1983, Andreas Reuter and Theo Härder coined the acronym *ACID* to describe them.[2]

Characteristics

Atomicity

Atomicity requires that each transaction is "all or nothing": if one part of the transaction fails, the entire transaction fails, and the database state is left unchanged. An atomic system must guarantee atomicity in each and every situation, including power failures, errors, and crashes. To the outside world, a committed transaction appears (by its effects on the database) to be indivisible ("atomic"), and an aborted transaction does not happen.

Consistency

The consistency property ensures that any transaction will bring the database from one valid state to another. Any data written to the database must be valid according to all defined rules, including but not limited to constraints, cascades, triggers, and any combination thereof. This does not guarantee correctness of the transaction in all ways the application programmer might have wanted (that is the responsibility of application-level code) but merely that any programming errors do not violate any defined rules.

Isolation

The isolation property ensures that the concurrent execution of transactions results in a system state that would be obtained if transactions were executed serially, i.e. one after the other. Providing isolation is the main goal of concurrency control. Depending on concurrency control method, the effects of an incomplete transaction might not even be visible to another transaction.[*citation needed*]

Durability

Durability means that once a transaction has been committed, it will remain so, even in the event of power loss, crashes, or errors. In a relational database, for instance, once a group of SQL statements execute, the results need to be stored permanently (even if the database crashes immediately thereafter). To defend against power loss, transactions (or their effects) must be recorded in a non-volatile memory.

Examples

The following examples further illustrate the ACID properties. In these examples, the database table has two columns, A and B. An integrity constraint requires that the value in A and the value in B must sum to 100. The following SQL code creates a table as described above:

```
CREATE TABLE acidtest (A INTEGER, B INTEGER CHECK (A + B = 100));
```

Atomicity failure

Assume that a transaction attempts to subtract 10 from A and add 10 to B. This is a valid transaction, since the data continue to satisfy the constraint after it has executed. However, assume that after removing 10 from A, the transaction is unable to modify B. If the database retained A's new value, atomicity requires that both parts of this transaction, or neither, be complete.

Consistency failure

Consistency is a very general term which demands that the data must meet all validation rules. In the previous example, the validation is a requirement that A + B = 100. Also, it may be inferred that both A and B must be integers. A valid range for A and B may also be inferred. All validation rules must be checked to ensure consistency.

Assume that a transaction attempts to subtract 10 from A without altering B. Because consistency is checked after each transaction, it is known that A + B = 100 before the transaction begins. If the transaction removes 10 from A successfully, atomicity will be achieved. However, a validation check will show that A + B = 90, which is inconsistent with the rules of the database. The entire transaction must be cancelled and the affected rows rolled back to their pre-transaction state. If there had been other constraints, triggers, or cascades, every single change operation would have been checked in the same way as above before the transaction was committed.

Isolation failure

To demonstrate isolation, we assume two transactions execute at the same time, each attempting to modify the same data. One of the two must wait until the other completes in order to maintain isolation.

Consider two transactions. T_1 transfers 10 from A to B. T_2 transfers 10 from B to A. Combined, there are four actions:

- T_1 subtracts 10 from A.
- T_1 adds 10 to B.
- T_2 subtracts 10 from B.
- T_2 adds 10 to A.

If these operations are performed in order, isolation is maintained, although T_2 must wait. Consider what happens if T_1 fails half-way through. The database eliminates T_1's effects, and T_2 sees only valid data.

By interleaving the transactions, the actual order of actions might be:

- T_1 subtracts 10 from A.
- T_2 subtracts 10 from B.
- T_2 adds 10 to A.
- T_1 adds 10 to B.

Again, consider what happens if T_1 fails halfway through. By the time T_1 fails, T_2 has already modified A; it cannot be restored to the value it had before T_1 without leaving an invalid database. This is known as a write-write failure,[*citation needed*] because two transactions attempted to write to the same data field. In a typical system, the problem would be resolved by reverting to the last known good state, canceling the failed transaction T_1, and restarting the interrupted transaction T_2 from the good state.

Durability failure

Assume that a transaction transfers 10 from A to B. It removes 10 from A. It then adds 10 to B. At this point, a "success" message is sent to the user. However, the changes are still queued in the disk buffer waiting to be committed to the disk. Power fails and the changes are lost. The user assumes (understandably) that the changes have been made.

Implementation

Processing a transaction often requires a sequence of operations that is subject to failure for a number of reasons. For instance, the system may have no room left on its disk drives, or it may have used up its allocated CPU time.

There are two popular families of techniques: write ahead logging and shadow paging. In both cases, locks must be acquired on all information that is updated, and depending on the level of isolation, possibly on all data that is read as well. In write ahead logging, atomicity is guaranteed by copying the original (unchanged) data to a log before changing the database.Wikipedia:Disputed statement That allows the database to return to a consistent state in the event of a crash.

In shadowing, updates are applied to a partial copy of the database, and the new copy is activated when the transaction commits.

Locking vs multiversioning

Many databases rely upon locking to provide ACID capabilities. Locking means that the transaction marks the data that it accesses so that the DBMS knows not to allow other transactions to modify it until the first transaction succeeds or fails. The lock must always be acquired before processing data, including data that are read but not modified. Non-trivial transactions typically require a large number of locks, resulting in substantial overhead as well as blocking other transactions. For example, if user A is running a transaction that has to read a row of data that user B wants to modify, user B must wait until user A's transaction completes. Two phase locking is often applied to guarantee full isolation.[*citation needed*]

An alternative to locking is multiversion concurrency control, in which the database provides each reading transaction the prior, unmodified version of data that is being modified by another active transaction. This allows readers to operate without acquiring locks, i.e. writing transactions do not block reading transactions, and readers do not block writers. Going back to the example, when user A's transaction requests data that user B is modifying, the database provides A with the version of that data that existed when user B started his transaction. User A gets a consistent view of the database even if other users are changing data. One implementation, namely snapshot isolation, relaxes the isolation property.

Distributed transactions

Guaranteeing ACID properties in a distributed transaction across a distributed database where no single node is responsible for all data affecting a transaction presents additional complications. Network connections might fail, or one node might successfully complete its part of the transaction and then be required to roll back its changes, because of a failure on another node. The two-phase commit protocol (not to be confused with two-phase locking) provides atomicity for distributed transactions to ensure that each participant in the transaction agrees on whether the transaction should be committed or not.[*citation needed*] Briefly, in the first phase, one node (the coordinator) interrogates the other nodes (the participants) and only when all reply that they are prepared does the coordinator, in the second phase, formalize the transaction.

[2] These four properties, atomicity, consistency, isolation, and durability (ACID), describe the major highlights of the transaction paradigm, which has influenced many aspects of development in database systems.

Atomicity (database systems)

In database systems, **atomicity** (or **atomicness**; from Greek *a-tomos*, *undividable*) is one of the ACID transaction properties. In an **atomic transaction**, a series of database operations either *all* occur, or *nothing* occurs. A guarantee of atomicity prevents updates to the database occurring only partially, which can cause greater problems than rejecting the whole series outright. In other words, atomicity means *indivisibility* and *irreducibility*.

The etymology of the phrase originates in the Classical Greek concept of a fundamental and indivisible component; see atom.

An example of atomicity is ordering an airline ticket where two actions are required: payment, and a seat reservation. The potential passenger must either:

1. both pay for and reserve a seat; OR
2. neither pay for nor reserve a seat.

The booking system does not consider it acceptable for a customer to pay for a ticket without securing the seat, nor to reserve the seat without payment succeeding.

Another example: If one wants to transfer some amount of money from one account to another, then he/she would start a procedure to do it. However, if a failure occurs, then due to atomicity, the amount will either be transferred completely or will not even start. Thus atomicity protects the user from losing money due to a failed transaction.

Orthogonality

Atomicity does not behave completely orthogonally with regard to the other ACID properties of the transactions. For example, isolation relies on atomicity to roll back changes in the event of isolation failures such as deadlock; consistency also relies on rollback in the event of a consistency-violation by an illegal transaction. Finally, atomicity itself relies on durability to ensure the atomicity of transactions even in the face of external failures.

As a result of this, failure to detect errors and roll back the enclosing transaction may cause failures of isolation and consistency.

Implementation

Typically, systems implement atomicity by providing some mechanism to indicate which transactions have started and which finished; or by keeping a copy of the data before any changes occurred (read-copy-update). Several filesystems have developed methods for avoiding the need to keep multiple copies of data, using journaling (see journaling file system). Databases usually implement this using some form of logging/journaling to track changes. The system synchronizes the logs (often the metadata) as necessary once the actual changes have successfully taken place. Afterwards, crash recovery simply ignores incomplete entries. Although implementations vary depending on factors such as concurrency issues, the principle of atomicity — i.e. complete success or complete failure — remain.

Ultimately, any application-level implementation relies on operating-system functionality. At the file-system level, POSIX-compliant systems provide system calls such as `open(2)` and `flock(2)` that allow applications to atomically open or lock a file. At the process level, POSIX Threads provide adequate synchronization primitives.

The hardware level requires atomic operations such as Test-and-set, Fetch-and-add, Compare-and-swap, or Load-Link/Store-Conditional, together with memory barriers. Portable operating systems cannot simply block interrupts to implement synchronization, since hardware that lacks actual concurrent execution such as hyper-threading or multi-processing is now extremely rare.

In NoSQL data stores with eventual consistency, the atomicity is also weaker specified than in relational database systems, and exists only in *row*s (i.e. column families).

References

Isolation (database systems)

In database systems, **isolation** is a property that defines how/when the changes made by one operation become visible to other concurrent operations. Isolation is one of the ACID (Atomicity, Consistency, Isolation, Durability) properties.

Concurrency control

Concurrency control comprises the underlying mechanisms in a DBMS which handles isolation and guarantees related correctness. It is heavily utilized by the database and storage engines (see above) both to guarantee the correct execution of concurrent transactions, and (different mechanisms) the correctness of other DBMS processes. The transaction-related mechanisms typically constrain the database data access operations' timing (transaction schedules) to certain orders characterized as the serializability and recoverability schedule properties. Constraining database access operation execution typically means reduced performance (rates of execution), and thus concurrency control mechanisms are typically designed to provide the best performance possible under the constraints. Often, when possible without harming correctness, the serializability property is compromised for better performance. However, recoverability cannot be compromised, since such typically results in a quick database integrity violation.

Two-phase locking is the most common transaction concurrency control method in DBMSs, used to provide both serializability and recoverability for correctness. In order to access a database object a transaction first needs to acquire a lock for this object. Depending on the access operation type (e.g., reading or writing an object) and on the lock type, acquiring the lock may be blocked and postponed, if another transaction is holding a lock for that object.

Isolation levels

Of the four ACID properties in a DBMS (Database Management System), the isolation property is the one most often relaxed. When attempting to maintain the highest level of isolation, a DBMS usually acquires locks on data or implements multiversion concurrency control, which may result in a loss of concurrency. This requires adding logic for the application to function correctly.

Most DBMSs offer a number of *transaction isolation levels*, which control the degree of locking that occurs when selecting data. For many database applications, the majority of database transactions can be constructed to avoid requiring high isolation levels (e.g. SERIALIZABLE level), thus reducing the locking overhead for the system. The programmer must carefully analyze database access code to ensure that any relaxation of isolation does not cause software bugs that are difficult to find. Conversely, if higher isolation levels are used, the possibility of deadlock is increased, which also requires careful analysis and programming techniques to avoid.

The isolation levels defined by the ANSI/ISO SQL standard are listed as follows.

Serializable

This is the *highest* isolation level.

With a lock-based concurrency control DBMS implementation, serializability requires read and write locks (acquired on selected data) to be released at the end of the transaction. Also *range-locks* must be acquired when a SELECT query uses a ranged *WHERE* clause, especially to avoid the *phantom reads* phenomenon (see below).

When using non-lock based concurrency control, no locks are acquired; however, if the system detects a *write collision* among several concurrent transactions, only one of them is allowed to commit. See *snapshot isolation* for more details on this topic.

Repeatable reads

In this isolation level, a lock-based concurrency control DBMS implementation keeps read and write locks (acquired on selected data) until the end of the transaction. However, *range-locks* are not managed, so the *phantom reads* phenomenon can occur (see below).

Read committed

In this isolation level, a lock-based concurrency control DBMS implementation keeps write locks (acquired on selected data) until the end of the transaction, but read locks are released as soon as the SELECT operation is performed (so the *non-repeatable reads* phenomenon can occur in this isolation level, as discussed below). As in the previous level, *range-locks* are not managed.

Putting it in simpler words, read committed is an isolation level that guarantees that any data read is committed at the moment it is read. It simply restricts the reader from seeing any intermediate, uncommitted, 'dirty' read. It makes no promise whatsoever that if the transaction re-issues the read, it will find the same data; data is free to change after it is read.

Read uncommitted

This is the *lowest* isolation level. In this level, ***dirty reads*** are allowed (see below), so one transaction may see *not-yet-committed* changes made by other transactions.

Since each isolation level is stronger than those below, in that no higher isolation level allows an action forbidden by a lower one, the standard permits a DBMS to run a transaction at an isolation level stronger than that requested (e.g., a "Read committed" transaction may actually be performed at a "Repeatable read" isolation level).

Default isolation level

The *default isolation level* of different DBMS's varies quite widely. Most databases that feature transactions allow the user to set any isolation level. Some DBMS's also require additional syntax when performing a SELECT statement to acquire locks (e.g. *SELECT ... FOR UPDATE* to acquire exclusive write locks on accessed rows).

However, the definitions above have been criticised as being ambiguous, and as not accurately reflecting the isolation provided by many databases:

> This paper shows a number of weaknesses in the anomaly approach to defining isolation levels. The three ANSI phenomena are ambiguous. Even their broadest interpretations do not exclude anomalous behavior. This leads to some counter-intuitive results. In particular, lock-based isolation levels have different characteristics than their ANSI equivalents. This is disconcerting because commercial database systems typically use locking. Additionally, the ANSI phenomena do not distinguish among several isolation levels popular in commercial systems.

There are also other criticisms concerning ANSI SQL's isolation definition, in that it encourages implementors to do "bad things":

> ... it relies in subtle ways on an assumption that a locking schema is used for concurrency control, as opposed to an optimistic or multi-version concurrency scheme. This implies that the proposed semantics are *ill-defined*.

Read phenomena

The ANSI/ISO standard SQL 92 refers to three different *read phenomena* when Transaction 1 reads data that Transaction 2 might have changed.

In the following examples, two transactions take place. In the first, Query 1 is performed. Then, in the second transaction, Query 2 is performed and committed. Finally, in the first transaction, Query 1 is performed again.

The queries use the following data table:

users

id	name	age
1	Joe	20
2	Jill	25

Dirty reads (Uncommitted Dependency)

A dirty read occurs when a transaction is allowed to read data from a row that has been modified by another running transaction and not yet committed.

Dirty reads work similarly to non-repeatable reads; however, the second transaction would not need to be committed for the first query to return a different result. The only thing that may be prevented in the READ UNCOMMITTED isolation level is updates appearing out of order in the results; that is, earlier updates will always appear in a result set before later updates.

In our example, Transaction 2 changes a row, but does not commit the changes. Transaction 1 then reads the uncommitted data. Now if Transaction 2 rolls back its changes (already read by Transaction 1) or updates different changes to the database, then the view of the data may be wrong in the records of Transaction 1.

Transaction 1

```
<font size="9.40">
/* Query 1 */
SELECT age FROM users WHERE id = 1;
/* will read 20 */
</font>
```

Transaction 2

```
<font size="9.40">
/* Query 2 */
UPDATE users SET age = 21 WHERE id = 1;
/* No commit here */
</font>
```

```
<font size="9.40">
/* Query 1 */
SELECT age FROM users WHERE id = 1;
/* will read 21 */
</font>
```

```
<font size="9.40">
ROLLBACK; /* lock-based DIRTY READ */
</font>
```

But in this case no row exists that has an id of 1 and an age of 21.

Non-repeatable reads

A *non-repeatable read* occurs, when during the course of a transaction, a row is retrieved twice and the values within the row differ between reads.

Non-repeatable reads phenomenon may occur in a lock-based concurrency control method when read locks are not acquired when performing a SELECT, or when the acquired locks on affected rows are released as soon as the SELECT operation is performed. Under the multiversion concurrency control method, *non-repeatable reads* may occur when the requirement that a transaction affected by a commit conflict must roll back is relaxed.

Transaction 1	Transaction 2

`<font size="9.40">`
`/* Query 1 */`
`SELECT * FROM users WHERE id = 1;`
`</font>`	

	`<font size="9.40">`
	`/* Query 2 */`
	`UPDATE users SET age = 21 WHERE id = 1;`
	`COMMIT; /* in multiversion concurrency control, or lock-based READ COMMITTED */`
	`</font>`

`<font size="9.40">`
`/* Query 1 */`
`SELECT * FROM users WHERE id = 1;`
`COMMIT; /* lock-based REPEATABLE READ */`
`</font>`	

In this example, Transaction 2 commits successfully, which means that its changes to the row with id 1 should become visible. However, Transaction 1 has already seen a different value for *age* in that row. At the SERIALIZABLE and REPEATABLE READ isolation levels, the DBMS must return the old value for the second SELECT. At READ COMMITTED and READ UNCOMMITTED, the DBMS may return the updated value; this is a non-repeatable read.

There are two basic strategies used to prevent non-repeatable reads. The first is to delay the execution of Transaction 2 until Transaction 1 has committed or rolled back. This method is used when locking is used, and produces the serial schedule **T1, T2**. A serial schedule exhibits *repeatable reads* behaviour.

In the other strategy, as used in *multiversion concurrency control*, Transaction 2 is permitted to commit first, which provides for better concurrency. However, Transaction 1, which commenced prior to Transaction 2, must continue to operate on a past version of the database — a snapshot of the moment it was started. When Transaction 1 eventually tries to commit, the DBMS checks if the result of committing Transaction 1 would be equivalent to the schedule **T1, T2**. If it is, then Transaction 1 can proceed. If it cannot be seen to be equivalent, however, Transaction 1 must roll back with a serialization failure.

Using a lock-based concurrency control method, at the REPEATABLE READ isolation mode, the row with ID = 1 would be locked, thus blocking Query 2 until the first transaction was committed or rolled back. In READ COMMITTED mode, the second time Query 1 was executed, the age would have changed.

Under multiversion concurrency control, at the SERIALIZABLE isolation level, both SELECT queries see a snapshot of the database taken at the start of Transaction 1. Therefore, they return the same data. However, if Transaction 1 then attempted to UPDATE that row as well, a serialization failure would occur and Transaction 1 would be forced to roll back.

At the READ COMMITTED isolation level, each query sees a snapshot of the database taken at the start of each query. Therefore, they each see different data for the updated row. No serialization failure is possible in this mode (because no promise of serializability is made), and Transaction 1 will not have to be retried.

Phantom reads

A *phantom read* occurs when, in the course of a transaction, two identical queries are executed, and the collection of rows returned by the second query is different from the first.

This can occur when *range locks* are not acquired on performing a *SELECT ... WHERE* operation. The *phantom reads* anomaly is a special case of *Non-repeatable reads* when Transaction 1 repeats a ranged *SELECT ... WHERE* query and, between both operations, Transaction 2 creates (i.e. INSERT) new rows (in the target table) which fulfill that *WHERE* clause.

Transaction 1	Transaction 2

`<font size="9.50">`
`/* Query 1 */`
`SELECT * FROM users`
`WHERE age BETWEEN 10 AND 30;`
`</font>`	

	`<font size="9.50">`
	`/* Query 2 */`
	`INSERT INTO users VALUES ( 3, 'Bob', 27 );`
	`COMMIT;`
	`</font>`

`<font size="9.50">`
`/* Query 1 */`
`SELECT * FROM users`
`WHERE age BETWEEN 10 AND 30;`
`COMMIT;`
`</font>`	

Note that Transaction 1 executed the same query twice. If the highest level of isolation were maintained, the same set of rows should be returned both times, and indeed that is what is mandated to occur in a database operating at the SQL SERIALIZABLE isolation level. However, at the lesser isolation levels, a different set of rows may be returned the second time.

In the SERIALIZABLE isolation mode, Query 1 would result in all records with age in the range 10 to 30 being locked, thus Query 2 would block until the first transaction was committed. In REPEATABLE READ mode, the range would not be locked, allowing the record to be inserted and the second execution of Query 1 to include the new row in its results.

Isolation Levels, Read Phenomena and Locks

Isolation Levels vs Read Phenomena

Isolation level	Dirty reads	Non-repeatable reads	Phantoms
Read Uncommitted	may occur	may occur	may occur
Read Committed	-	may occur	may occur
Repeatable Read	-	-	may occur
Serializable	-	-	-

Anomaly Serializable is not the same as Serializable. That is, it is necessary, but not sufficient that a Serializable schedule should be free of all three phenomena types. See [1] below.

"may occur" means that the isolation level suffers that phenomenon, while "-" means that it does not suffer it.

Isolation Levels vs Lock Duration

[*citation needed*]

In lock-based concurrency control, isolation level determines the duration that locks are held.
"C" - Denotes that locks are held until the transaction commits.
"S" - Denotes that the locks are held only during the currently executing statement. Note that if locks are released after a statement, the underlying data could be changed by another transaction before the current transaction commits, thus creating a violation.

Isolation level	Write Operation	Read Operation	Range Operation (...where...)
Read Uncommitted	S	S	S
Read Committed	C	S	S
Repeatable Read	C	C	S
Serializable	C	C	C

Durability (database systems)

In database systems, **durability** is the ACID property which guarantees that transactions that have committed will survive permanently. For example, if a flight booking reports that a seat has successfully been booked, then the seat will remain booked even if the system crashes.

Durability can be achieved by flushing the transaction's log records to non-volatile storage before acknowledging commitment.

In distributed transactions, all participating servers must coordinate before commit can be acknowledged. This is usually done by a two-phase commit protocol.

Many DBMSs implement durability by writing transactions into a transaction log that can be reprocessed to recreate the system state right before any later failure. A transaction is deemed committed only after it is entered in the log.

Atomic commit

An **atomic commit** is an operation in which a set of distinct changes is applied as a single operation. If the changes are applied then the atomic commit is said to have succeeded. If there is a failure before the atomic commit can be completed then all of the changes completed in the atomic commit are reversed. This ensures that the system is always left in a consistent state. The other key property of isolation comes from their nature as atomic operations. Isolation ensures that only one atomic commit is processed at a time. The most common uses of atomic commits are in database systems and revision control systems.

The problem with atomic commits is that they require coordination between multiple systems. As computer networks are unreliable services this means no algorithm can coordinate with all systems as proven in the Two Generals Problem. As databases become more and more distributed this coordination will increase the difficulty of making truly atomic commits.

Necessity for Atomic Commits

Atomic commits are essential for multi-step updates to data. This can be clearly shown in a simple example of a money transfer between two checking accounts.

This example is complicated by a transaction to check the balance of account Y during a transaction for transferring 100 dollars from account X to Y. To start, first 100 dollars is removed from account X. Second, 100 dollars is added to account Y. If the entire operation is not completed as one atomic commit, then several problems could occur. If the system fails in the middle of the operation, after removing the money from X and before adding into Y, then 100 dollars has just disappeared. Another issue is if the balance of Y is checked before the 100 dollars is added. The wrong balance for Y will be reported.

With atomic commits neither of these cases can happen, in the first case of the system failure, the atomic commit would be rolled back and the money returned to X. In the second case, the request of the balance of Y cannot occur until the atomic commit is fully completed.

Database System

Atomic commits in database systems fulfil two of the key properties of ACID, atomicity and consistency. Consistency is only achieved if each change in the atomic commit is consistent.

As shown in the example atomic commits are critical to multistep operations in databases. Due to modern hardware design the physical disk on which the database resides true atomic commits cannot exist. The smallest area that can be written to on disk is known as a sector. A single database entry may span several different sectors. Only one sector can be written at a time. This writing limit is why true atomic commits are not possible. After the database entries in memory have been modified they are queued up to be written to disk. This means the same problems identified in the example have reoccurred. Any algorithmic solution to this problem will still encounter the Two Generals' Problem. The two-phase commit protocol and three-phase commit protocol attempt to solve this and some of the other problems associated with atomic commits.

The two-phase commit protocol requires a coordinator to maintain all the information needed to recover the original state of the database if something goes wrong. As the name indicates there are two phases, voting and commit.

During the voting phase each node writes the changes in the atomic commit to its own disk. The nodes then report their status to the coordinator. If any node does not report to the coordinator or their status message is lost the coordinator assumes the node's write failed. Once all of the nodes have reported to the coordinator the second phase begins.

During the commit phase the coordinator sends a commit message to each of the nodes to record in their individual logs. Until this message is added to a node's log, any changes made will be recorded as incomplete. If any of the nodes reported a failure the coordinator will instead send a rollback message. This will remove any changes the nodes have written to disk.

The three-phase commit protocol seeks to remove the main problem with the two phase commit protocol which occurs if a coordinator and another node fail at the same time during the commit phase neither can tell what action should occur. To solve this problem a third phase is added to the protocol. The prepare to commit phase occurs after the voting phase and before the commit phase.

In the voting phase, similar to the two-phase commit, the coordinator requests that each node is ready to commit. If any node fails the coordinator will timeout while waiting for the failed node. If this happens the coordinator sends an abort message to every node. The same action will be undertaken if any of the nodes return a failure message.

Upon receiving success messages from each node in the voting phase the prepare to commit phase begins. During this phase the coordinator sends a prepare message to each node. Each node must acknowledge the prepare message and reply. If any reply is missed or any node return that they are not prepared then the coordinator sends an abort message. Any node that does not receive a prepare message before the timeout expires aborts the commit.

After all nodes have replied to the prepare message then the commit phase begins. In this phase the coordinator sends a commit message to each node. When each node receives this message it performs the actual commit. If the commit message does not reach a node due to the message being lost or the coordinator fails they will perform the commit if the timeout expires. If the coordinator fails upon recovery it will send a commit message to each node.

Revision Control

The other area where atomic commits are employed is revision control systems. This allows multiple modified files to be uploaded and merged into the source. Most revision control systems support atomic commits (CVS and VSS are the major exceptions).

Like database systems commits may fail due to a problem in applying the changes on disk. Unlike a database system which overwrites any existing data with the data from the changeset, revision control systems merge the modification in the changeset into the existing data. If the system cannot complete the merge then the commit will be rejected. If a merge cannot be resolved by the revision control software it is up to the user to merge the changes. For revision control systems that support atomic commits, this failure in merging would result in a failed commit.

Atomic commits are crucial for maintaining a consistent state in the repository. Without atomic commits some changes a developer has made may be applied but other changes may not. If these changes have any kind of coupling this will result in errors. Atomic commits prevent this by not applying partial changes which would create these errors. Note that if the changes already contain errors, atomic commits offer no fix.

Atomic Commit Convention

When using a revision control systems a common convention is to use small commits. These are sometimes referred to as atomic commits as they (ideally) only affect a single aspect of the system. These atomic commits allow for greater understandability, less effort to roll back changes, easier bug identification.

The greater understandability comes from the small size and focused nature of the commit. It is much easier to understand what is changed and reasoning behind the changes if you are only looking for one kind of change. This becomes especially important when making format changes to the source code. If format and functional changes are combined it becomes very difficult to identify useful changes. Imagine if the spacing in a file is changed from using tabs to three spaces every tab in the file will show as having been changed. This becomes critical if some functional changes are also made as a reviewer may simply not see the functional changes.

If only atomic commits are made then commits that introduce errors become much simpler to identify. You are not required to look though every commit to see if it was the cause of the error, only the commits dealing with that functionality need to be examined. If the error is to be rolled back, atomic commits again make the job much simpler. Instead of having to revert to the offending revision and remove the changes manually before integrating any later changes; the developer can simply revert any changes in the identified commit. This also reduces the risk of a developer accidentally removing unrelated changes that happened to be in the same commit.

Atomic commits also allow bug fixes to be easily reviewed if only a single bug fixes committed at a time. Instead of having to check multiple potentially unrelated files the reviewer must only check files and changes that directly impact the bug being fixed. This also means that bug fixes can be easily packaged for testing as only the changes that fix the bug are in the commit.

Schedule (computer science)

In the fields of databases and transaction processing (transaction management), a **schedule** (or **history**) of a system is an abstract model to describe execution of transactions running in the system. Often it is a *list* of operations (actions) ordered by time, performed by a set of transactions that are executed together in the system. If order in time between certain operations is not determined by the system, then a *partial order* is used. Examples of such operations are requesting a read operation, reading, writing, aborting, committing, requesting lock, locking, etc. Not all transaction operation types should be included in a schedule, and typically only selected operation types (e.g., data access operations) are included, as needed to reason about and describe certain phenomena. Schedules and schedule properties are fundamental concepts in database concurrency control theory.

Formal description

The following is an example of a schedule:

$$D = \begin{bmatrix} T1 & T2 & T3 \\ R(X) & & \\ W(X) & & \\ Com. & & \\ & R(Y) & \\ & W(Y) & \\ & Com. & \\ & & R(Z) \\ & & W(Z) \\ & & Com. \end{bmatrix}$$

In this example, the horizontal axis represents the different transactions in the schedule D. The vertical axis represents time order of operations. Schedule D consists of three transactions T1, T2, T3. The schedule describes the actions of the transactions as seen by the DBMS. First T1 Reads and Writes to object X, and then Commits. Then T2 Reads and Writes to object Y and Commits, and finally T3 Reads and Writes to object Z and Commits. This is an example of a *serial* schedule, i.e., sequential with no overlap in time, because the actions of in all three transactions are sequential, and the transactions are not interleaved in time.

Representing the schedule D above by a table (rather than a list) is just for the convenience of identifying each transaction's operations in a glance. This notation is used throughout the article below. A more common way in the technical literature for representing such schedule is by a list:

D = R1(X) W1(X) Com1 R2(Y) W2(Y) Com2 R3(Z) W3(Z) Com3

Usually, for the purpose of reasoning about concurrency control in databases, an operation is modeled as *atomic*, occurring at a point in time, without duration. When this is not satisfactory start and end time-points and possibly other point events are specified (rarely). Real executed operations always have some duration and specified respective times of occurrence of events within them (e.g., "exact" times of beginning and completion), but for concurrency control reasoning usually only the precedence in time of the whole operations (without looking into the quite complex details of each operation) matters, i.e., which operation is before, or after another operation. Furthermore, in many cases the before/after relationships between two specific operations do not matter and should not be specified, while being specified for other pairs of operations.

In general operations of transactions in a schedule can interleave (i.e., transactions can be executed concurrently), while time orders between operations in each transaction remain unchanged as implied by the transaction's program. Since not always time orders between all operations of all transactions matter and need to be specified, a schedule is, in general, a *partial order* between operations rather than a *total order* (where order for each pair is determined, as in

a list of operations). Also in the general case each transaction may consist of several processes, and itself be properly represented by a partial order of operations, rather than a total order. Thus in general a schedule is a partial order of operations, containing (embedding) the partial orders of all its transactions.

Time-order between two operations can be represented by an *ordered pair* of these operations (e.g., the existence of a pair (OP1,OP2) means that OP1 is always before OP2), and a schedule in the general case is a set of such ordered pairs. Such a set, a schedule, is a partial order which can be represented by an *acyclic directed graph* (or *directed acyclic graph*, DAG) with operations as nodes and time-order as a directed edge (no cycles are allowed since a cycle means that a first (any) operation on a cycle can be both before and after (any) another second operation on the cycle, which contradicts our perception of Time). In many cases a graphical representation of such graph is used to demonstrate a schedule.

Comment: Since a list of operations (and the table notation used in this article) always represents a total order between operations, schedules that are not a total order cannot be represented by a list (but always can be represented by a DAG).

Types of schedule

Serial

The transactions are executed non-interleaved (see example above) i.e., a serial schedule is one in which no transaction starts until a running transaction has ended.

Serializable

A schedule that is equivalent (in its outcome) to a serial schedule has the serializability property.

In schedule E, the order in which the actions of the transactions are executed is not the same as in D, but in the end, E gives the same result as D.

$$E = \begin{bmatrix} T1 & T2 & T3 \\ R(X) & & \\ & R(Y) & \\ & & R(Z) \\ W(X) & & \\ & W(Y) & \\ & & W(Z) \\ Com. & Com. & Com. \end{bmatrix}$$

Conflicting actions

Two actions are said to be in conflict (conflicting pair) if:

1. The actions belong to different transactions.
2. At least one of the actions is a write operation.
3. The actions access the same object (read or write).

The following set of actions is conflicting:

- R1(X), W2(X), W3(X) (3 conflicting pairs)

While the following sets of actions are not:

- R1(X), R2(X), R3(X)
- R1(X), W2(Y), R3(X)

Conflict equivalence

The schedules S1 and S2 are said to be conflict-equivalent if following two conditions are satisfied:

1. Both schedules S1 and S2 involve the same set of transactions (including ordering of actions within each transaction).
2. The set of conflicting pairs in S1 is the same as in S2.

Conflict-serializable

A schedule is said to be conflict-serializable when the schedule is conflict-equivalent to one or more serial schedules.

Another definition for conflict-serializability is that a schedule is conflict-serializable if and only if its precedence graph/serializability graph, when only committed transactions are considered, is acyclic (if the graph is defined to include also uncommitted transactions, then cycles involving uncommitted transactions may occur without conflict serializability violation).

$$G = \begin{bmatrix} T1 & T2 \\ R(A) & \\ & R(A) \\ W(B) & \\ Com. & \\ & W(A) \\ & Com. \end{bmatrix}$$

Which is conflict-equivalent to the serial schedule <T1,T2>, but not <T2,T1>.

Commitment-ordered

A schedule is said to be commitment-ordered (commit-ordered), or commitment-order-serializable, if it obeys the Commitment ordering (CO; also commit-ordering or commit-order-serializability) schedule property. This means that the order in time of transactions' commitment events is compatible with the precedence (partial) order of the respective transactions, as induced by their schedule's acyclic precedence graph (serializability graph, conflict graph). This implies that it is also conflict-serializable. The CO property is especially effective for achieving Global serializability in distributed systems.

Comment: Commitment ordering, which was discovered in 1990, is obviously not mentioned in (Bernstein et al. 1987). Its correct definition appears in (Weikum and Vossen 2001), however the description there of its related techniques and theory is partial, inaccurate, and misleading.Wikipedia:Avoid weasel words For an extensive coverage of commitment ordering and its sources see *Commitment ordering* and *The History of Commitment Ordering*.

View equivalence

Two schedules S1 and S2 are said to be view-equivalent when the following conditions are satisfied:

1. If the transaction T_i in S1 reads an initial value for object X, so does the transaction T_i in S2.
2. If the transaction T_i in S1 reads the value written by transaction T_j in S1 for object X, so does the transaction T_i in S2.
3. If the transaction T_i in S1 is the final transaction to write the value for an object X, so is the transaction T_i in S2.

View-serializable

A schedule is said to be view-serializable if it is view-equivalent to some serial schedule. Note that by definition, all conflict-serializable schedules are view-serializable.

$$G = \begin{bmatrix} T1 & T2 \\ R(A) & \\ & R(A) \\ W(B) & \end{bmatrix}$$

Notice that the above example (which is the same as the example in the discussion of conflict-serializable) is both view-serializable and conflict-serializable at the same time.) There are however view-serializable schedules that are not conflict-serializable: those schedules with a transaction performing a blind write:

$$H = \begin{bmatrix} T1 & T2 & T3 \\ R(A) & & \\ & W(A) & \\ & Com. & \\ W(A) & & \\ Com. & & \\ & & W(A) \\ & & Com. \\ & & \end{bmatrix}$$

The above example is not conflict-serializable, but it is view-serializable since it has a view-equivalent serial schedule <T1, T2, T3>.

Since determining whether a schedule is view-serializable is NP-complete, view-serializability has little practical interest.

Recoverable

Transactions commit only after all transactions whose changes they read, commit.

$$F = \begin{bmatrix} T1 & T2 \\ R(A) & \\ W(A) & \\ & R(A) \\ & W(A) \\ Com. & \\ & Com. \\ & \end{bmatrix} \quad F2 = \begin{bmatrix} T1 & T2 \\ R(A) & \\ W(A) & \\ & R(A) \\ & W(A) \\ Abort & \\ & Abort \\ & \end{bmatrix}$$

These schedules are recoverable. F is recoverable because T1 commits before T2, that makes the value read by T2 correct. Then T2 can commit itself. In F2, if T1 aborted, T2 has to abort because the value of A it read is incorrect. In both cases, the database is left in a consistent state.

Unrecoverable

If a transaction T1 aborts, and a transaction T2 commits, but T2 relied on T1, we have an unrecoverable schedule.

$$G = \begin{bmatrix} T1 & T2 \\ R(A) & \\ W(A) & \\ & R(A) \\ & W(A) \\ & Com. \\ Abort & \\ & \end{bmatrix}$$

In this example, G is unrecoverable, because T2 read the value of A written by T1, and committed. T1 later aborted, therefore the value read by T2 is wrong, but since T2 committed, this schedule is unrecoverable.

Avoids cascading aborts (rollbacks)

Also named cascadeless. A single transaction abort leads to a series of transaction rollback. Strategy to prevent cascading aborts is to disallow a transaction from reading uncommitted changes from another transaction in the same schedule.

The following examples are the same as the one from the discussion on recoverable:

$$F = \begin{bmatrix} T1 & T2 \\ R(A) & \\ W(A) & \\ & R(A) \\ & W(A) \\ Com. & \\ & Com. \\ & \end{bmatrix} \quad F2 = \begin{bmatrix} T1 & T2 \\ R(A) & \\ W(A) & \\ & R(A) \\ & W(A) \\ Abort & \\ & Abort \\ & \end{bmatrix}$$

In this example, although F2 is recoverable, it does not avoid cascading aborts. It can be seen that if T1 aborts, T2 will have to be aborted too in order to maintain the correctness of the schedule as T2 has already read the uncommitted value written by T1.

The following is a recoverable schedule which avoids cascading abort. Note, however, that the update of A by T1 is always lost (since T1 is aborted).

$$F3 = \begin{bmatrix} T1 & T2 \\ & R(A) \\ R(A) & \\ W(A) & \\ & W(A) \\ Abort & \\ & Commit \\ & \end{bmatrix}$$

Cascading aborts avoidance is sufficient but not necessary for a schedule to be recoverable.

Strict

A schedule is strict - has the strictness property - if for any two transactions T1, T2, if a write operation of T1 precedes a *conflicting* operation of T2 (either read or write), then the commit event of T1 also precedes that conflicting operation of T2.

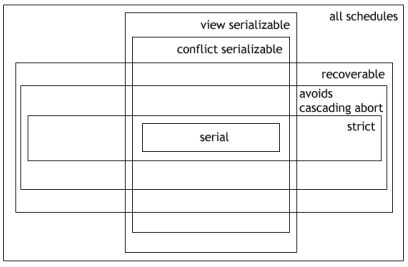
Any strict schedule is cascadeless, but not the converse. Strictness allows efficient recovery of databases from failure.

Hierarchical relationship between serializability classes

The following expressions illustrate the hierarachical (containment) relationships between serializability and recoverability classes:

- Serial ⊂ commitment-ordered ⊂ conflict-serializable ⊂ view-serializable ⊂ all schedules
- Serial ⊂ strict ⊂ avoids cascading aborts ⊂ recoverable ⊂ all schedules

The Venn diagram (below) illustrates the above clauses graphically.



Venn diagram for serializability and recoverability classes

Practical implementations

In practice, most general purpose database systems employ conflict-serializable and recoverable (primarily strict) schedules.

Serializability

In concurrency control of databases,[1][2] transaction processing (transaction management), and various transactional applications (e.g., transactional memory[3] and software transactional memory), both centralized and distributed, a transaction schedule is **serializable** if its outcome (e.g., the resulting database state) is equal to the outcome of its transactions executed serially, i.e., sequentially without overlapping in time. Transactions are normally executed concurrently (they overlap), since this is the most efficient way. Serializability is the major correctness criterion for concurrent transactions' executions. It is considered the highest level of isolation between transactions, and plays an essential role in concurrency control. As such it is supported in all general purpose database systems. *Strong strict two-phase locking* (SS2PL) is a popular serializability mechanism utilized in most of the database systems (in various variants) since their early days in the 1970s.

Serializability theory provides the formal framework to reason about and analyze serializability and its techniques. Though it is mathematical in nature, its fundamentals are informally (without Mathematics notation) introduced below.

Database transaction

For this discussion a *database transaction* is a specific intended run (with specific parameters, e.g., with transaction identification, at least) of a computer program (or programs) that accesses a database (or databases). Such a program is written with the assumption that it is running in *isolation* from other executing programs, i.e., when running, its accessed data (after the access) are not changed by other running programs. Without this assumption the transaction's results are unpredictable and can be wrong. The same transaction can be executed in different situations, e.g., in different times and locations, in parallel with different programs. A *live* transaction (i.e., exists in a computing environment with already allocated computing resources; to distinguish from a *transaction request*, waiting to get execution resources) can be in one of three states, or phases:

1. *Running* - Its program(s) is (are) executing.
2. *Ready* - Its program's execution has ended, and it is waiting to be *Ended (Completed)*.
3. *Ended* (or *Completed*) - It is either *Committed* or *Aborted (Rolled-back)*, depending whether the execution is considered a success or not, respectively . When committed, all its *recoverable* (i.e., with states that can be controlled for this purpose), *durable* resources (typically *database data*) are put in their *final* states, states after running. When aborted, all its recoverable resources are put back in their *initial* states, as before running.

A failure in transaction's computing environment before ending typically results in its abort. However, a transaction may be aborted also for other reasons as well (e.g., see below).

Upon being ended (completed), transaction's allocated computing resources are released and the transaction disappears from the computing environment. However, the effects of a committed transaction remain in the database, while the effects of an aborted (rolled-back) transaction disappear from the database. The concept of *atomic transaction* ("all or nothing" semantics) was designed to exactly achieve this behavior, in order to control correctness in complex faulty systems.

Correctness

Correctness - serializability

Serializability is a property of a transaction schedule (history). It relates to the *isolation* property of a database transaction.

> **Serializability** of a schedule means equivalence (in the outcome, the database state, data values) to a *serial schedule* (i.e., sequential with no transaction overlap in time) with the same transactions. It is the major criterion for the correctness of concurrent transactions' schedule, and thus supported in all general purpose database systems.
>
> **The rationale behind serializability** is the following:
>
> If each transaction is correct by itself, i.e., meets certain integrity conditions, then a schedule that comprises any *serial* execution of these transactions is correct (its transactions still meet their conditions): "Serial" means that transactions do not overlap in time and cannot interfere with each other, i.e, complete *isolation* between each other exists. Any order of the transactions is legitimate, if no dependencies among them exist, which is assumed (see comment below). As a result, a schedule that comprises any execution (not necessarily serial) that is equivalent (in its outcome) to any serial execution of these transactions, is correct.

Schedules that are not serializable are likely to generate erroneous outcomes. Well known examples are with transactions that debit and credit accounts with money: If the related schedules are not serializable, then the total sum of money may not be preserved. Money could disappear, or be generated from nowhere. This and violations of possibly needed other invariant preservations are caused by one transaction writing, and "stepping on" and erasing what has been written by another transaction before it has become permanent in the database. It does not happen if serializability is maintained.

If any specific order between some transactions is requested by an application, then it is enforced independently of the underlying serializability mechanisms. These mechanisms are typically indifferent to any specific order, and generate some unpredictable partial order that is typically compatible with multiple serial orders of these transactions. This partial order results from the scheduling orders of concurrent transactions' data access operations, which depend on many factors.

Correctness - recoverability

A major characteristic of a database transaction is *atomicity*, which means that it either *commits*, i.e., all its operations' results take effect in the database, or *aborts* (rolled-back), all its operations' results do not have any effect on the database ("all or nothing" semantics of a transaction). In all real systems transactions can abort for many reasons, and serializability by itself is not sufficient for correctness. Schedules also need to possess the *recoverability* (from abort) property. **Recoverability** means that committed transactions have not read data written by aborted transactions (whose effects do not exist in the resulting database states). While serializability is currently compromised on purpose in many applications for better performance (only in cases when application's correctness is not harmed), compromising recoverability would quickly violate the database's integrity, as well as that of transactions' results external to the database. A schedule with the recoverability property (a *recoverable* schedule) "recovers" from aborts by itself, i.e., aborts do not harm the integrity of its committed transactions and resulting database. This is false without recoverability, where the likely integrity violations (resulting incorrect database data) need special, typically manual, corrective actions in the database.

Implementing recoverability in its general form may result in *cascading aborts*: Aborting one transaction may result in a need to abort a second transaction, and then a third, and so on. This results in a waste of already partially executed transactions, and may result also in a performance penalty. **Avoiding cascading aborts** (ACA, or Cascadelessness) is a special case of recoverability that exactly prevents such phenomenon. Often in practice a

special case of ACA is utilized: **Strictness**. Strictness allows an efficient database recovery from failure.

Note that the *recoverability* property is needed even if no database failure occurs and no database *recovery* from failure is needed. It is rather needed to correctly automatically handle aborts, which may be unrelated to database failure and recovery from failure.

Relaxing serializability

In many applications, unlike with finances, absolute correctness is not needed. For example, when retrieving a list of products according to specification, in most cases it does not matter much if a product, whose data was updated a short time ago, does not appear in the list, even if it meets the specification. It will typically appear in such a list when tried again a short time later. Commercial databases provide concurrency control with a whole range of isolation levels which are in fact (controlled) serializability violations in order to achieve higher performance. Higher performance means better transaction execution rate and shorter average transaction response time (transaction duration). *Snapshot isolation* is an example of a popular, widely utilized efficient relaxed serializability method with many characteristics of full serializability, but still short of some, and unfit in many situations.

Another common reason nowadays for distributed serializability relaxation (see below) is the requirement of availability of internet products and services. This requirement is typically answered by large-scale data replication. The straightforward solution for synchronizing replicas' updates of a same database object is including all these updates in a single atomic distributed transaction. However, with many replicas such a transaction is very large, and may span several computers and networks that some of them are likely to be unavailable. Thus such a transaction is likely to end with abort and miss its purpose. Consequently Optimistic replication (Lazy replication) is often utilized (e.g., in many products and services by Google, Amazon, Yahoo, and alike), while serializability is relaxed and compromised for eventual consistency. Again in this case, relaxation is done only for applications that are not expected to be harmed by this technique.

Classes of schedules defined by *relaxed serializability* properties either contain the serializability class, or are incomparable with it.

View and conflict serializability

Mechanisms that enforce serializability need to execute in real time, or almost in real time, while transactions are running at high rates. In order to meet this requirement special cases of serializability, sufficient conditions for serializability which can be enforced effectively, are utilized.

Two major types of serializability exist: *view-serializability*, and *conflict-serializability*. View-serializability matches the general definition of serializability given above. Conflict-serializability is a broad special case, i.e., any schedule that is conflict-serializable is also view-serializable, but not necessarily the opposite. Conflict-serializability is widely utilized because it is easier to determine and covers a substantial portion of the view-serializable schedules. Determining view-serializability of a schedule is an NP-complete problem (a class of problems with only difficult-to-compute, excessively time-consuming known solutions).

> **View-serializability** of a schedule is defined by equivalence to a serial schedule (no overlapping transactions) with the same transactions, such that respective transactions in the two schedules read and write the same data values ("view" the same data values).
>
> **Conflict-serializability** is defined by equivalence to a serial schedule (no overlapping transactions) with the same transactions, such that both schedules have the same sets of respective chronologically ordered pairs of conflicting operations (same precedence relations of respective conflicting operations).

Operations upon data are *read* or *write* (a write: either *insert* or *modify* or *delete*). Two operations are *conflicting*, if they are of different transactions, upon the same datum (data item), and at least one of them is *write*. Each such pair of conflicting operations has a *conflict type*: It is either a *read-write*, or *write-read*, or a *write-write* conflict. The

transaction of the second operation in the pair is said to be *in conflict* with the transaction of the first operation. A more general definition of conflicting operations (also for complex operations, which may consist each of several "simple" read/write operations) requires that they are noncommutative (changing their order also changes their combined result). Each such operation needs to be atomic by itself (by proper system support) in order to be considered an operation for a commutativity check. For example, read-read operations are commutative (unlike read-write and the other possibilities) and thus read-read is not a conflict. Another more complex example: the operations *increment* and *decrement* of a *counter* are both *write* operations (both modify the counter), but do not need to be considered conflicting (write-write conflict type) since they are commutative (thus increment-decrement is not a conflict; e.g., already has been supported in the old IBM's IMS "fast path"). Only precedence (time order) in pairs of conflicting (non-commutative) operations is important when checking equivalence to a serial schedule, since different schedules consisting of the same transactions can be transformed from one to another by changing orders between different transactions' operations (different transactions' interleaving), and since changing orders of commutative operations (non-conflicting) does not change an overall operation sequence result, i.e., a schedule outcome (the outcome is preserved through order change between non-conflicting operations, but typically not when conflicting operations change order). This means that if a schedule can be transformed to any serial schedule without changing orders of conflicting operations (but changing orders of non-conflicting, while preserving operation order inside each transaction), then the outcome of both schedules is the same, and the schedule is conflict-serializable by definition.

Conflicts are the reason for blocking transactions and delays (non-materialized conflicts), or for aborting transactions due to serializability violations prevention. Both possibilities reduce performance. Thus reducing the number of conflicts, e.g., by commutativity (when possible), is a way to increase performance.

A transaction can issue/request a conflicting operation and be *in conflict* with another transaction while its conflicting operation is delayed and not executed (e.g., blocked by a lock). Only executed (*materialized*) conflicting operations are relevant to *conflict serializability* (see more below).

Enforcing conflict serializability

Testing conflict serializability

Schedule compliance with conflict serializability can be tested with the precedence graph (*serializability graph*, *serialization graph*, *conflict graph*) for committed transactions of the schedule. It is the directed graph representing precedence of transactions in the schedule, as reflected by precedence of conflicting operations in the transactions.

> In the **precedence graph** transactions are nodes and precedence relations are directed edges. There exists an edge from a first transaction to a second transaction, if the second transaction is *in conflict* with the first (see Conflict serializability above), and the conflict is **materialized** (i.e., if the requested conflicting operation is actually executed: in many cases a requested/issued conflicting operation by a transaction is delayed and even never executed, typically by a lock on the operation's object, held by another transaction, or when writing to a transaction's temporary private workspace and materializing, copying to the database itself, upon commit; as long as a requested/issued conflicting operation is not executed upon the database itself, the conflict is **non-materialized**; non-materialized conflicts are not represented by an edge in the precedence graph).
>
> **Comment:** In many text books only *committed transactions* are included in the precedence graph. Here all transactions are included for convenience in later discussions.

The following observation is a **key characterization of conflict serializability**:

> A schedule is *conflict-serializable* if and only if its precedence graph of *committed transactions* (when only *committed* transactions are considered) is *acyclic*. This means that a cycle consisting of committed transactions only is generated in the (general) precedence graph, if and only if conflict-serializability is violated.

Cycles of committed transactions can be prevented by aborting an *undecided* (neither committed, nor aborted) transaction on each cycle in the precedence graph of all the transactions, which can otherwise turn into a cycle of committed transactions (and a committed transaction cannot be aborted). One transaction aborted per cycle is both required and sufficient number to break and eliminate the cycle (more aborts are possible, and can happen in some mechanisms, but unnecessary for serializability). The probability of cycle generation is typically low, but nevertheless, such a situation is carefully handled, typically with a considerable overhead, since correctness is involved. Transactions aborted due to serializability violation prevention are *restarted* and executed again immediately.

Serializability enforcing mechanisms typically do not maintain a precedence graph as a data structure, but rather prevent or break cycles implicitly (e.g., SS2PL below).

Common mechanism - SS2PL

Strong strict two phase locking (SS2PL) is a common mechanism utilized in database systems since their early days in the 1970s (the "SS" in the name SS2PL is newer though) to enforce both conflict serializability and *strictness* (a special case of recoverability which allows effective database recovery from failure) of a schedule. In this mechanism each datum is locked by a transaction before accessing it (any read or write operation): The item is marked by, associated with a *lock* of a certain type, depending on operation (and the specific implementation; various models with different lock types exist; in some models locks may change type during the transaction's life). As a result access by another transaction may be blocked, typically upon a conflict (the lock delays or completely prevents the conflict from being materialized and be reflected in the precedence graph by blocking the conflicting operation), depending on lock type and the other transaction's access operation type. Employing an SS2PL mechanism means that all locks on data on behalf of a transaction are released only after the transaction has ended (either committed or aborted).

SS2PL is the name of the resulting schedule property as well, which is also called *rigorousness*. SS2PL is a special case (proper subset) of Two-phase locking (2PL)

Mutual blocking between transactions results in a *deadlock*, where execution of these transactions is stalled, and no completion can be reached. Thus deadlocks need to be resolved to complete these transactions' execution and release related computing resources. A deadlock is a reflection of a potential cycle in the precedence graph, that would occur without the blocking when conflicts are materialized. A deadlock is resolved by aborting a transaction involved with such potential cycle, and breaking the cycle. It is often detected using a *wait-for graph* (a graph of conflicts blocked by locks from being materialized; it can be also defined as the graph of non-materialized conflicts; conflicts not materialized are not reflected in the precedence graph and do not affect serializability), which indicates which transaction is "waiting for" lock release by which transaction, and a cycle means a deadlock. Aborting one transaction per cycle is sufficient to break the cycle. Transactions aborted due to deadlock resolution are *restarted* and executed again immediately.

Other enforcing techniques

Other known mechanisms include:

- Precedence graph (or Serializability graph, Conflict graph) cycle elimination
- Two-phase locking (2PL)
- Timestamp ordering (TO)
- Serializable snapshot isolation[4] (SerializableSI)

The above (conflict) serializability techniques in their general form do not provide recoverability. Special enhancements are needed for adding recoverability.

Optimistic versus pessimistic techniques

Concurrency control techniques are of three major types:

1. *Pessimistic*: In Pessimistic concurrency control a transaction blocks data access operations of other transactions upon conflicts, and conflicts are *non-materialized* until blocking is removed. This is done to ensure that operations that may violate serializability (and in practice also recoverability) do not occur.
2. *Optimistic*: In Optimistic concurrency control data access operations of other transactions are not blocked upon conflicts, and conflicts are immediately *materialized*. When the transaction reaches the *ready* state, i.e., its *running* state has been completed, possible serializability (and in practice also recoverability) violation by the transaction's operations (relatively to other running transactions) is checked: If violation has occurred, the transaction is typically *aborted* (sometimes aborting *another* transaction to handle serializability violation is preferred). Otherwise it is *committed*.
3. *Semi-optimistic*: Mechanisms that mix blocking in certain situations with not blocking in other situations and employ both materialized and non-materialized conflicts

The main differences between the technique types is the conflict types that are generated by them. A pessimistic method blocks a transaction operation upon conflict and generates a non-materialized conflict, while an optimistic method does not block and generates a materialized conflict. A semi-optimistic method generates both conflict types. Both conflict types are generated by the chronological orders in which transaction operations are invoked, independently of the type of conflict. A cycle of committed transactions (with materialized conflicts) in the *precedence graph* (conflict graph) represents a serializability violation, and should be avoided for maintaining serializability. A cycle of (non-materialized) conflicts in the *wait-for graph* represents a deadlock situation, which should be resolved by breaking the cycle. Both cycle types result from conflicts, and should be broken. At any technique type conflicts should be detected and considered, with similar overhead for both materialized and non-materialized conflicts (typically by using mechanisms like locking, while either blocking for locks, or not blocking but recording conflict for materialized conflicts). In a blocking method typically a context switching occurs upon conflict, with (additional) incurred overhead. Otherwise blocked transactions' related computing resources remain idle, unutilized, which may be a worse alternative. When conflicts do not occur frequently, optimistic methods typically have an advantage. With different transactions loads (mixes of transaction types) one technique type (i.e., either optimistic or pessimistic) may provide better performance than the other.

Unless schedule classes are *inherently blocking* (i.e., they cannot be implemented without data-access operations blocking; e.g., 2PL, SS2PL and SCO above; see chart), they can be implemented also using optimistic techniques (e.g., Serializability, Recoverability).

Serializable multi-version concurrency control

See also Multiversion concurrency control (partial coverage)

and Serializable_Snapshot_Isolation in Snapshot isolation

Multi-version concurrency control (MVCC) is a common way today to increase concurrency and performance by generating a new version of a database object each time the object is written, and allowing transactions' read operations of several last relevant versions (of each object), depending on scheduling method. MVCC can be combined with all the serializability techniques listed above (except SerializableSI which is originally MVCC based). It is utilized in most general-purpose DBMS products.

MVCC is especially popular nowadays through the *relaxed serializability* (see above) method *Snapshot isolation* (SI) which provides better performance than most known serializability mechanisms (at the cost of possible serializability violation in certain cases). SerializableSI, which is an efficient enhancement of SI to make it serializable, is intended to provide an efficient serializable solution. SerializableSI has been analyzed[5] via a general theory of MVCC

Distributed serializability

Overview

Distributed serializability is the serializability of a schedule of a transactional distributed system (e.g., a distributed database system). Such system is characterized by *distributed transactions* (also called *global transactions*), i.e., transactions that span computer processes (a process abstraction in a general sense, depending on computing environment; e.g., operating system's thread) and possibly network nodes. A distributed transaction comprises more than one *local sub-transactions* that each has states as described above for a database transaction. A local sub-transaction comprises a single process, or more processes that typically fail together (e.g., in a single processor core). Distributed transactions imply a need in Atomic commit protocol to reach consensus among its local sub-transactions on whether to commit or abort. Such protocols can vary from a simple (one-phase) hand-shake among processes that fail together, to more sophisticated protocols, like Two-phase commit, to handle more complicated cases of failure (e.g., process, node, communication, etc. failure). Distributed serializability is a major goal of distributed concurrency control for correctness. With the proliferation of the Internet, Cloud computing, Grid computing, and small, portable, powerful computing devices (e.g., smartphones) the need for effective distributed serializability techniques to ensure correctness in and among distributed applications seems to increase.

Distributed serializability is achieved by implementing distributed versions of the known centralized techniques. Typically all such distributed versions require utilizing conflict information (either of materialized or non-materialized conflicts, or equivalently, transaction precedence or blocking information; conflict serializability is usually utilized) that is not generated locally, but rather in different processes, and remote locations. Thus information distribution is needed (e.g., precedence relations, lock information, timestamps, or tickets). When the distributed system is of a relatively small scale, and message delays across the system are small, the centralized concurrency control methods can be used unchanged, while certain processes or nodes in the system manage the related algorithms. However, in a large-scale system (e.g., *Grid* and *Cloud*), due to the distribution of such information, substantial performance penalty is typically incurred, even when distributed versions of the methods (Vs. centralized) are used, primarily due to computer and communication latency. Also, when such information is distributed, related techniques typically do not scale well. A well-known example with scalability problems is a distributed lock manager, which distributes lock (non-materialized conflict) information across the distributed system to implement locking techniques.

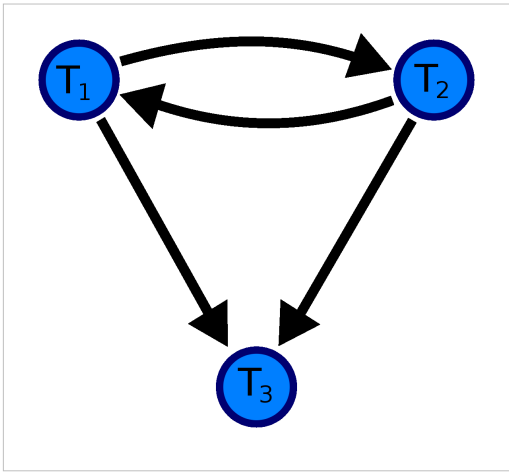
Precedence graph

A **precedence graph**, also named **conflict graph** and **serializability graph**, is used in the context of concurrency control in databases.

The precedence graph for a schedule S contains:

- A node for each committed transaction in S
- An arc from T_i to T_j if an action of T_i precedes and conflicts with one of T_j's actions.

Precedence graph example



$$D = \begin{bmatrix} T1 & T2 & T3 \\ R(A) & & \\ & W(A) & \\ & Com. & \\ W(A) & & \\ Com. & & \\ & & W(A) \\ & & Com. \end{bmatrix}$$

or

$$D = R1(A)\ W2(A)\ Com.2\ W1(A)\ Com.1\ W3(A)\ Com.3$$

A precedence graph of the schedule D, with 3 transactions. As there is a cycle (of length 2; with two edges) through the committed transactions T1 and T2, this schedule (history) is *not* Conflict serializable.

Testing Serializability with Precedence Graph

The drawing sequence for the precedence graph:-

1. For each transaction T_i participating in schedule S, create a node labelled T_i in the precedence graph. So the precedence graph contains T_1, T_2, T_3
2. For each case in S where T_i executes a write_item(X) then T_j executes a read_item(X), create an edge (T_i --> T_j) in the precedence graph. This occurs nowhere in the above example, as there is no read after write.
3. For each case in S where T_i executes a read_item(X) then T_j executes a write_item(X), create an edge (T_i --> T_j) in the precedence graph. This will bring to front a directed graph from T_1 to T_2.
4. For each case in S where T_i executes a write_item(X) then T_j executes a write_item(X), create an edge (T_i --> T_j) in the precedence graph. It creates a directed graph from T_2 to T_1, T_1 to T_3, and T_2 to T_3.
5. The schedule S is serializable if the precedence graph has no cycles. As T_1 and T_2 constitute a bicycle, then we cannot declare S as serializable or not and serializability has to be checked using other methods.

Serializability theory

In concurrency control of databases,[1][2] transaction processing (transaction management), and various transactional applications (e.g., transactional memory[3] and software transactional memory), both centralized and distributed, a transaction schedule is **serializable** if its outcome (e.g., the resulting database state) is equal to the outcome of its transactions executed serially, i.e., sequentially without overlapping in time. Transactions are normally executed concurrently (they overlap), since this is the most efficient way. Serializability is the major correctness criterion for concurrent transactions' executions. It is considered the highest level of isolation between transactions, and plays an essential role in concurrency control. As such it is supported in all general purpose database systems. *Strong strict two-phase locking* (SS2PL) is a popular serializability mechanism utilized in most of the database systems (in various variants) since their early days in the 1970s.

Serializability theory provides the formal framework to reason about and analyze serializability and its techniques. Though it is mathematical in nature, its fundamentals are informally (without Mathematics notation) introduced below.

Database transaction

For this discussion a *database transaction* is a specific intended run (with specific parameters, e.g., with transaction identification, at least) of a computer program (or programs) that accesses a database (or databases). Such a program is written with the assumption that it is running in *isolation* from other executing programs, i.e., when running, its accessed data (after the access) are not changed by other running programs. Without this assumption the transaction's results are unpredictable and can be wrong. The same transaction can be executed in different situations, e.g., in different times and locations, in parallel with different programs. A *live* transaction (i.e., exists in a computing

environment with already allocated computing resources; to distinguish from a *transaction request*, waiting to get execution resources) can be in one of three states, or phases:

1. *Running* - Its program(s) is (are) executing.
2. *Ready* - Its program's execution has ended, and it is waiting to be *Ended (Completed)*.
3. *Ended* (or *Completed*) - It is either *Committed* or *Aborted (Rolled-back)*, depending whether the execution is considered a success or not, respectively . When committed, all its *recoverable* (i.e., with states that can be controlled for this purpose), *durable* resources (typically *database data*) are put in their *final* states, states after running. When aborted, all its recoverable resources are put back in their *initial* states, as before running.

A failure in transaction's computing environment before ending typically results in its abort. However, a transaction may be aborted also for other reasons as well (e.g., see below).

Upon being ended (completed), transaction's allocated computing resources are released and the transaction disappears from the computing environment. However, the effects of a committed transaction remain in the database, while the effects of an aborted (rolled-back) transaction disappear from the database. The concept of *atomic transaction* ("all or nothing" semantics) was designed to exactly achieve this behavior, in order to control correctness in complex faulty systems.

Correctness

Correctness - serializability

Serializability is a property of a transaction schedule (history). It relates to the *isolation* property of a database transaction.

> **Serializability** of a schedule means equivalence (in the outcome, the database state, data values) to a *serial schedule* (i.e., sequential with no transaction overlap in time) with the same transactions. It is the major criterion for the correctness of concurrent transactions' schedule, and thus supported in all general purpose database systems.
>
> **The rationale behind serializability** is the following:
>
> If each transaction is correct by itself, i.e., meets certain integrity conditions, then a schedule that comprises any *serial* execution of these transactions is correct (its transactions still meet their conditions): "Serial" means that transactions do not overlap in time and cannot interfere with each other, i.e, complete *isolation* between each other exists. Any order of the transactions is legitimate, if no dependencies among them exist, which is assumed (see comment below). As a result, a schedule that comprises any execution (not necessarily serial) that is equivalent (in its outcome) to any serial execution of these transactions, is correct.

Schedules that are not serializable are likely to generate erroneous outcomes. Well known examples are with transactions that debit and credit accounts with money: If the related schedules are not serializable, then the total sum of money may not be preserved. Money could disappear, or be generated from nowhere. This and violations of possibly needed other invariant preservations are caused by one transaction writing, and "stepping on" and erasing what has been written by another transaction before it has become permanent in the database. It does not happen if serializability is maintained.

If any specific order between some transactions is requested by an application, then it is enforced independently of the underlying serializability mechanisms. These mechanisms are typically indifferent to any specific order, and generate some unpredictable partial order that is typically compatible with multiple serial orders of these transactions. This partial order results from the scheduling orders of concurrent transactions' data access operations, which depend on many factors.

Correctness - recoverability

A major characteristic of a database transaction is *atomicity*, which means that it either *commits*, i.e., all its operations' results take effect in the database, or *aborts* (rolled-back), all its operations' results do not have any effect on the database ("all or nothing" semantics of a transaction). In all real systems transactions can abort for many reasons, and serializability by itself is not sufficient for correctness. Schedules also need to possess the *recoverability* (from abort) property. **Recoverability** means that committed transactions have not read data written by aborted transactions (whose effects do not exist in the resulting database states). While serializability is currently compromised on purpose in many applications for better performance (only in cases when application's correctness is not harmed), compromising recoverability would quickly violate the database's integrity, as well as that of transactions' results external to the database. A schedule with the recoverability property (a *recoverable* schedule) "recovers" from aborts by itself, i.e., aborts do not harm the integrity of its committed transactions and resulting database. This is false without recoverability, where the likely integrity violations (resulting incorrect database data) need special, typically manual, corrective actions in the database.

Implementing recoverability in its general form may result in *cascading aborts*: Aborting one transaction may result in a need to abort a second transaction, and then a third, and so on. This results in a waste of already partially executed transactions, and may result also in a performance penalty. **Avoiding cascading aborts** (ACA, or Cascadelessness) is a special case of recoverability that exactly prevents such phenomenon. Often in practice a special case of ACA is utilized: **Strictness**. Strictness allows an efficient database recovery from failure.

Note that the *recoverability* property is needed even if no database failure occurs and no database *recovery* from failure is needed. It is rather needed to correctly automatically handle aborts, which may be unrelated to database failure and recovery from failure.

Relaxing serializability

In many applications, unlike with finances, absolute correctness is not needed. For example, when retrieving a list of products according to specification, in most cases it does not matter much if a product, whose data was updated a short time ago, does not appear in the list, even if it meets the specification. It will typically appear in such a list when tried again a short time later. Commercial databases provide concurrency control with a whole range of isolation levels which are in fact (controlled) serializability violations in order to achieve higher performance. Higher performance means better transaction execution rate and shorter average transaction response time (transaction duration). *Snapshot isolation* is an example of a popular, widely utilized efficient relaxed serializability method with many characteristics of full serializability, but still short of some, and unfit in many situations.

Another common reason nowadays for distributed serializability relaxation (see below) is the requirement of availability of internet products and services. This requirement is typically answered by large-scale data replication. The straightforward solution for synchronizing replicas' updates of a same database object is including all these updates in a single atomic distributed transaction. However, with many replicas such a transaction is very large, and may span several computers and networks that some of them are likely to be unavailable. Thus such a transaction is likely to end with abort and miss its purpose. Consequently Optimistic replication (Lazy replication) is often utilized (e.g., in many products and services by Google, Amazon, Yahoo, and alike), while serializability is relaxed and compromised for eventual consistency. Again in this case, relaxation is done only for applications that are not expected to be harmed by this technique.

Classes of schedules defined by *relaxed serializability* properties either contain the serializability class, or are incomparable with it.

View and conflict serializability

Mechanisms that enforce serializability need to execute in real time, or almost in real time, while transactions are running at high rates. In order to meet this requirement special cases of serializability, sufficient conditions for serializability which can be enforced effectively, are utilized.

Two major types of serializability exist: *view-serializability*, and *conflict-serializability*. View-serializability matches the general definition of serializability given above. Conflict-serializability is a broad special case, i.e., any schedule that is conflict-serializable is also view-serializable, but not necessarily the opposite. Conflict-serializability is widely utilized because it is easier to determine and covers a substantial portion of the view-serializable schedules. Determining view-serializability of a schedule is an NP-complete problem (a class of problems with only difficult-to-compute, excessively time-consuming known solutions).

> **View-serializability** of a schedule is defined by equivalence to a serial schedule (no overlapping transactions) with the same transactions, such that respective transactions in the two schedules read and write the same data values ("view" the same data values).
>
> **Conflict-serializability** is defined by equivalence to a serial schedule (no overlapping transactions) with the same transactions, such that both schedules have the same sets of respective chronologically ordered pairs of conflicting operations (same precedence relations of respective conflicting operations).

Operations upon data are *read* or *write* (a write: either *insert* or *modify* or *delete*). Two operations are *conflicting*, if they are of different transactions, upon the same datum (data item), and at least one of them is *write*. Each such pair of conflicting operations has a *conflict type*: It is either a *read-write*, or *write-read*, or a *write-write* conflict. The transaction of the second operation in the pair is said to be *in conflict* with the transaction of the first operation. A more general definition of conflicting operations (also for complex operations, which may consist each of several "simple" read/write operations) requires that they are noncommutative (changing their order also changes their combined result). Each such operation needs to be atomic by itself (by proper system support) in order to be considered an operation for a commutativity check. For example, read-read operations are commutative (unlike read-write and the other possibilities) and thus read-read is not a conflict. Another more complex example: the operations *increment* and *decrement* of a *counter* are both *write* operations (both modify the counter), but do not need to be considered conflicting (write-write conflict type) since they are commutative (thus increment-decrement is not a conflict; e.g., already has been supported in the old IBM's IMS "fast path"). Only precedence (time order) in pairs of conflicting (non-commutative) operations is important when checking equivalence to a serial schedule, since different schedules consisting of the same transactions can be transformed from one to another by changing orders between different transactions' operations (different transactions' interleaving), and since changing orders of commutative operations (non-conflicting) does not change an overall operation sequence result, i.e., a schedule outcome (the outcome is preserved through order change between non-conflicting operations, but typically not when conflicting operations change order). This means that if a schedule can be transformed to any serial schedule without changing orders of conflicting operations (but changing orders of non-conflicting, while preserving operation order inside each transaction), then the outcome of both schedules is the same, and the schedule is conflict-serializable by definition.

Conflicts are the reason for blocking transactions and delays (non-materialized conflicts), or for aborting transactions due to serializability violations prevention. Both possibilities reduce performance. Thus reducing the number of conflicts, e.g., by commutativity (when possible), is a way to increase performance.
